Temnocephalans are small ectosymbiotic flatworms which are known from a variety of freshwater invertebrates from mainly South America and Australia. Their taxonomic status has shown some variation (Williams, 1981), but they are generally considered to be close to the dalyellioid turbellarians. The Australasian region seems the centre of diversity (Cannon, 1991), but here the diversity of hosts recognised has been low, i.e., they have been reported almost exclusively from crayfish of the family Parastacidae. Crabs and shrimps have been reported as hosts in southern Asia and South America; however, this is the first such report from Australia.

Crabs and shrimps were trapped or collected in dip nets from streams and ponds throughout eastern Australia. Hosts were retained for short periods until the hosts could be examined in the field or laboratory with a dissecting microscope and the worms removed into clean water. Worms were fixed when possible in 10% cold buffered formalin, AFA (alcohol, formalin and acetic acid), SUSA or Bouin's fluid: some were obtained from hosts fixed in 70% alcohol or from hosts killed by near boiling water. Whole mounts were stained with Mayer's haemalum or Harris' haematoxylin and mounted in Canada balsam. Serial sections were obtained from worms embedded in 56°C Paraplast and cut at 5-7μm and stained with Mayer's haematoxylin and eosin, though occasionally Mallory's trichrome was used.

Descriptions were prepared with the aid of DELTA (Dallwitz & Paine, 1986). Over 130 characters were designated, though not all were applicable to all descriptions, e.g. egg capsule characters were not included if egg capsules were not found. With limited material of some species and variation in the quality of fixation dependent upon the immediacy of treatment some characters are included as 'inconspicuous', '(absent?)' or simply qualified with '(?)'. All measurements were obtained with the aid of a camera lucida. Material is deposited in the collections of the Queensland Museum (QM) and wholemounts are designated (W) and serial sections (LS, TS or FS -longitudinal, transverse or facial sections: the number of slides in the series given in [ ]).

Abbreviations used in figures: c cirrus, dg disc glands, e eye, es ejaculatory sac, ex excretory ampulla, g gut, ga genital atrium, gc genital capsule, gp gonopore, Hc Haswell's cells, og ootype gland, ov ovary, ph pharynx, plg postero-lateral glands, pr prostate, rg rhabdite glands, ro rosette organ, sg shell glands, sr seminal receptacle, sv seminal vesicle, t testis, v vagina, vit vitellaria, vitd vitelline duct, vr vesicula resorbens.

TERMINOLOGY

Hickman (1967) drew attention to the variety of names used for various parts of the reproductive organs of temnocephalans. I happily accept the term vesicula resorbens (not resorbiens) for this structure described in detail by Haswell (1924). Earlier I have tried to provide a consensus regarding the terminology relating to all turbellarians (Cannon, 1986). Within the male temnocephalan I agree with Haswell (1893) and Baer (1953) that the swollen part of the system storing sperm prior to release is appropriately called the seminal vesicle. The ejaculatory duct leaves the seminal vesicle distally and enters the (usually muscular) base of the intromittent organ. Haswell

(1893) called this muscular base the cirrus bulb, but since this is where the prostate glands join the ejaculatory duct and surround it 'prostate bulb' (or simply 'prostate') is the most appropriate functional term. The prostate is sometimes no wider than the sclerotic base of the male organ, but may be a much enlarged bulb.

As Baer (1953) pointed out, Australian species of temnocephalans also have an additional sac, evidently absent from South American species. This is variably developed: in some it is a discrete sac or vesicle opening, via a narrow duct, into the prostate adjacent to the ejaculatory duct; in others it is merely a proximal extension from the prostate beyond the ejaculatory duct entrance. Haswell (1893) called this the ejaculatory sac, a term I accept. Hickman (1967) called it a prostate vesicle mistakenly attributing this term to Baer (1953) who called such a structure in *Dicerato-cephala boschmai* a prostate, but said 'elle est sans doute homologue de la vesicle ejaculatrice des autres Temnocephales'. This sac is frequently empty or contains only a few sperm: it does not contain prostatic secretion.

The male intromittent organ in most temnocephalans consists of a hard sclerotic tube the terminal part of which has spines or more often rows of spinelets which are eversible. The terminal part may or may not be enlarged. Haswell (1893) called the organ a cirrus and the terminal part the introvert. Cirrus is the appropriate term for a spiny eversible male organ. The basal rigid section could be considered a stylet, but is here called the shaft, and the term 'cirrus' of Haswell is accepted here, not 'penis' as used by Hickman (1967).

Finally, in many temnocephalans there are distinctly staining cells anterior to or adjacent to the brain. Haswell (1893) first referred to them as 'problematic cells'. They have also been called 'schokoladenbraune Drüsen' (see Cannon, 1991). Hickman (1967) figures and describes these cells which he says may be paranephrocytes, though cautiously, as these latter are wandering cells: the cells in question are constant in position. There are often two pairs and their position near the brain suggests they may be neurosecretory. Until a function can be ascribed I propose to call them Haswell's cells.

Family TEMNOCEPHALIDAE Monticelli, 1899

Temnocephala Blanchard, 1849

Generic diagnosis. Temnocephalidae with five anterior tentacles, a posterior adhesive disc and paired lateral testes.

Temnocephala athertonensis n.sp.
(Figs 1,11a-c)

MATERIAL EXAMINED

HOLOTYPE: ex carapace of *Holthuisana agassizi* (Sundathelphusidae), Rocky Ck, nr Carbeen (17.11.2°S, 145.26.8°E), 26 Sep. 1990, L. Cannon & K. Sewell, Hot water/AFA/Hx GL14562 (W).

PARATYPES: same data as holotype, AFA/Hx GL14563-7 (W); Hot water/Bouin's/H&E GL14569 (LS[2]); Hot water/AFA/H&E GL14570 (LS[2]); Hot-water/Bouin's/Mallory's GL14571 (LS[1]).

OTHER MATERIAL: same data as holotype, AFA/Hx GL14568 (W); Hot water/Bouin's/Mallory's GL14572 (LS[1]); Bouin's/H&E GL14573 (LS[2]); Hot water/AFA/H&E GL14574 (LS[2]); Bouin's/Mallory's GL14575 (LS[1]).

DESCRIPTION

External characteristics. Body about 1.2-2mm (mean=1.7mm) long, and about 0.5-0.9mm (mean=0.7mm) wide; oval or elliptical, dorso-ventrally compressed, but without flanges, or not dorso- ventrally compressed. Pigment creates impression of grey, actually a well defined pattern: dorsally a tracery extends from the base of the tentacles posteriorly and laterally to near the body margins, but becomes less dense towards the posterior. The pigment extends through the body outlining nerve tracts and major structures, and some is seen ventrally especially anterior to the mouth. Posterior adhesive disc pedunculate: disc diameter 280μm at rim, disc peduncle about 145μm in diameter. Epidermis syncitial with scattered nuclei, about 5-6μm high dorsally and ventrally. Cilia entirely absent.

Alimentary system. Mouth mid-ventral in anterior quarter of body. Buccal cavity or prepharynx inconspicuous. Pharynx directed antero-ventrally, as wide as long, about 180μm in diameter; strong, divided into anterior and posterior sphincter blocks by a region containing nucleated cells but few muscle fibres; lacking a non-cellular lip, with a conspicuous non-cellular lining (extending to buccal region), muscles not forming an obvious crenulate buccal rim. Pharynx sphincters slightly stronger posteriorly. Oesophagus inconspicuous. Gut darkly coloured, longer than wide to as wide as long; with ill-defined septa. Gastrodermis about 90μm high. Gut with diatoms.

Excretory system. Excretory pores lateral to mouth. Excretory ampulla a simple vacuole, thick

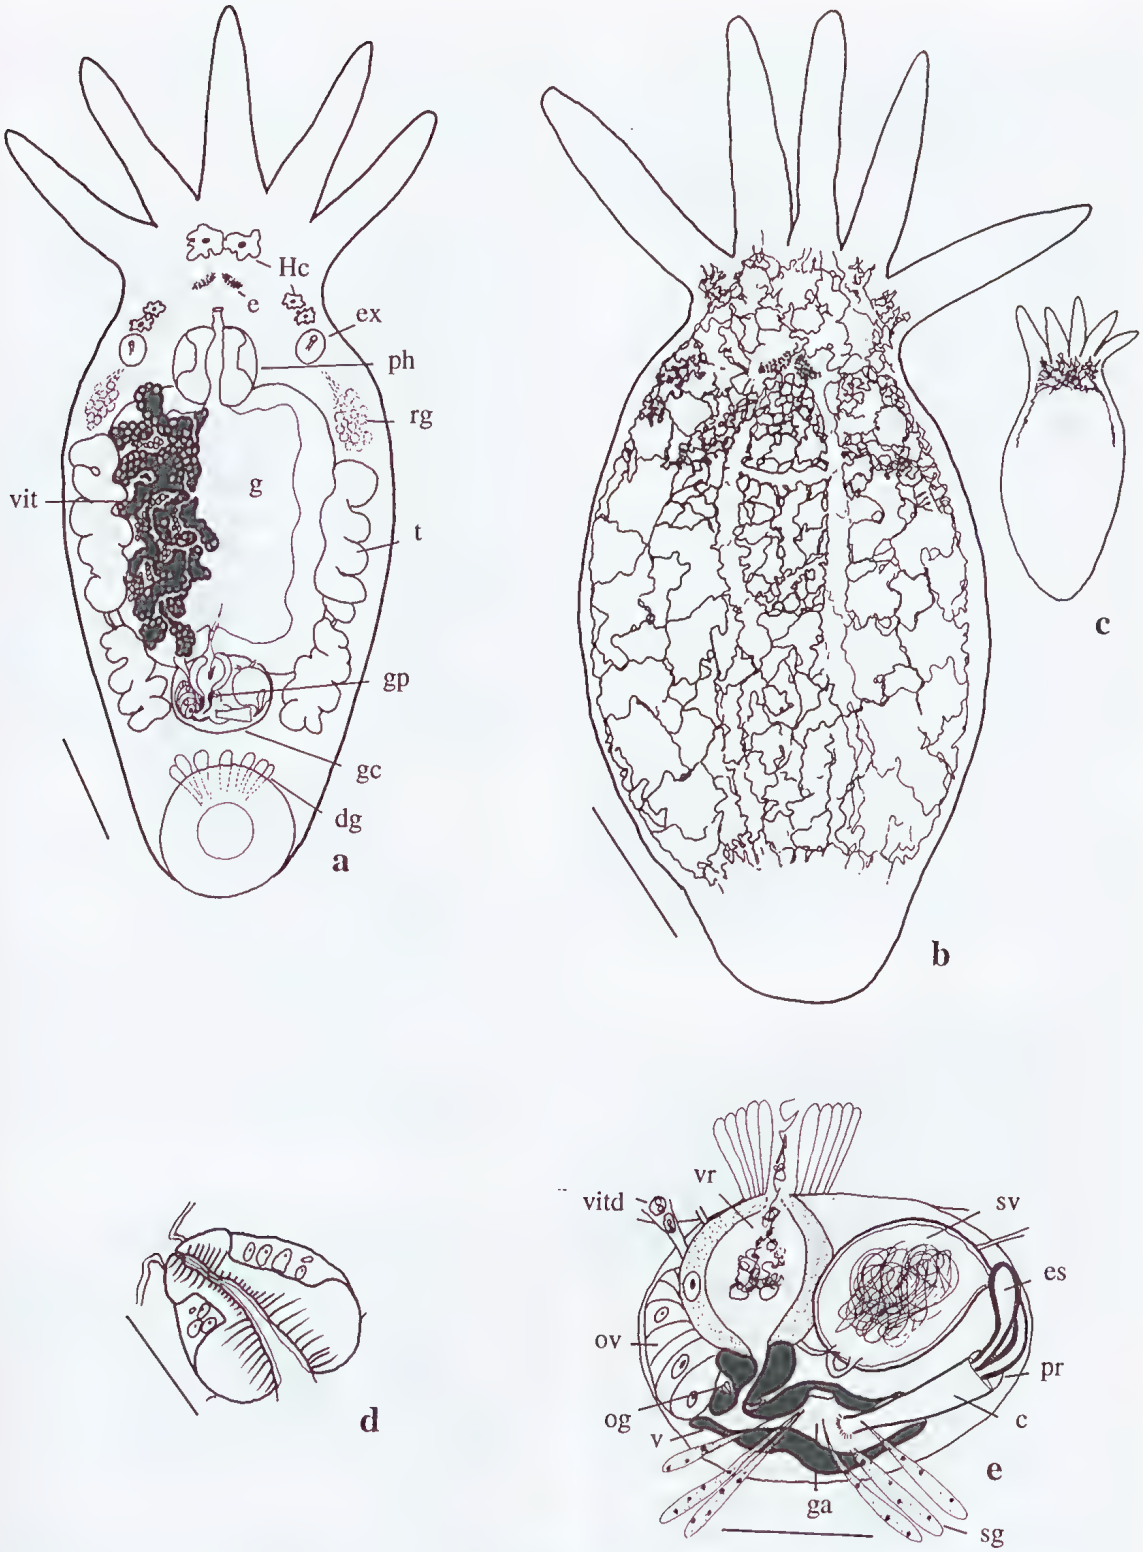

FIG. 1. *Temnocephala athertonensis* n.sp. a, internal anatomy of whole animal; b, dorsal pigment pattern; c, ventral pigment pattern; d, pharynx; e, detail of genital capsule. Scales: a,b, 250μm; c, not to scale; d,e, 100μm.

walled, about 75μm in diameter. Major excretory ducts conspicuous posterior to ampullae.

Nervous and sensory systems. Brain compact, transverse band. Major nerve trunks conspicuous in sections although pigment pattern outlines some. Eyes present, adjacent, with pigment mesh forming a single dark region, each about 40×25μm. Eye pigment granules irregular, mostly small (extremely fine), red-black.

Glands. Rhabdite glands in lateral fields anterior to anterior testes, numerous, 10 or more each side; each about 30μm across, with inconspicuous rhabdite tracts. Rhabdites only accumulate on tentacles. Haswell's cells conspicuous, six, a pair before brain, beside brain and before excretory pores (but median and lateral glands close together), each of the larger anterior pair irregular and about 50μm across, median pairs, smaller, about 30- 40μm across. Oesophageal glands inconspicuous (absent?). Ootype glands present (restricted to a small field). Shell glands present (a small group of eosinophilic glands posterior to gonopore). Posterio-lateral glands present, but difficult to see in whole mounts. Disc glands prominent, a discrete cluster.

Muscles. Longitudinal muscles of body wall of equal size or strength dorsally and ventrally. Circular muscles of body wall similar dorsally and ventrally. Dorso-ventral muscles weak. Attachment muscles of pharynx weak. Attachment muscles of adhesive disc moderately strong. Muscles controlling male organ strong immediately about the cirrus.

Reproductive system ♀. Gonopore mid-ventral, in posterior quarter of body. Genital atrium commodious. Genital complex contained in a connective tissue capsule. Ovary about 70μm in diameter. Vesicula resorbens present, about 80-100μm across, 15μm thick wall, with strong muscular duct or sphincter joining it to vagina; lying free of gut wall (in capsule), can open to gut. Seminal receptacles not present. Vagina strongly muscular, becoming less so proximally. Vitellaria dendritic, dorsal to ventral.

Reproductive system ♂. Testes elliptical: anterior about 170×230μm, lobulate, lateral to gut, posterior about 140×210μm, lobulate, lateral or posterior to gut. Vasa deferentia narrow, entering seminal vesicle separately. Seminal vesicle about 100μm in diameter. Ejaculatory sac present, with narrowed neck. Prostate bulb incorporated, i.e. continuation of cirrus base. Cirrus shaft gently curved. Cirrus hardly tapering, 80μm long, 35μm wide at base. Cirrus introvert not swollen, about 15μm or 1/6 length, only a weak collar of spinelets. Cirrus spinelets minute, few rows, i.e. <20.

ETYMOLOGY

The specific name pertains to the locality.

REMARKS

These worms from small freshwater crabs resemble most closely *T. minor* Haswell, 1888, the only species described with a grey tracery of pigment. The present species is only half the size of *T. minor* and the cirrus completely lacks the swollen introvert of that species. Furthermore, Haswell (1893) makes no mention of a capsule surrounding the genital organs, a characteristic of the present species. The pharynx of the present species is also distinctive. Posterio-lateral glands are present, but barely discernible. The only species described with such glands is *T. chaeropsis* Hett, 1925 from the crayfish '*Chaerops preissi*' (an old name: several species are now recognised from WA) from the region of Mammoth Cave, WA. In that species, however, the glands are conspicuous, adjacent and, furthermore, the worms lack conspicuous pigment except for the eyes (Hett, 1925).

Temnocephala butlerae n.sp.
(Figs 2,11d)

MATERIAL EXAMINED

HOLOTYPE: ex carapace *Holthuisana transversa* (Sundathelphusidae), Bore drain, Augathella (25.48°S, 146.35°E), 20 Apr. 1987, S. Butler, AFA/Haemalum GL14558 (W).

PARATYPES: same data as holotype, AFA/Hx GL14559 (W); Bouin's/H&E GL14560 (LS[3]).

OTHER MATERIAL: same data as holotype, AFA/H&E GL14561 (LS[1]).

DESCRIPTION

External characteristics. Body about 1.5mm long, and about 0.66mm wide; oval or elliptical, dorso-ventrally compressed, but without flanges. Pigment a light tracery over most of dorsal surface, extends to ventral surface (below eyes anterior to mouth). Posterior adhesive disc pedunculate: disc diameter 300μm at rim, disc peduncle 150μm in diameter. Epidermis syncitial, about 4μm high dorsally and ventrally. Cilia entirely absent.

Alimentary system. Mouth mid-ventral in anterior quarter of body. Buccal cavity or prepharynx conspicuous. Pharynx directed antero-ventrally, as wide as long, and about 160μm in diameter;

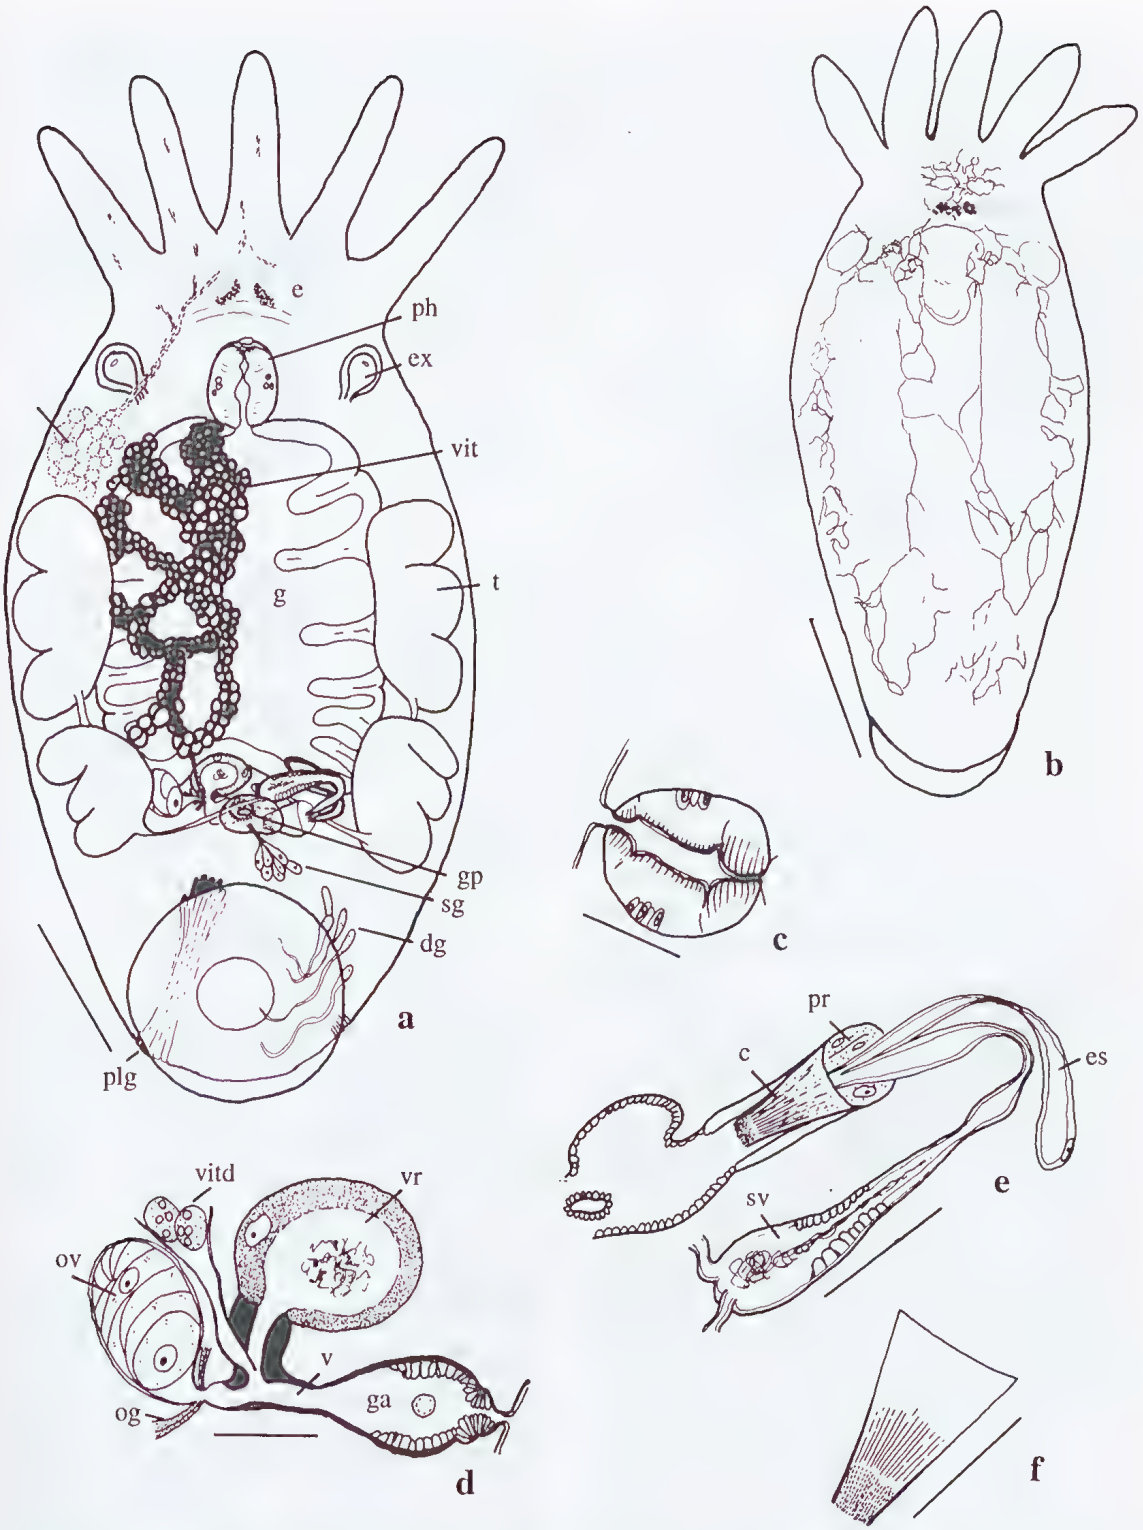

FIG. 2. *Temnocephala butlerae* n.sp. a, internal anatomy of whole animal; b, dorsal pigment pattern; c, pharynx; d, detail female reproductive system; e, detail male reproductive system; f, cirrus. Scales: a,b, 250μm; c-e, 100μm; f, 50μm.

strong, divided into anterior and posterior parts, containing nucleated cells within muscle blocks (concentrated between first and second blocks); lacking a non-cellular lip, with a conspicuous non-cellular lining, muscles forming a crenulate buccal rim. Pharynx sphincters stronger posteriorly. Oesophagus inconspicuous. Gut darkly coloured, longer than wide, weakly septate. Gastrodermis about 20-40μm high (numerous large cells filled with eosinophilic granules lie in gastrodermis).

Excretory system. Excretory pores posterior to mouth. Excretory ampulla a simple vacuole, thick walled (9- 10μm), about 90μm in diameter. Major excretory ducts inconspicuous.

Nervous and sensory systems. Brain compact, transverse band (20μm wide). Major nerve trunks inconspicuous. Eyes present, adjacent, with pigment mesh forming a single dark region, each about 35×25μm. Eye pigment granules irregular, mostly small, red-black.

Glands. Rhabdite glands in lateral fields anterior to anterior testes (well formed, resembling a bunch of grapes), numerous, 10 or more each side; each about 30μm in diameter, with prominent rhabdite tracts to tentacles. Rhabdites evident in ventral epidermis (anteriorly, as well as on tentacles). Two Haswell's cells outlined by pigment. Oesophageal glands prominent. Ootype glands present (not well developed). Shell glands present (eosinophilic, lying posterior to gonopore). Postero-lateral glands present (well developed, but hard to see as they are refractory to haematoxylin and eosin stains). Disc glands present (long tracks spread from peduncle/posterior body to discharge over the disc surface).

Muscles. Longitudinal muscles of body wall of equal size or strength dorsally and ventrally. Circular muscles of body wall similar dorsally and ventrally. Dorso-ventral muscles, attachment muscles of pharynx, of adhesive disc and those controlling male organ all weak.

Reproductive system ♀. Gonopore mid-ventral, in posterior third of body. Genital atrium commodious (sphincter present and muscular festoons about the walls). Genital complex scattered. Ovary about 80×50μm. Vesicula resorbens present, about 100×60μm, with 15μm thick wall, strong muscular duct or sphincter joining it to vagina; lying free of gut wall, not open to gut. Seminal receptacles not present. Vagina short, inner region weakly muscular, opening directly to atrium. Vitellaria dendritic, dorsal to ventral.

Reproductive system ♂. Testes elliptical: anterior about 270×200μm, lobulate, lateral to gut; posterior) about 230×210μm, lobulate, posterior or postero-lateral to gut. Vasa deferentia swollen, entering seminal vesicle separately. Seminal vesicle 95×55μm, with long reflexed ejaculatory duct from it to base of cirrus. Ejaculatory sac present (long), with narrowed neck. Prostate bulb incorporated, i.e. continuation of cirrus base. Cirrus shaft straight. Cirrus strongly tapering, about 70μm long, about 54μm wide at base. Cirrus introvert not swollen, weakly sclerotic, inner surface thrown in to fine ridges becoming a few rows of spinelets.

Etymology

The specific name refers to the collector, Dr Shirley Butler.

Remarks

As with *T. athertonensis* there is a tracery of pigment over the dorsal surface which resembles only one previously described species, *T. minor* Haswell, 1888. The nature of the cirrus and the presence of the postero-lateral glands separates it clearly from *T. minor*. It is close to *T. athertonensis*, but differs in having much finer pigment, a pharynx with a stronger central muscle region, a less muscular vagina, a small, broad cirrus, and most obviously in lacking the conspicuous capsule about the genital organs.

Temnocephala improcera n.sp.

(Figs 3,11e)

Material Examined

Holotype: ex *Caridina indistincta* (Atyidae), Murray R., nr Kirrama (18.01°S, 145.53°E), 26 Jul. 1984, L. Winsor, Form./H&E GL14576 (LS[2]).

Paratypes: same data as holotype, Form./Mallory's GL14577 (LS[1]).

Other Material: same data as holotype, Form./Hx GL14578 (damaged W).

Description

External characteristics. Body about 700μm long, and 350μm wide; oval or elliptical, not dorso-ventrally compressed. Pigment extends through body, prominent on dorsal and ventral surfaces. Posterior adhesive disc pedunculate: disc diameter 230μm at rim, disc peduncle about 100μm across. Epidermis syncitial, 3.5μm high dorsally, 5.5μm high ventrally. Cilia entirely absent.

Alimentary system. Mouth mid-ventral in anterior quarter of body. Buccal cavity or prepharynx

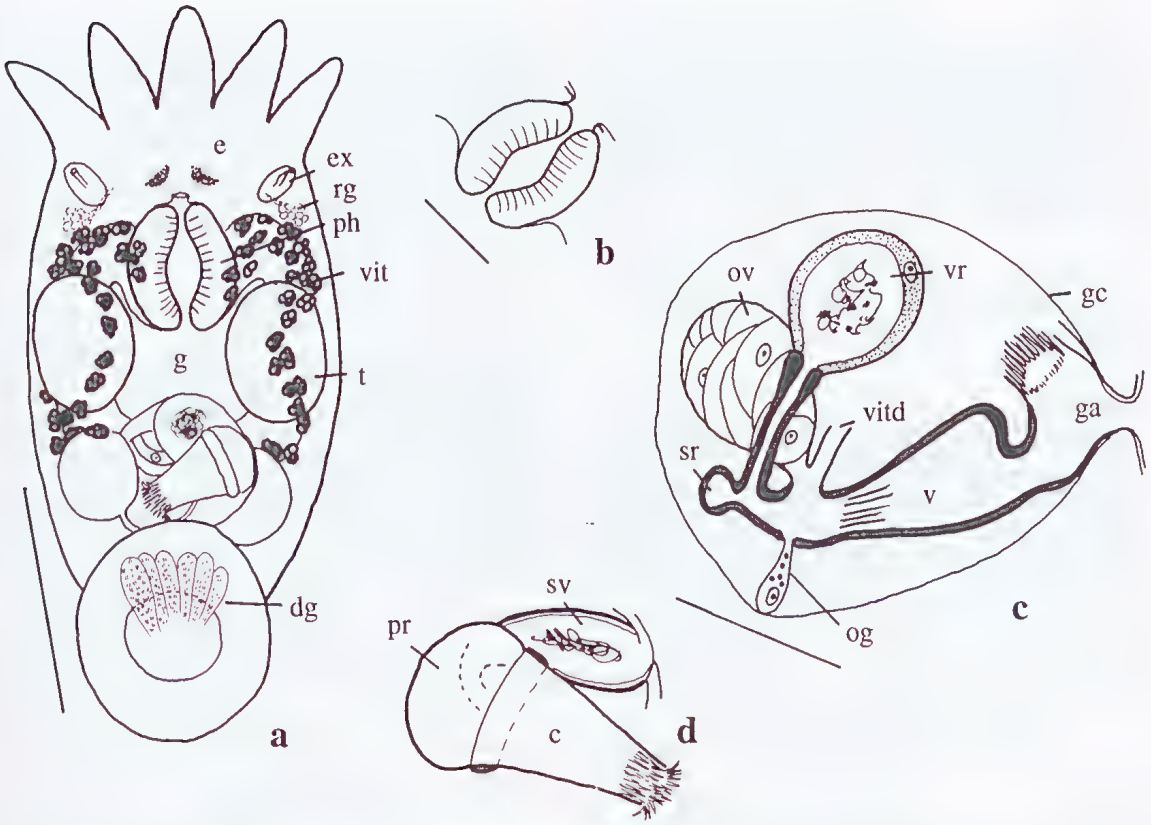

FIG. 3. *Temnocephala improcera* n.sp. a, internal anatomy of whole animal; b, pharynx; c, detail of female reproductive system; d, detail of male reproductive system. Scales: a, 250μm; b,c-d,100μm.

inconspicuous. Pharynx directed antero-ventrally, as wide as long, about 145×130μm; strong, undivided, with a few tiny eosinophilic glands in the muscle block; lacking a non- cellular lip, without a conspicuous non-cellular lining, muscles not forming an obvious crenulate buccal rim. Pharynx sphincters equal. Oesophagus inconspicuous. Gut darkly coloured (filled with brown globular (about 5-10μm) inclusions), longer than wide; with septa. Gastrodermis 60μm high.

Excretory system. Excretory pores anterior to mouth. Excretory ampulla a simple vacuole (but elongate), thick walled (12-14μm), about 70×30μm.

Nervous and sensory systems. Brain compact, transverse band. Major nerve trunks inconspicuous. Eyes present, discrete, well separated, about 20×30μm. Eye pigment granules irregular, mostly small, black-brown.

Glands. Rhabdite glands in lateral fields anterior to anterior testes. Rhabdites only accumulate on tentacles (?). Haswell's cells and oesophageal glands inconspicuous (absent?). Ootype glands present. Shell glands and postero-lateral glands absent. Disc glands conspicuous, filling the posterior body.

Muscles. Longitudinal muscles of body wall stronger ventrally. Circular muscles of body wall similar dorsally and ventrally. Dorso-ventral muscles weak. Attachment muscles of pharynx weak. Attachment muscles of adhesive disc strong. Muscles controlling male organ weak.

Reproductive system ♀. Gonopore mid-ventral, in posterior third of body. Genital atrium small. Genital complex contained in a connective tissue capsule. Ovary about 120×60μm. Vesicula resorbens present, about 70×35μm, 7μm thick wall; lying free of gut wall, not open to gut. Seminal receptacle single. Vaginal teeth absent. Vagina long, compartmentalised. Vitellaria scattered laterally, dorsal to ventral.

Reproductive system ♂. Testes rounded: anterior about 150μm in diameter, smooth, lateral to gut, posterior about 100μm in diameter, smooth, lateral or postero-lateral to gut. Vasa deferentia narrow, entering seminal vesicle separately. Seminal vesicle about 35×100μm. Ejaculatory

sac absent (?). Prostate bulb separate, i.e. wider than cirrus base. Cirrus shaft straight. Cirrus hardly tapering, 100μm long, 70μm wide at base, with basal collar. Cirrus introvert not swollen, about 25μm or 1/4 of the cirrus length. Cirrus spinelets moderately sized, filling inside, few rows, i.e. <20.

ETYMOLOGY

From *improcerus* L. = short, referring to the cirrus.

REMARKS

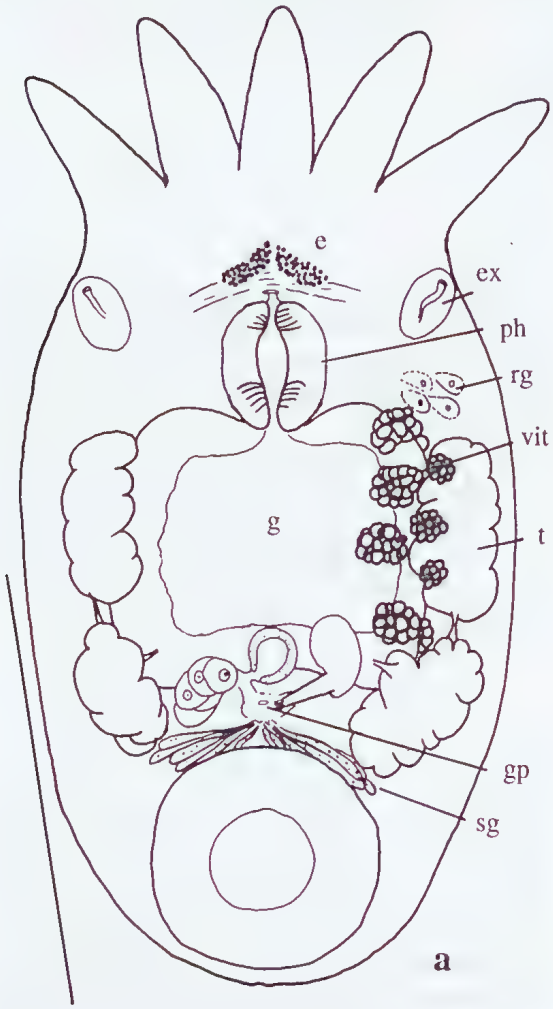
The combination of a pigmented body and the presence of a genital capsule means this species resembles most closely *T. athertonensis* (see above). However, it is much smaller, lacks the postero-lateral glands (though these are poorly developed in *T. athertonensis*), has smooth not lobulate testes, possesses a single seminal receptacle and has a short broad cirrus with a distinctive basal collar: none of these characters are shared with *T. athertonensis*.

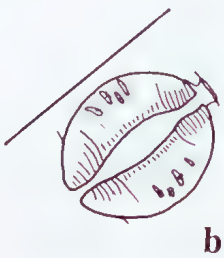
Temnocephala minuta n.sp.
(Fig. 4)

MATERIAL EXAMINED

HOLOTYPE: ex *Paratya australiensis* (Atyidae), Sandy Ck tributary of Dawson R. nr Taroom (25.39°S, 149.48°E), 3 Dec. 1986, L. Cannon & J. Jennings, AFA/Haemalum., GL14555 (W).

PARATYPE: same data as holotype, AFA/H&E GL14556 (LS[2]).





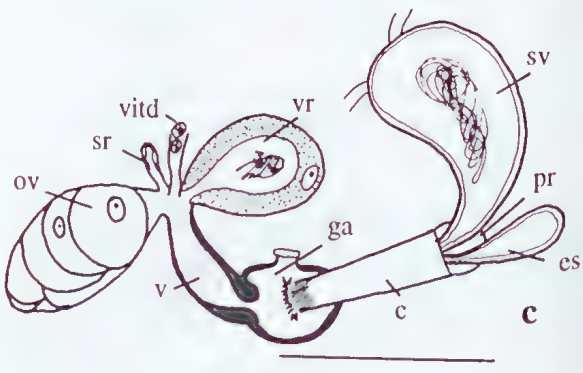


FIG. 4. *Temnocephala minuta* n.sp. a, internal anatomy of whole animal; b, pharynx; c, detail of reproductive systems. Scales: a, 250μm; b, 100μm; c, 50μm.

DESCRIPTION

External characteristics. Body about 550μm long, and 300μm wide; rounded to oval or elliptical, dorso-ventrally compressed, but without flanges. Pigment confined to eyes. Posterior adhesive disc pedunculate: disc diameter 120μm at rim, disc peduncle about 50μm in diameter. Epidermis syncitial, about 2μm high dorsally and ventrally. Cilia entirely absent.

Alimentary system. Mouth mid-ventral in anterior quarter of body. Buccal cavity or prepharynx inconspicuous. Pharynx directed antero-ventrally, as wide as long, about 80μm; strong, undivided, with nucleated cells in muscle blocks; lacking a non-cellular lip, without a conspicuous non-cellular lining, muscles not forming a crenulate buccal rim. Pharynx sphincters stronger posteriorly. Oesophagus inconspicuous. Gut lacking colour, as wide as long; without septa. Gastrodermis about 20-30μm high. Gut contains bacteria.

Excretory system. Excretory pores lateral to mouth. Excretory ampulla a simple vacuole, thick walled, about 30μm in diameter. Major excretory ducts inconspicuous.

Nervous and sensory systems. Brain compact, transverse band. Eyes present, contiguous, 25×15μm. Eye pigment granules irregular, mostly small, red-black.

Glands. Rhabdite glands in lateral fields anterior to anterior testes, few <10 each side; 12-15μm in diameter, with inconspicuous rhabdite tracts. Rhabdites apparently only accumulate on tentacles. Oesophageal glands and ootype glands inconspicuous (absent?). Shell glands present (a small cluster ventral to gonopore). Postero-lateral glands absent. Disc glands present.

Muscles. Longitudinal muscles of body wall stronger ventrally (especially at base of tentacles). Circular muscles of body wall similar dorsally and ventrally. Dorso-ventral muscles strong. Attachment muscles of pharynx weak. Attachment muscles of adhesive disc strong. Muscles controlling male organ weak.

Reproductive system ♀. Genital atrium small (but muscular). Genital complex scattered. Ovary about 30-50μm in diameter. Vesicula resorbens present, about 25-30μm across, 5μm thick wall; lying free of gut wall, not open to gut. Seminal receptacle, single, 7×3μm. Vagina short, simple (but with sphincter at opening to genital atrium). Vitellaria clustered, laterally above and below testes.

Reproductive system ♂. Testes elliptical: anterior about 110×66μm, lobulate, lateral to gut, posterior about 100×63μm, lobulate, posterior to gut. Vasa deferentia narrow. Seminal vesicle about 63×40μm. Ejaculatory sac present, with narrowed neck. Prostate bulb incorporated, i.e. continuation of cirrus base. Cirrus shaft straight. Cirrus hardly tapering, 36μm long, 11μm wide at base. Cirrus introvert not swollen, 7μm or 1/5 of the cirrus length. Cirrus spinelets minute, few rows, i.e. <20.

ETYMOLOGY

From *minutus* L. = small, refers to body size.

REMARKS

This species resembles most closely *T. cita* Hickman, 1967 in lacking pigment except for the eyes and in possession of a cirrus without a median spine. *T. cita* is very much larger, has a cirrus about 5× as big, 4 seminal receptacles (not one), and smooth, unequal testes (not subequal, lobed ones). The only other unpigmented species are *T. dendyi* Haswell, 1893 and *T. engaei* Haswell, 1893. Both these species have a median spine within the cirrus.

Temnocephala neqae n.sp.
(Figs 5,11f)

MATERIAL EXAMINED

HOLOTYPE: ex gills of *Macrobrachium rosenbergii* (Palaemonidae), Mitchell R. at Mt Carbine (16.32°S,145.08°E), Nov. 1981, J. Short, Form./Hx., GL14518 (W).

PARATYPES: same data as holotype, GL14519 (W); ex gills of *M. rosenbergii* (Palaemonidae), Mitchell R., Dec. 1981, B. Power, Form./Mallory's GL14525-6 (LS[2,3]); Form./Gomori's GL14527 (TS[2]).

OTHER MATERIAL: same data as holotype, GL14520-35 (W); Form./H&E GL14537 (LS[3]); GL14538 (egg on gills of host); ex gills of *M. rosenbergii* (Palaemonidae), Mitchell R., Dec. 1981, B. Power, Form./Mallory's GL14536 (W).

DESCRIPTION

External characteristics. Body about 800-1400μm (mean=1040μm) long, and 430-720μm (mean=540μm) wide; oval or elliptical, dorso-ventrally compressed, with flanged edges. Pigment confined to eyes. Posterior adhesive disc pedunculate: disc diameter 220μm at rim, disc peduncle about 125μm across. Epidermis syncitial, 5μm high dorsally, 3μm high ventrally. Cilia entirely absent.

Alimentary system. Mouth mid-ventral in anterior quarter of body. Buccal cavity or prepharynx inconspicuous. Pharynx directed ventrally, wider

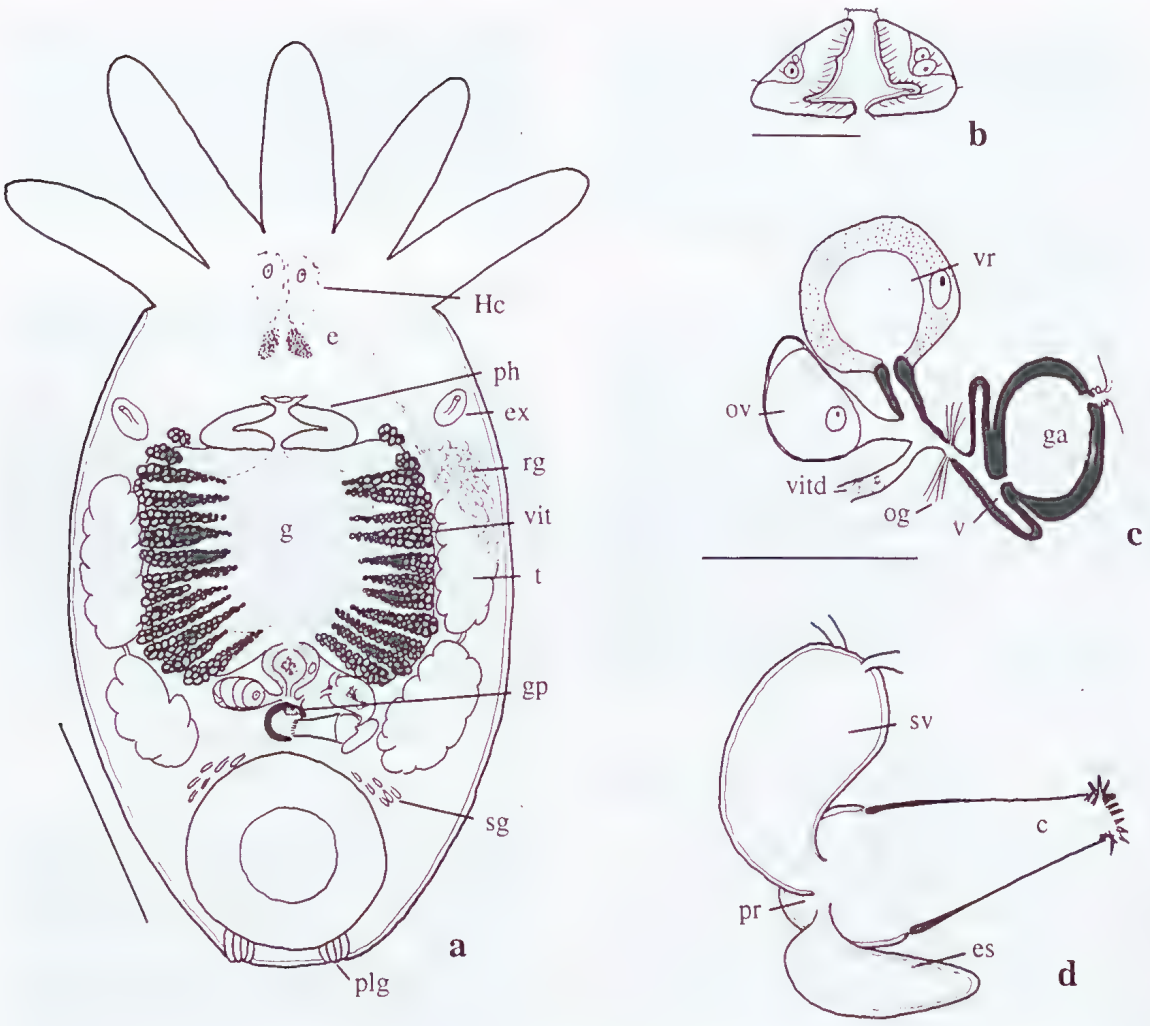

FIG. 5. *Temnocephala neqae* n.sp. a, internal anatomy of whole animal; b, pharynx; c, detail of female reproductive system; d, detail of male reproductive system. Scales: a, 250μm; b, 100μm; c-d, 50μm.

than long, about 95×180μm; strong, undivided, with nucleated cells within muscle blocks; lacking a non-cellular lip, with a conspicuous non-cellular lining, muscles forming a crenulate buccal rim. Pharynx sphincters stronger posteriorly. Oesophagus inconspicuous. Gut lacking colour, as wide as long; without septa. Gastrodermis to 16μm high. Gut contains ?rotifers.

Excretory system. Excretory pores posterior to mouth. Excretory ampulla a simple vacuole, thick walled (12μm), about 50×36μm. Major excretory ducts conspicuous.

Nervous and sensory systems. Brain compact, transverse band. Major nerve trunks inconspicuous. Eyes present, contiguous, about 40×30μm. Eye pigment granules irregular, mostly small, black-brown.

Glands. Rhabdite glands in lateral fields anterior to anterior testes, numerous, 10 or more each side; about 20μm in diameter, with prominent rhabdite tracts to tentacles. Rhabdites only accumulate on tentacles (?). Haswell's cells inconspicuous (only two before brain), each ill defined about 80×50μm. Oesophageal glands present. Ootype glands prominent. Shell glands in prominent lateral fields discharging to gonopore. Postero-lateral glands prominent. Disc glands present.

Muscles. Longitudinal muscles of body wall stronger ventrally. Circular muscles of body wall similar dorsally and ventrally. Dorso-ventral muscles and attachment muscles of pharynx weak. Attachment muscles of adhesive disc mod-

erately strong. Muscles controlling male organ strong.

Reproductive system ♀. Gonopore mid-ventral, in posterior third of body. Genital atrium large, muscular. Genital complex scattered. Ovary about 62×50μm. Vesicula resorbens present, about 48×80μm, 13μm thick wall; embedded in gut wall, opens to gut (in some). Seminal receptacles not present. Vaginal teeth absent. Vagina simple (muscular). Vitellaria dendritic, lateral. Egg capsules ellipsoid, about 300×100μm; attached on end on a stalk, on gills.

Reproductive system ♂. Testes elliptical: anterior about 170×85μm, lobulate, lateral to gut; posterior about 165×95μm, lobulate, lateral to or posterior to gut. Vasa deferentia narrow, entering seminal vesicle separately. Seminal vesicle about 70×30μm. Ejaculatory sac present, with narrowed neck. Prostate bulb separate, i.e. wider than cirrus base. Cirrus shaft straight. Cirrus hardly tapering, 52μm long, 30μm wide at base. Cirrus introvert not swollen, only about 12μm or 1/4 of the cirrus length, i.e. about the length of the 2-3 rows of cirral spines. Cirrus spinelets moderately sized, few rows, i.e. <20.

Etymology

The specific name refers to northeast Queensland.

Remarks

The only described species with prominent postero-lateral glands is *Temnocephala chaeropsis* Hett, 1925 from a crayfish '*Chaerops preissi*' from near Mammoth Cave, WA. Unlike the present species, the glands are very close together; among other differences *T. chaeropsis* is much bigger, has four seminal receptacles, evidently lacks an ejaculatory sac and the introvert of the cirrus is more elaborate. Both *T. athertonensis* and *T. butlerae* (see above) also have postero-lateral glands; in neither species are they prominent and easily seen; furthermore, both species are pigmented, unlike the present species.

Temnocephala queenslandensis n.sp.
(Fig. 6)

Material Examined

Holotype: ex *Macrobrachium australiense* (Palaemonidae), Hayes Ck off Moggill Ck Brisbane (27.30.4°S, 152.55.8°E), 7 Mar. 1990, L. Cannon & K. Sewell, AFA/Haemalum GL14539 (W).

DESCRIPTION

External characteristics. Body about 650-950μm (mean=775μm) long, and 290- 350μm (mean=315μm) wide; oval or elliptical, not dorso-ventrally compressed. Pigment confined to eyes. Posterior adhesive disc pedunculate: disc diameter 155μm at rim, disc peduncle about 70μm across. Epidermis syncitial (a strongly staining basement membrane and numerous cell walls seen), 2μm high dorsally and ventrally. Cilia entirely absent.

Alimentary system. Mouth mid-ventral in anterior quarter of body. Buccal cavity or prepharynx conspicuous. Pharynx directed antero-ventrally, as wide as long, about 80μm in diameter; strong, not divided into anterior and posterior parts, without conspicuous nucleate cells within muscle blocks; lacking a non-cellular lip, with a conspicuous non-cellular lining, muscles not forming an obvious crenulate buccal rim. Pharynx sphinc-

ters stronger posteriorly. Oesophagus inconspicuous. Gut lacking colour, as wide as long; without septa. Gastrodermis 50μm high.

Excretory system. Excretory pores lateral to mouth. Excretory ampulla a simple vacuole, thick walled (10μm), about 40×20μm. Major excretory ducts inconspicuous.

Nervous and sensory systems. Brain compact, transverse band. Major nerve trunks inconspicuous. Eyes present, contiguous, about 20×10μm. Eye pigment granules medium, even sized, black-brown.

Glands. Rhabdite glands extending laterally beyond testes, numerous, 10 or more each side; 7-10μm in diameter, with prominent rhabdite tracts to tentacles. Rhabdites only accumulate on tentacles. Haswell's cells present, 2 before eyes and two before each excretory ampulla. Oesophageal glands present. Ootype glands present. Shell glands in prominent lateral fields discharging to gonopore. Postero-lateral glands inconspicuous (absent?). Disc glands present.

Muscles. Longitudinal muscles of body wall of equal size or strength dorsally and ventrally. Circular muscles of body wall similar dorsally and ventrally. Dorso-ventral muscles moderately strong. Attachment muscles of pharynx weak. Attachment muscles of adhesive disc strong (moderately). Muscles controlling male organ weak.

Reproductive system ♀. Gonopore mid-ventral, in posterior third of body. Genital atrium commodious. Genital complex in weak capsule. Ovary about 115×40μm. Vesicula resorbens present, about 40μm in diameter, 8-10μm thick wall; embedded in gut wall, opens to gut (in some). Seminal receptacles absent. Vagina short, simple. Vitellaria in lateral clusters.

Reproductive system ♂. Testes elliptical: anterior about 115×40μm, lobulate, lateral to gut; posterior about 100×50μm, lobulate, posterior to gut. Vasa deferentia swollen, entering seminal vesicle separately. Seminal vesicle about 50×20μm. Ejaculatory sac present, but small with narrowed neck. Prostate bulb incorporated, i.e. continuation of cirrus base (not well defined). Cirrus shaft gently curved (proximally very fine). Cirrus hardly tapering, 45μm long, 17μm wide at base. Cirrus introvert not swollen (slightly thickened and noticeably more thickened than shaft), about 9μm or nearly 1/5 of the cirrus length. Cirrus spinelets moderately sized, few rows, i.e. <20.

ETYMOLOGY

The specific name refers to the locality, Queensland.

REMARKS

Four species completely lack pigment except for the eyes, viz., *T. cita* Hickman, 1967, *T. dendyi* Haswell, 1893 *T. engaei* Haswell, 1893 and *T. minuta* (see above). Only *T. cita* and *T. minuta* have a cirrus without a median spine, but the cirrus is much larger (3-4×) in *T. cita*, and is slightly smaller and straighter in *T. minuta*, than in the present species. *T. cita* also has smooth, oval testes of unequal size and possesses 4 seminal receptacles, whereas *T. minuta* has a single seminal receptacle. These characters distinguish these worms from *T. queenslandensis*.

Temnocephala sp.

MATERIAL EXAMINED

ex shrimp (Atyidae), Sandy Ck nr Taroom (25.39°S, 149.48°E), 3 Dec. 1986, L. Cannon & J. Jennings, Form./Haemalum., GL14517 (W).

DESCRIPTION

External characteristics. Body about 315μm long, and 200μm wide; rounded, dorso-ventrally compressed, but without flanges. Pigment entirely absent, i.e. not even eyes. Posterior adhesive disc pedunculate: disc diameter 100μm at rim, disc peduncle about 60μm across. Epidermis syncitial (?). Cilia entirely absent.

Alimentary system. Mouth mid-ventral in anterior quarter of body. Buccal cavity or prepharynx inconspicuous. Pharynx directed antero-ventrally, wider than long, about 56×42μm; strong, undivided, without prominent nucleate cells in muscle blocks; lacking a non-cellular lip, without a conspicuous non-cellular lining, muscles forming a slightly crenulate buccal rim. Pharynx sphincters stronger posteriorly. Oesophagus inconspicuous. Gut lacking colour, as wide as long; without septa.

Excretory system. Excretory pores dorso-lateral, lateral to mouth. Excretory ampullae about 40×35μm, thick walled (about 5μm). Major excretory ducts inconspicuous.

Nervous and sensory systems. Brain bilobed. Major nerve trunks inconspicuous. Eyes absent.

Glands. Rhabdite glands lateral to testes; with inconspicuous rhabdite tracts.

Muscles. Longitudinal muscles of body wall of equal size or strength dorsally and ventrally.

Reproductive system ♀. Gonopore mid-ven-

tral, in posterior third of body. Genital atrium small (but muscular). Genital complex scattered. Ovary about 18×10μm. Vesicula resorbens present, about 31×21μm; lying free of gut wall. Seminal receptacles not present (?). Vagina short, simple. Vitellaria dendritic.

Reproductive system ♂. Testes elliptical: anterior about 70×35μm, lobulate, lateral to gut, posterior about 35×40μm, lobulate, posterior to gut. Vasa deferentia swollen. Seminal vesicle about 35×18μm. Ejaculatory sac present. Cirrus shaft gently curved. Cirrus hardly tapering, 36μm long, 14μm wide at base. Cirrus introvert not swollen, about 9μm or 1/4 of the cirrus length. Cirrus spinelets minute, few rows, i.e. <20.

REMARKS

As this is a single immature specimen no type designation is made. The complete lack of eyes, however, strongly suggests this will prove a new species.

Temnohaswellia Pereira & Cuocolo, 1941

Generic diagnosis. Temnocephalidae with 6 anterior tentacles, a posterior adhesive disc, two pairs of testes postero-lateral to gut.

Temnohaswellia pugna n.sp.
(Figs 7,11g)

MATERIAL EXAMINED

HOLOTYPE: ex *Caridina* sp. (*?nilotica*) (Atyidae), Aplin Weir on Ross R., Townsville (19.22°S, 146.44°E), 1976, L. Winsor, Form./Picrocarmine GL14579 (W).

DESCRIPTION

External characteristics. Body about 1700μm long (tentacles about 500μm), and 1000μm wide; rounded, dorso-ventrally compressed, with flanged edges. Pigment confined to eyes and adjacent area (just a scatter between eyes). Posterior adhesive disc pedunculate: disc diameter 350μm at rim, disc peduncle about 180μm across. Disc musculature does not create surface ridges. Epidermis syncitial (?). Cilia entirely absent.

Alimentary system. Mouth mid-ventral in anterior quarter of body. Buccal cavity or prepharynx inconspicuous. Pharynx directed antero-ven-

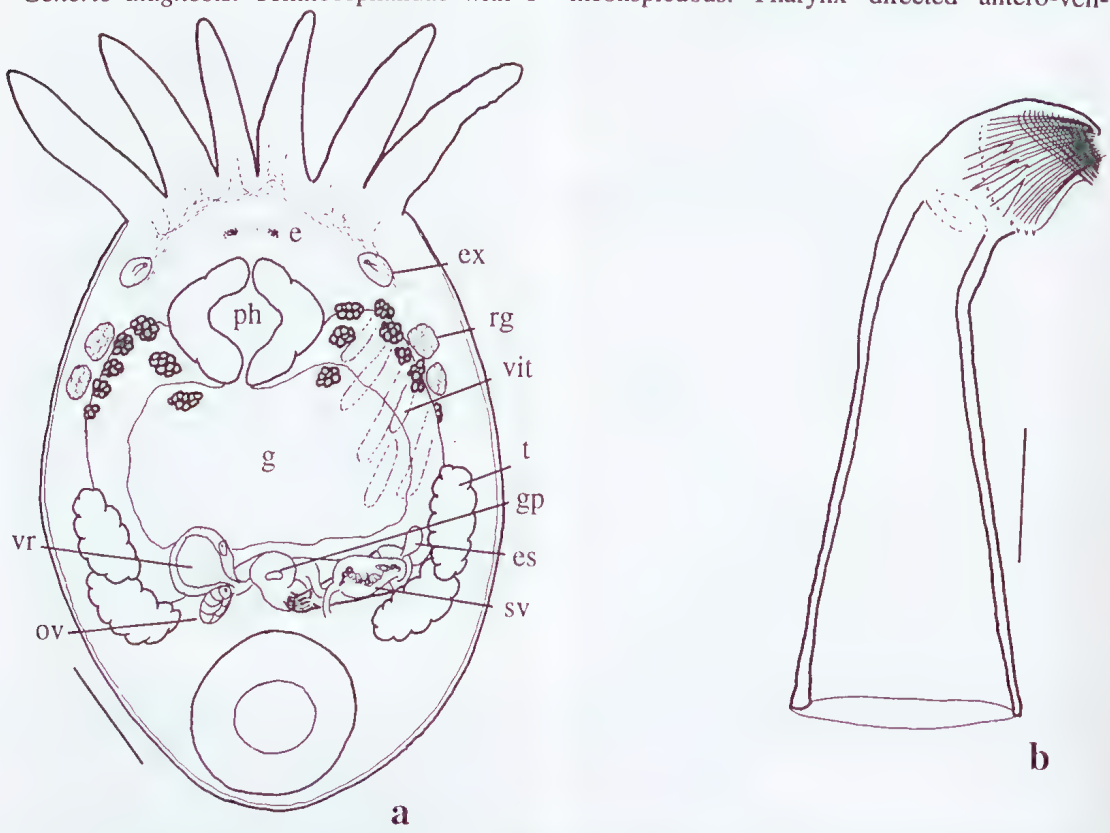

FIG. 7. *Temnohaswellia pugna* n.sp. a, internal anatomy of whole animal; b, cirrus. Scales: a, 250μm; b, 50μm.

trally, wider than long, about 360×270μm; strong, undivided, with nucleate cells within muscle blocks; lacking a non-cellular lip, without a conspicuous non-cellular lining, muscles forming a crenulate buccal rim. Pharynx sphincters subequal, slightly stronger posteriorly. Oesophagus inconspicuous. Gut lacking colour, with 3 ill-defined septa per side. Gastrodermis about 80μm high. Gut contains muscle, crustacea and diatoms.

Excretory system. Excretory pores lateral to mouth. Excretory ampulla strongly coiled, thin walled (10μm), about 90×70μm. Major excretory ducts inconspicuous.

Nervous and sensory systems. Brain compact, transverse band. Major nerve trunks inconspicuous. Eyes present, discrete, well separated (but scattered granules between them), about 20μm across. Eye pigment granules irregular, mostly small, black-brown.

Glands. Rhabdite glands? in lateral fields anterior to anterior testes, in two clumps (the smaller is posterior), with prominent rhabdite tracts to tentacles. Rhabdites evident in dorsal and ventral epidermis. Haswell's cells inconspicuous (absent?). Postero-lateral glands absent.

Reproductive system ♀. Gonopore mid-ventral, in posterior third of body. Genital atrium small. Genital complex scattered. Ovary about 70×5μm. Vesicula resorbens present, about 140μm across, 15μm thick wall; lying free of gut wall, not open to gut. Seminal receptacles absent (?). It is not clear from the specimen if vaginal teeth or muscular ribs are present. Vagina complex, outer region muscular, inner simpler. Vitellaria dendritic, dorsal over gut and lateral (plus some ventral behind pharynx).

Reproductive system ♂. Testes elliptical: anterior about 250×100μm, posterior about 220×100μm, lobulate, slightly overlapping. Vasa deferentia swollen. Seminal vesicle sinuous about same length as cirrus. Ejaculatory sac present, with narrowed neck. Prostate bulb incorporated, i.e. continuation of cirrus base. Cirrus shaft straight. Cirrus strongly tapering, 240μm long, 90μm wide at base. Cirrus introvert swollen, slightly thickened and reflexed as with a clenched fist, about 80×45μm or 1/3 of the cirrus length. Cirrus spines apparently at base of introvert. Cirrus spinelets minute to moderately sized, numerous rows, i.e. >20.

ETYMOLOGY

From *pugnus* L. = fist, referring to the shape of the cirrus introvert.

REMARKS

Pereira & Cuocolo (1941) erected the genus *Temnohaswellia* with *T. novaezealandiae* (Haswell, 1888) as the type species. They included in the genus *T. comes* (Haswell, 1893) and placed the poorly described *T. simulator* (Haswell, 1924) in synonymy with it. Baer (1953) rejected the genus believing the possession of 6 tentacles insufficient justification on which to erect a new genus, although he allowed that coupled with the vaginal teeth found in *T. novaezealandiae* there may be justification. This latter character is, however, absent from *T. comes*.

First, Haswell (1924) who was a careful worker clearly distinguished *T. simulator* from *T. comes*: *T. simulator* is here recognised as a valid species. Secondly, Haswell (on the same page) suggests the elaborate vagina of *T. novaezealandiae* may be 'an enormous extension of the thick sphincter of *T. comes* and the metraterm which subtends it.' Thus Haswell clearly saw a link between these species. Further, the relatively posterior position of the testes (overlapping and at the rear of the gut) and the presence of two pairs of clumped glands at the anterior lateral margin of the gut as Fyfe (1942) showed in *T. novaezealandiae* I believe provide characters coupled with the others to indicate these species are related. Fyfe (1942) claimed these paired anterior glands were prostate glands: their position certainly is in more keeping with rhabdite glands. The material available is not adequate to distinguish this character, and regrettably Haswell (1893) did not fully describe *T. comes*. Nevertheless, I believe the genus *Temnohaswellia* Pereira & Cuocolo, 1941 should be recognised as valid. Of the three known species, viz. *T. comes* (Haswell, 1893) which is unpigmented, and T. simulator (Haswell, 1924) and *T. novaezealandiae* (Haswell, 1888) which are pigmented, the present species more closely resembles *T. comes*, but may be distinguished by the cirrus which, though possessing a distinctive introvert, is not curved as in *T. comes*.

Temnohaswellia tetrica n.sp.
(Fig. 8)

MATERIAL EXAMINED

HOLOTYPE: ex *Caridina* sp. (*?nilotica*) (Atyidae), Aplin Weir on Ross R., Townsville (19.22°S, 146.44°E), 1976, L. Winsor, Form./Picrocarmine GL14580 (W).

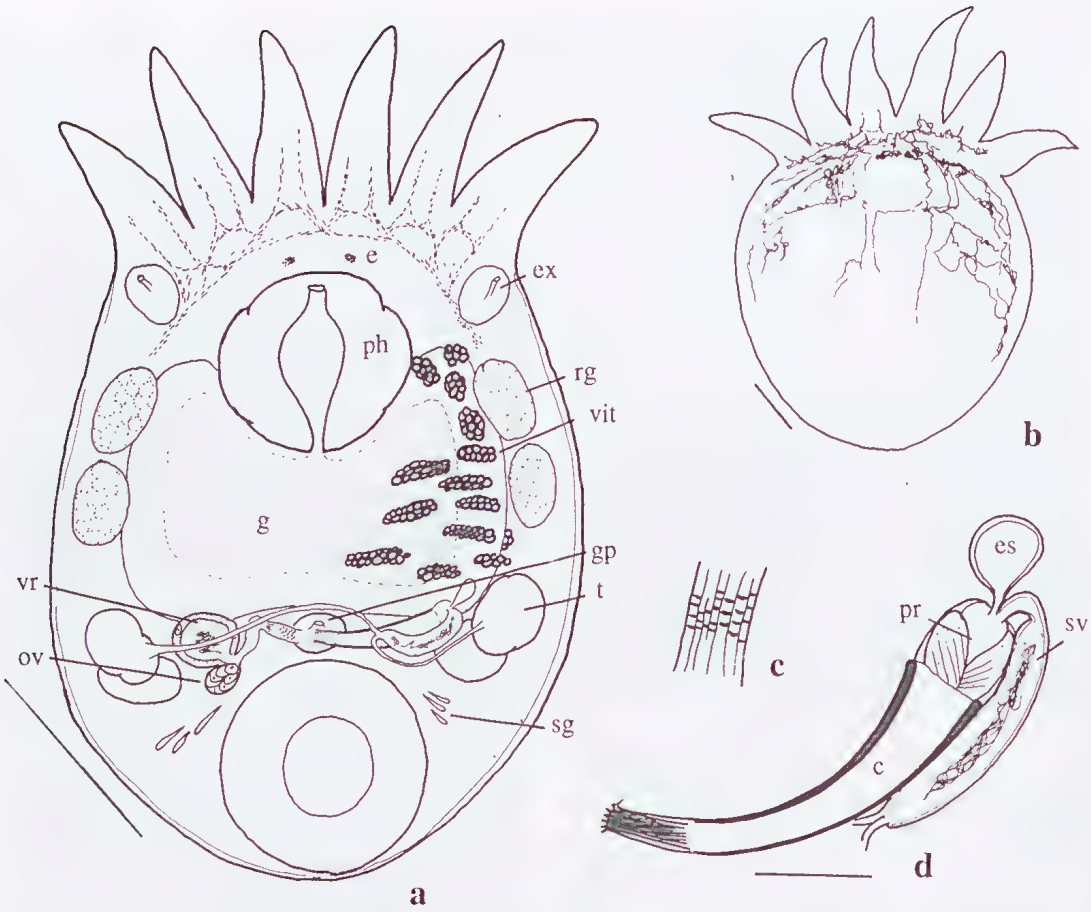

FIG. 8. *Temnohaswellia tetrica* n.sp. a, internal anatomy of whole animal; b, dorsal pigment pattern; c, detail of vaginal teeth; d, detail of male reproductive system. Scales: a,b, 250μm; c, not to scale; d, 100μm.

DESCRIPTION

External characteristics. Body about 2mm long (tentacles about 500μm), and 13mm wide; rounded, dorso-ventrally compressed, with flanged edges. Pigment a tracery over most of anterior dorsal surface. Posterior adhesive disc pedunculate: disc diameter 500μm at rim, disc peduncle about 250μm across. Epidermis syncitial (?). Cilia entirely absent (?).

Alimentary system. Mouth mid-ventral in anterior quarter of body. Buccal cavity or prepharynx conspicuous. Pharynx directed antero-ventrally, as wide as long, about 485μm across; strong, undivided, with nucleate cells within muscle blocks (?); lacking a non-cellular lip, without a conspicuous non-cellular lining, muscles forming a crenulate buccal rim. Pharynx sphincters equal (?). Oesophagus inconspicuous. Gut lacking colour, wider than long; without septa. Gut contains diatoms.

Excretory system. Excretory pores anterior to mouth. Excretory ampulla a simple vacuole, thick walled, about 180μm in diameter. Major excretory ducts inconspicuous.

Nervous and sensory systems. Eyes adjacent, about 30μm across, linked with a pigment mesh forming a single dark region. Eye pigment granules irregular, mostly small, black-brown.

Glands. Rhabdite glands? in lateral fields anterior to anterior testes (in two tandem clumps), individual gland cells within these clumps are not readily distinguishable; clumps 140-170 × 120 μm. With prominent rhabdite tracts to tentacles; rhabdites only accumulate on tentacles (?). Haswell's cells, oesophageal glands and ootype glands inconspicuous (absent?). Shell glands in

prominent lateral fields. Postero-lateral glands absent.

Reproductive system ♀. Gonopore mid-ventral, in posterior third of body. Genital atrium small. Genital complex scattered. Ovary about 80μm in diameter. Vesicula resorbens present, about 120μm across; lying free of gut wall, not open to gut. Seminal receptacles absent (?). Vaginal teeth present, about 5 or 6 rows of fine scale-like teeth in columns. Vagina long, compartmentalised. Vitellaria dendritic, dorsal to ventral.

Reproductive system ♂. Testes rounded, smooth, about 175μm in diameter, both posterior to the gut and slightly overlapping one another (the posterior more dorsal pair vacuolated and apparently invaded by nematodes). Vasa deferentia narrow (?), entering seminal vesicle separately. Seminal vesicle about 35×200μm. Ejaculatory sac present, with narrowed neck. Prostate bulb incorporated, i.e. continuation of cirrus base. Cirrus shaft curved. Cirrus hardly tapering, 350μm long, 70μm wide at base. Cirrus introvert not swollen, about 70μm or 1/5 of the cirrus length. Cirrus spinelets moderately sized, numerous rows, i.e. >20.

ETYMOLOGY

From *tetricus* L. = forbidding, refers to the *vagina dentata*.

REMARKS

The presence of pigment indicates this species resembles *T. simulator* (Haswell, 1924) and *T. novaezealandiae* (Haswell, 1888). *T. novaezealandiae* is said to contain 'a system of formidable chitinous teeth' (Haswell, 1924) and thus, on that account, differs substantially from the present species which has only fine teeth. *T. simulator* also has papillae which 'assume the appearance of teeth', but in the present species there can be little doubt that teeth, not papillae, are present.

The cirrus of the present species is long, slender and curved, so resembles that of *T. novaezealandiae* according to Haswell (1893: pl. XIII, figs 17-18), but not according to Fyfe (1942) who, dealing with *T. novaezealandiae* with prominent vaginal teeth, illustrates and states that the cirrus (penis) is L-shaped. Details of *T. simulator* are sketchy; however, Haswell (1924) stated 'the entire reproductive system closely resembles that of *T. comes*': certainly the cirrus of *T. comes* is much less slender with a more pronounced introvert than occurs in the present species.

The presence of nematodes in the testes of the present species echoes a similar observation made by Haswell (1893) with regard to *T. comes* who said 'many of them had parasitic Nematodes or their eggs or embryos lodged in the testes'.

Achenella n. gen.

Type species. Achenella sathonota n.sp.

Generic diagnosis. Temnocephalidae with 5 anterior tentacles, a single pair of testes posterior to the gut, genital organs contained in a connective tissue capsule, vesicular resorbens posterior - not pushing up into or adjacent to the gut, a rosette organ (a cluster of single cells subtending a small disc embedded in the epidermis) anterior to the excretory ampulla, and vitellaria clustered along the lateral margins of the gut.

Species included in Achenella. A. sathonota n.sp., *A. cougal* n.sp.

Etymology. From *achen* L. = poor, impoverished; pertaining to having only one pair of testes. Temnocephalidae has several genera with two or more pairs of testes.

Achenella sathonota n.sp.

DESCRIPTION

External characteristics. Body about 500-900μm (mean=710μm) long, and 250- 380μm (mean=330μm) wide [specimens from NSW slightly larger, to 1200μm long]; oval or elliptical, not dorso-ventrally compressed. Pigment extends to ventral surface (through parenchyma: especially dense about gut where it outlines the inner limits of the vitellaria). Posterior adhesive disc pedunculate: disc diameter 160μm at rim, disc peduncle 120μm across. Rosette organ about 50μm anterior to excretory ampulla. Epidermis syncitial, 5μm high dorsally, 9μm high ventrally. Cilia entirely absent.

Alimentary system. Mouth mid-ventral in anterior quarter of body. Buccal cavity or prepharynx conspicuous. Pharynx directed antero-ventrally, as wide as long, about 50μm across; very weak, undivided, with prominent cells within muscle blocks (though muscles barely discernible); lacking a non-cellular lip, with a conspicuous non-cellular lining, muscles not forming an obvious crenulate buccal rim. Pharynx sphincters equal but very weak. Oesophagus inconspicuous. Gut lacking colour, wider than long; without septa. Gastrodermis 50μm high. Gut contains eggs (of temnocephalan?), diatoms, cladocerans and nematodes.

Excretory system. Excretory pores lateral to mouth. Excretory ampulla a simple vacuole, thick walled, about 50×30μm in diameter. Major excretory ducts inconspicuous.

Nervous and sensory systems. Brain compact, transverse band. Major nerve trunks conspicuous ventrally. Eyes present, discrete, well separated (but joined by body pigment), about 20μm across. Eye pigment granules medium, even sized (about 1.5μm across), black-brown.

Glands. Rhabdite glands apparently a scatter of ventro-lateral glands about 20μm in diameter, with inconspicuous rhabdite tracts. Rhabdites only accumulate on tentacles (?). Haswell's cells conspicuous, four (a pair before brain, another before excretory pores) about 20μm across. Oesophageal glands inconspicuous (absent?). Ootype glands present. Shell glands in prominent lateral fields discharging to gonopore. Posterio-lateral glands inconspicuous (absent?). Disc glands prominent, a discrete eosinophilic cluster.

Muscles. Longitudinal muscles of body wall of equal size or strength dorsally and ventrally (and quite strong, about 3- 4μm wide). Circular muscles of body wall similar dorsally and ventrally (also 3-4μm wide). Dorso-ventral muscles and attachment muscles of pharynx weak. Attachment muscles of adhesive disc strong. Muscles controlling male organ strong (about stylet and seminal vesicle and also strong as dorso-lateral bands extending antero-lateral and postero-lateral from the region of the gonopore).

Reproductive system ♀. Gonopore mid-ventral, in posterior third of body. Genital atrium commodious. Ovary to about 50×90μm. Vesicula resorbens present, about 50×60μm, 210μm thick wall. Seminal receptacle single, hardly cut off from female canal. Vaginal teeth absent. Vagina long, compartmentalised (proximal region to about 75μm long with muscle walls 4μm thick, distal region to about 150μm long with walls 25μm thick). Vitellaria clumped, lateral (from excretory ampulla to testes - numerous large glands 75μm across).

Reproductive system ♂. Testes rounded, about 80μm in diameter, smooth. Vasa deferentia swollen, entering seminal vesicle separately. Seminal vesicle about 90×60μm, walls 20μm thick. Ejaculatory sac present. Prostate bulb separate, i.e. wider than cirrus base. Cirrus shaft gently curved. Cirrus hardly tapering, 170μm long, 25μm wide at base. Cirrus introvert swollen, but only very little, about 45μm or 1/4 of the cirrus length. Cirrus spines absent. Cirrus spinelets minute on a series of long sclerotic ridges, many rows i.e. >20.

ETYMOLOGY

From *sathon* Gr. = one with a large penis, referring to the relative size of the cirrus to body size.

REMARKS

Only one 5 tentacled species of temnocephalan has been described with one pair of testes, *Temnocephala brenesi* Jennings, 1968, from the shrimps, *Macrobrachium americanum*, in Costa Rica. The correct position of this species must await further study, but it does not appear to conform to *Achenella* n. gen.

In the present species the cirrus is slightly larger for specimens from Kin Kin and considerably larger (280μm long and 55μm wide at base) for those from *C. mccullochi* from NSW. This latter difference in size of the cirrus may reflect just bigger specimens or perhaps indicates these specimens from a different host and a distant

locality belong to a distinct species. Unless other differences become apparent all these specimens should be considered of the same species.

Achenella cougal n.sp.
(Fig. 10)

MATERIAL EXAMINED

HOLOTYPE: ex *Paratya australiensis* (Atyidae), Upper Currumbin Ck, Gold Coast (28.14.6°S, 153.20.8°E), 12 Apr. 1991, L. Cannon & K. Sewell, Hot water Form./H&E GL14581 (LS[2]).

OTHER MATERIAL: same data as holotype, Hx GL14582 (damaged W).

DESCRIPTION

External characteristics. Body about 950μm long, and 400μm wide; oval or elliptical, not dorso-ventrally compressed. Pigment confined to eyes. Posterior adhesive disc broadly pedunculate: disc diameter 180μm at rim. Rosette organ about 100μm anterior to excretory pores. Epidermis syncitial about 5μm high dorsally and ventrally. Cilia entirely absent.

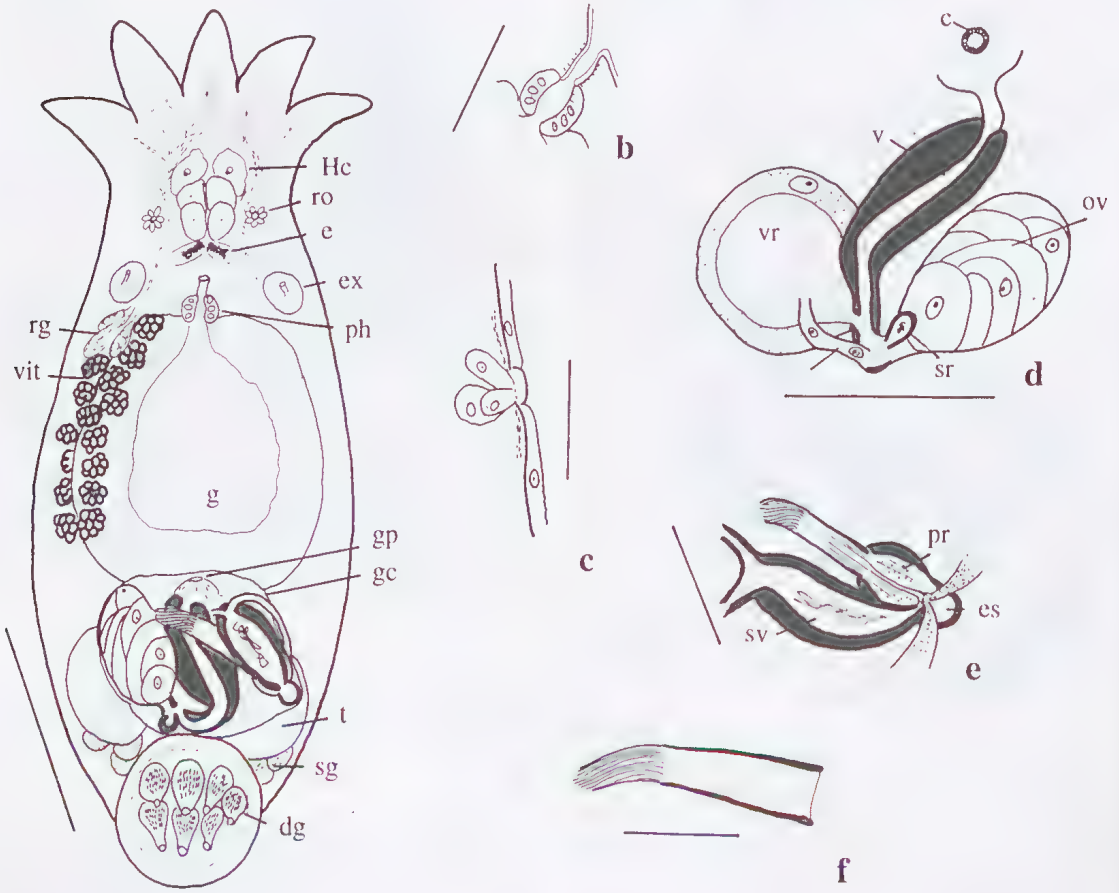

FIG. 10. *Achenella cougal* n.sp. a, internal anatomy of whole animal; b, pharynx; c, rosette organ; d, detail female reproductive system; e, detail of male reproductive system; f, cirrus. Scales: a, 250μm; b, 100μm; c, 50μm; d-e, 100μm; f, 50μm.

FIG. 11. Photomicrographs of new temnocephalans from crabs and shrimps. a-c, *Temnocephala athertonensis* n.sp.: a, pharynx showing prominent cells between sphincter blocks; b, genital capsule; c, weak postero-lateral glands; d, *Temnocephala butlerae* n.sp. genital region showing prominent ejaculatory sac; e, *Temnocephala improcera* n.sp. showing simple muscular pharynx: note pigment below body wall; f, *Temnocephala neqae* n.sp. posterior end showing prominent postero-lateral glands; g, *Temnohaswellia pugna* n.sp. cirrus; h, *Temnohaswellia tetrica* n.sp. showing shaft of cirrus and vaginal teeth, overlaying the introvert. Scales: 1cm = 100μm (a,b,e,g,h); 1cm = 50μm (c,d,f). Nomarski f,g,h.

Alimentary system. Mouth mid-ventral in anterior quarter of body. Buccal cavity or prepharynx conspicuous (muscular, about 50μm deep). Pharynx directed antero-ventrally, as wide as long, about 72μm in diameter; weak, undivided, with prominent cells within muscle blocks; lacking a non-cellular lip, with a conspicuous non-cellular lining, muscles not forming an obvious crenulate buccal rim. Pharynx sphincters equal (very little musculature). Oesophagus inconspicuous. Gut lacking colour, as wide as long; without septa. Gastrodermis about 70μm high.

Excretory system. Excretory pores lateral to mouth. Excretory ampulla a simple vacuole, thick walled (12- 15μm), about 50μm in diameter. Major excretory ducts inconspicuous.

Nervous and sensory systems. Brain bilobed (with large bilobed ?forebrain). Eyes present, discrete, well separated, about 30-40μm across. Eye pigment granules medium, even sized, about 2μm, black-brown to red-black.

Glands. Rhabdite glands in lateral fields anterior to anterior testes (and anterior and lateral to pharynx), few, less than 10 each side; 15-25μm in diameter, with rhabdite tracts to base of tentacles. Rhabdites only accumulate on tentacles. Haswell's cells conspicuous, two together before ?forebrain, about 70×30μm. Oesophageal glands and ootype glands inconspicuous (absent?). Shell glands present postero-lateral to testes open to gonopore. Postero-lateral glands absent. Disc glands prominent, scattered around testes with a cluster of deeply eosinophilic club shaped cisternae opening on to disc.

Muscles. Longitudinal muscles of body wall stronger ventrally. Dorso-ventral muscles and attachment muscles of pharynx weak. Attachment muscles of adhesive disc and muscles controlling male organ strong.

Reproductive system ♀. Gonopore mid-ventral, in posterior third of body. Genital atrium large. Ovary about 130×80μm. Vesicula resorbens present, about 90μm across, 15μm thick wall. Seminal receptacle single, about 20μm across. Vaginal teeth absent. Vagina long, compartmentalised, distally muscular 145μm long walls 25μm thick, proximally 40μm long walls 7-8μm thick. Vitellaria discrete (scattered), lateral about 20μm across.

Reproductive system ♂. Testes a single pair, rounded, about 140μm in diameter, smooth, posterior to gut. Vasa deferentia swollen (to about 20μm), entering seminal vesicle separately. Seminal vesicle about 100×70μm with thick (10μm) walls. Ejaculatory sac present about 50μm in diameter, with wide neck (joins directly to back of prostate bulb). In holotype a very large prostate gland (110-125μm across) lies anterior to testes. Prostate bulb incorporated, i.e. continuation of cirrus base. Cirrus shaft straight. Cirrus hardly tapering, 100μm long, 20μm wide at base. Cirrus introvert not swollen, about 40μm long tapering to 10μm wide; 1/3 of the cirrus length. Cirrus spines present, on about 20 strong ribs spiralling out.

ETYMOLOGY

The specific name refers to the name of the locality. Currumbin Ck rises in Cougal National Park.

REMARKS

The lack of pigment in the body and the much smaller, more gracile cirrus serve to clearly distinguish this species from the only other member of the genus *A. sathonota.*

Achenella sp.

MATERIAL EXAMINED

ex *Austratya striolata* (Austratyidae); Yuccabine Ck, Kirrama (18.13°S, 145.45°E), 10 Jul. 1985, R. Smith, Bouin's/H&E GL14557 (TS[3]).

DESCRIPTION

External characteristics. Body about 500μm long, and 400μm wide; oval or elliptical, not dorso-ventrally compressed. Pigment confined to eyes. Posterior adhesive disc pedunculate: disc diameter 140μm at rim, disc peduncle about 90μm across. Epidermis about 7μm high dorsally and ventrally. Cilia entirely absent (?).

Alimentary system. Mouth mid-ventral in anterior quarter of body. Buccal cavity or prepharynx inconspicuous. Pharynx directed antero-ventrally (?), as wide as long, about 70μm in diameter; weak, with nucleate cells within muscle blocks (?); without a conspicuous non-cellular lining.

FIG. 12. Photomicrographs of new temnocephalans from crabs and shrimps. a-d,f-i, *Achenella sathonota* n. gen., n.sp. a, weak pharynx, brain and eye; b, excretory pore and anterior to it the rosette organ; c, brain, ?forebrain and Haswell's cell; d, genital capsule and posterior testis; e, *Achenella cougal* n.sp. genital capsule and prominent cisternae of disc glands with a weakly pedunculate adhesive disc; f, specimen from Capalaba; g, posterior showing cirrus, specimen from Stretton; h, posterior (lateral) showing cirrus, specimen from Kin Kin; i, specimen from Orara R., NSW. Scales: 1cm = 50μm (a-c); 1cm = 100μm (d,e,g,f); 1cm = 250μm (f,i).

Pharynx sphincters equal (?). Gut lacking colour, as wide as long (?). Gastrodermis about 40μm high.

Excretory system. Excretory pores lateral to mouth. Excretory ampulla a simple vacuole, thick walled (20μm), about 35-40μm across. Major excretory ducts inconspicuous.

Nervous and sensory systems. Brain compact, transverse band. Major nerve trunks inconspicuous. Eyes present, discrete, well separated, about 25×20μm. Eye pigment granules medium, even sized, red-black.

Glands. Rhabdite glands in lateral fields anterior to anterior testes (?); about 15μm across. Shell glands present. Disc glands prominent, a discrete cluster.

Muscles. Longitudinal muscles of body wall of equal size or strength dorsally and ventrally. Circular muscles of body wall similar dorsally and ventrally. Dorso-ventral muscles weak; attachment muscles of pharynx and of adhesive disc weak. Muscles controlling male organ strong, about 25μm thick.

Reproductive system ♀. Gonopore mid-ventral, in posterior quarter of body. Genital atrium commodious. Ovary about 50×70μm. Vesicula resorbens present, about 75μm in diameter, about 20μm thick wall. Vagina chambered and strongly muscular. Egg capsules ovoid or pyriform, about 225μm in diameter; attached on side without stalk, on cephalothorax (inside branchial chamber).

Reproductive system ♂. Testes rounded. Seminal vesicle about 50μm across. Ejaculatory sac present, with narrowed neck? Cirrus shaft straight. Cirrus hardly tapering, 100μm long, 32μm wide at base. Cirrus introvert not swollen, about 10μm long or 1/9 of cirrus. Cirrus spinelets minute, few rows, i.e. <20.

Remarks

This one sectioned specimen is tentatively placed in *Achenella* as there appears but one pair of testes, the genital organs are in a capsule and disc glands are prominent. Until better material is available it is not appropriate to provide a specific name.

ACKNOWLEDGEMENTS

I wish to acknowledge the generous support of the Australian Biological Resources Survey and the considerable help in the field from Mr Kim Sewell. For help in the laboratory I am indebted to Lucille Gillespie and especially Christine Lee. John Short provided confirmation of identification of the various hosts. Thanks are also extended to Leigh Winsor, James Cook University, and Stephen Cook, Queensland Museum for some specimens.

NOTES ON *PARMULARIA* MACGILLIVRAY (BRYOZOA: CHEILOSTOMIDA) FROM AUSTRALIA

P.J. CHIMONIDES AND P.L. COOK

Chimonides, P.J. & Cook, P.L. 1993 06 30: Notes on *Parmularia* MacGillivray (Bryozoa: Cheilostomida) from Australia. *Memoirs of the Queensland Museum* 33(1): 41-48. Brisbane. ISSN 0079-8835.

Colonies of *Parmularia* form leaf-like lobes, anchored above the surface of particulate sea-bottoms by a wide, turgid, extrazooidal rhizoid system. In spite of this distinctive colony form, species generally show striking similarities with those of two normally encrusting genera, *Emballotheca* Levinsen and *Calyptotheca* Harmer, and all three genera are here included in the family Parmulariidae Canu & Bassler. Four species, *P. obliqua* (MacGillivray), *P. quadlingi* (Haswell), *P. arnoldi* sp.nov. and *P. occidenta* sp.nov. are described. □ *Bryozoa, Parmularia, Cheilostomida, Parmulariidae, Emballotheca, Calyptotheca, new species.*

Pantelakis J. Chimonides, Zoology Department, The Natural History Museum, Cromwell Rd, London SW7 5BD, United Kingdom; Patricia L. Cook, Associate, Museum of Victoria, Swanston St, Melbourne, Victoria 3000, Australia; 16 March, 1993.

Parmularia was introduced by MacGillivray (1887) who quoted a manuscript name mentioned in correspondence by George Busk. The distinctive leaf-like colonies, with large rhizoid systems, which support them above the surface of the substratum, are well-known in Recent Australasian bryozoan sand-faunas; fragments of colonies frequently occur in fossil assemblages from the Tertiary of Victoria. Living specimens have been described by Maplestone (1910), Bock (1982) and Cook & Chimonides (1985), all of whom particularly noted the brilliant red and orange pigments of embryos and coelomic tissues. Recognition of the genus is relatively easy, even from fragmented specimens, as the astogenetic pattern is a simple but distinctive one, and the ontogenetic changes during colony life are not profound.

Lanceopora d'Orbigny (1852) was introduced for Recent *L. elegans* from Malacca (d'Orbigny, 1852: 187(bis), pl.680, figs 7-10), and is almost certainly a senior synonym of *Parmularia*. D'Orbigny's figures of *L. elegans* depict the budding pattern (including the marginal kenozooidal and extrazooidal structures) and show circular orifices of autozooids surrounded by a distinct raised peristome. The range of orifice shapes is wide among species assigned to *Parmularia* and *Lanceopora*. This range is so wide, the orifice shape might be a useful, subgeneric character. The circular orifices were fully discussed by Harmer (1957), who was undecided as to the synonomy of the two generic names (see Hastings in Harmer, 1957: 983 footnote).The type specimen of *L. elegans* no longer exists (Canu & Bassler, 1929: 398). The type colony was minute (less than 4mm long) and sexually immature, without any ovicells.The species will probably never be recognized again with certainty, especially as several different species of *Lanceopora* are known from the Indonesian and Australasian regions. Unlike *L. elegans*, the first Australian *Parmularia* had distinctly sinuate orifices. Until a neotype for *Lanceopora* is chosen, and in view of the frequent use of *Parmularia* in Australian literature, the species discussed here are referred to *Parmularia*.

Specimens were bleached in sodium hypochlorite solution and coated with AuPd for SEM. Abbreviations used: BMNH, Natural History Museum, London; WAM, Western Australian Museum; QM Queensland Museum.

STRUCTURE OF *PARMULARIA* COLONIES

Colonies appear to be bilaminar, the zooid ofifices opening on identical faces. There is only a single, central lamina, which is a basal wall common to both zooidal expanses. The lamina is pierced by septulae which allow communication between zooids of either face (Cook & Chimonides, 1985: fig. 4). Usually, at the earlier astogenetic stages, the colony is lanceolate, with several distally budded series. In several species, this is followed by lateral and disto-lateral series, which eventually form a discoid or trilobed colony. Zooids at the margins, especially where further growth has ceased, are usually kenozooids,

formed by basal calcified lamina, and shallow lateral walls, with a cuticular frontal wall. Towards the colony's base (the earlier astogenetic regions), these kenozooids become extrazooidal, as the lateral walls are marginally deficient. They form a narrow band of turgid coelomic tissue, bounded by cuticle and communicating with the extrazooidal rhizoid system. Later in astogeny, this system may produce extensions that form secondary rhizoids (Harmer, 1957).

In life, quite large colonies (4cm in diameter) are supported several centimetres above the bottom sediment by the wide, turgid, extrazooidal rhizoid, which is deeply buried, and divided terminally into numerous rootlets with adhesive cuticle. Calcification of the extrazooidal structures surrounding the origin of the rhizoid becomes much changed during ontogeny. The area becomes thickened by calcification, and is partitioned into a complex of partially opened chambers (Canu & Bassler, 1929; Harmer, 1957). At no time is communication between the zooids and the rhizoids interrupted because damaged rhizoids can be repaired and their turgidity regained (Cook & Chimonides, 1985, fig. 2).

The frontal shield of all autozooids consists of an interior, cryptocystidean calcified wall, overlain by a hypostegal coelom and bounded by frontal cuticle. Frontal septulae, which communicate with the visceral coelom, are placed marginally, especially at the distal and proximal corners of zooid frontals (Cook & Chimonides, 1981, 1985). Other pores are present in the frontal calcification, which may be thickened during ontogeny, particularly round the orifice, which then becomes sunken and obscured. The frontal calcification may be tuberculate, rising into suboral mucros in some species.

Autozooids are monomorphic, becoming larger with astogeny; their orifices may be variously rounded or sinuate proximally, with or without condyles and spinous outgrowths. Brooding zooids are produced fairly late in astogeny, and often have larger, wider orifices than the autozooids, although the kind and degree of dimorphism varies from species to species. Ovicells are prominent; the outer calcification formed from proximally directed outgrowths from the frontal shields of two or more autozooids placed distally to the maternal zooid which produces the egg. Ovicells often show distinct 'suture lines' (Harmer, 1957), which may indicate the number of distal contributory zooids. Ovicells are closed by the brooding zooid operculum, although the position of the operculum varies with preservation and the developmental state of the ovicells. Several species possess large, interzooidal avicularia, which may have triangular or rounded mandibles, but adventitious avicularia have not been reported.

SYSTEMATICS

Family relationships of *Parmularia* have been discussed by Harmer (1957: 985, 1087, footnote), who discounted an earlier suggestion by Livingstone (1928) that the genus had a close relationship with *Emballotheca* Levinsen. Harmer reasoned that the orifices in *Parmularia* were sinuate (unlike those of *Emballotheca*) and the colony growth forms were totally dissimilar in the two genera. The orifice shape of all species of *Emballotheca* is admittedly non-sinuate, but, as shown below, not all species of *Parmularia* have sinuate orifices. The kinds and degree of dimorphism of brooding zooids, and the structure of the ovicells is the same in both *Emballotheca* and *Parmularia* and, in these characters, both genera greatly resemble a third genus, *Calyptotheca* Harmer. However, there is a continuity among variable characteristics in all three genera, and Dumont (1981) has discussed the difficulties that have arisen from past attempts to define, or distinguish between, *Emballotheca* and *Calyptotheca*. *Calyptotheca* was introduced by Harmer (1957: 1008) to accommodate species with a sinuate or rounded orifice, which had previously been assigned to *Emballotheca*. Surprisingly, he did not discuss the similarities between *Calyptotheca* and *Parmularia*, particularly as *Calyptotheca* possessed sinuate orifices, the supposed distinction between *Parmularia* and *Emballotheca* (see above).

A further similarity between some species of *Calyptotheca* and *Parmularia* is the occurrence of large, interzooidal avicularia. These heterozooids have mandibles with robust sclerites and, in some cases, possess lophophores and viscera. Their function is unknown. Interzooidal avicularia occur in *Calyptotheca capitifera* (Canu & Bassler, 1929), *C. conica* Cook (1965), *Calyptotheca* sp. Harmer (1957), *Parmularia quadlingi* (Haswell, 1880, according to Livingstone, 1926) *P. cylindrica* (Canu & Bassler, 1929, according to Harmer, 1957) and *P. occidenta* sp.nov. Adventitious avicularia occur in most species of *Emballotheca* and *Calyptotheca* but, as noted, are apparently completely absent in *Parmularia*.

Although the colony form of *Parmularia* differs from that of all species of *Emballotheca*,

which is encrusting, it is of interest that several species of *Calyptotheca* exhibit equally distinctive, but different, adaptations of growth which are associated with life in a sand-fauna environment. Lunulitiform, rooted colonies occur in *C. orbicularis* Harmer and *C. circularis* Harmer (Harmer, 1957) and lunulitiform, unrooted colonies in *C. conica* Cook (1965).

A similar diversity of colony form, which also includes different kinds of adaptation to a sand-fauna existence, occurs in the Microporellidae (*Microporella, Flustramorpha* and *Diporula*: Cook, 1968; Hayward & Cook, 1983), Celleporariidae (*Celleporaria* and *Sphaeropora*: Harmer, 1957; Cook & Chimonides, 1981), Eurystomellidae (*Eurystomella* and *Selenariopsis*: Cook & Chimonides, 1981), and Petraliellidae (*Mucropetraliella* and *Riscodopa*: Cook & Chimonides, 1981; Gordon, 1989). In all respects other than colony form, the three genera *Emballotheca, Calyptotheca* and *Parmularia* comprise a fairly natural grouping that differs from other groups of genera often included informally in the family Schizoporellidae in the structure of the ovicells and the frequency of dimorphism of the brooding zooids.

Class GYMNOLAEMATA Allman, 1856
Order CHEILOSTOMIDA Busk, 1852
Family PARMULARIIDAE Canu & Bassler, 1927

Parmulariidae Canu & Bassler, 1927: 21,35.
Lanceoporidae Harmer, 1957: 983.

Type genus. Parmularia MacGillivray.
Genera included. Parmularia MacGillivray, 1887, *Lanceopora* d'Orbigny, 1852, *Emballotheca* Levinsen, 1909 and *Calyptotheca* Harmer, 1957.

Description

Cryptocystidean Ascophora with primary orifice rounded distally, but variable proximally; spines absent. Brooding zooid orifices usually dimorphic, large and wide. Ovicells usually formed by proximal extensions of calcified frontal shields of more than one distal zooid. Adventitious and interzooidal avicularia present or absent.

Remarks

Canu & Bassler (1927) introduced Parmulariidae, in spite of their use of 'Parmulariidae Maplestone 1912' as a reference, both in 1927 and in 1929 (p.397). This misquotation of the authorship was followed by Wass & Yoo (1983: 340) but it should be noted that Harmer (1957: 983) ascribed the family name to Canu & Bassler. Maplestone used *Parmularia* in 1910 and 1913: a work dated 1912 does not seem to exist.

Parmularia MacGillivray, 1887

Parmularia MacGillivray 1887: 191,211.
Lanceopora d'Orbigny: Harmer, 1957.

Type species. Eschara obliqua MacGillivray, 1869.

Description

Colonies erect, compressed, leaf-like, with orifices opening on both faces, supported by one or more turgid, extrazooidal cuticular rhizoids. Autozooids with orifices straight, rounded or sinuate proximally. Brooding zooids with larger, often distinctly dimorphic orifices. Adventitious avicularia absent; interzooidal avicularia sometimes present.

Remarks

Harmer (1957) gave a key to Indo-west Pacific species and introduced *Lanceopora formosa* (Harmer, 1957:987, pl.66, figs 10-13, 103-105), an elongated, lanceolate, very delicate species from the East Indes. He also redescribed *L. cylindrica* Canu & Bassler (1929) from the Philippines and somewhat doubtfully assigned his own Siboga material, which had interzooidal avicularia, to this species.

Schizoporella flabellata Maplestone (1902: 68, pl. 7, fig. 10), from the Tertiary of Victoria, was later included in *Parmularia* by Maplestone (1910, 1913). Ovicells do not seem to have been described in fossil specimens, which are usually fragmented or very small and sexually immature. The degree of dimorphism of the Tertiary species is therefore unknown, but the small, distinct, rounded sinus of the autozooid orifice has usually been taken as an indication of a close relationship between *P. flabellata* and *P. obliqua*, the Recent type species of *Parmularia* (see Livingstone, 1924:190). Stach (1935) referred his Lower Pliocene Australian specimens to *P. obliqua.*

WAM: off Jurien Bay, Western Australia 137m.

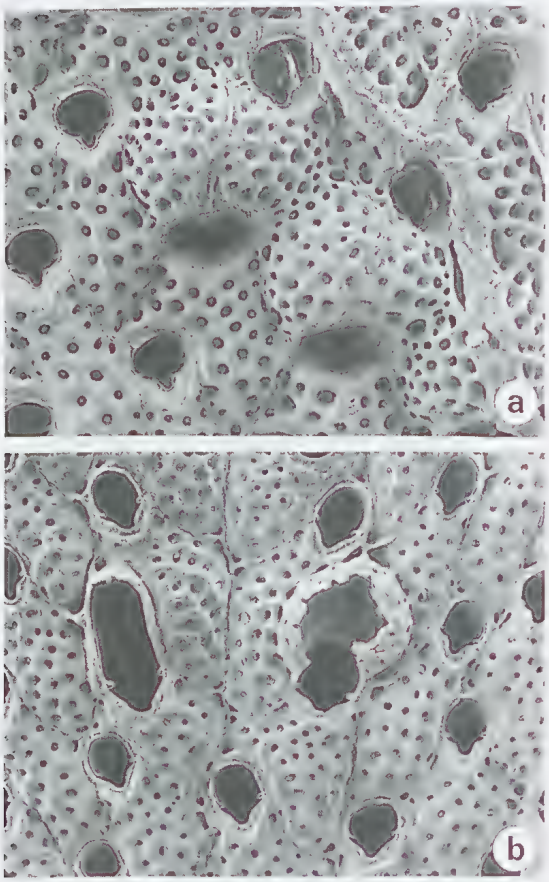

FIG. 1. a, *Parmularia obliqua*, Jurien Bay, autozooids and brooding zooids, ×57. b, *P. quadlingi*, Townsville, autozooids and one broken ovicell of brooding zooid, with one vicarious avicularium, ×49.

DESCRIPTION

Colonies kidney-shaped or nearly circular; wide, up to 4cm in diameter. Little evidence of an early lanceolate form. Autozooid orifices with very small, triangular-to-rounded proximal sinus and large, paired condyles. Brooding zooid orifices often large, wide and slit-like, sometimes with paired distal, but proximally directed, processes. Ovicells often very large, produced late in astogeny, with suture lines. Interzooidal avicularia absent.

REMARKS

P. obliqua has been reported from the coasts of Victoria, South Australia and Western Australia. With such a large distribution, some variation in characters may be expected. This seems to be most expressed in the degree of dimorphism of the brooding zooids. Specimens illustrated by Bock (1982) and Wass & Yoo (1983) show very wide, almost slit-like orifices of brooding zooids. The colonies from Jurien Bay have more open, proximally curved brooding zooid orifices, but a similar small autozooid sinus (Fig. 1a). Some specimens show a wide range of variation within a single colony.

Parmularia quadlingi (Haswell)
(Fig. 1b)

Lepralia (Schizoporella) quadlingi Haswell, 1880: 39, pl. 2, fig. 2.

Parmularia quadlingi Livingstone, 1926: 85, pl. 5, fig. 6, pl. 6. figs 1-2.

Lanceopora quadlingi Harmer, 1957: 990, pl. 66, fig. 11 c, 18, fig. 106.

MATERIAL EXAMINED

BMNH: 1910.6.16.5 (labelled 'Co-type'), Holborn Is., Queensland; 1935.2.22.1, Torres Strait; 1975.7.28.27, Torres Strait (figured by Harmer, 1957); 1975.7.28.28 (labelled 'from collection described by Haswell'), Port Denison, Queensland; 1987.1.10.1, off Townsville, Queensland, 1981, P. Arnold.

DESCRIPTION

Colonies lanceolate at first, becoming trilobed, up to 2cm in diameter. Autozooids with a small rounded or subtriangular sinus. Brooding zooid orifices larger. Interzooidal avicularia with an elongated, subtriangular mandible present.

REMARKS

Livingstone (1926) redescribed *P. quadlingi* from Haswell's 'type' (specimen in the Austra-

lian Museum, Sydney) and from his own material which was also from Queensland (and which possessed rhizoids). He noted that the 'type' specimen was fragmentary, and that it did not include any large, interzooidal avicularia. The autozooid orifices, each with a small, rounded,

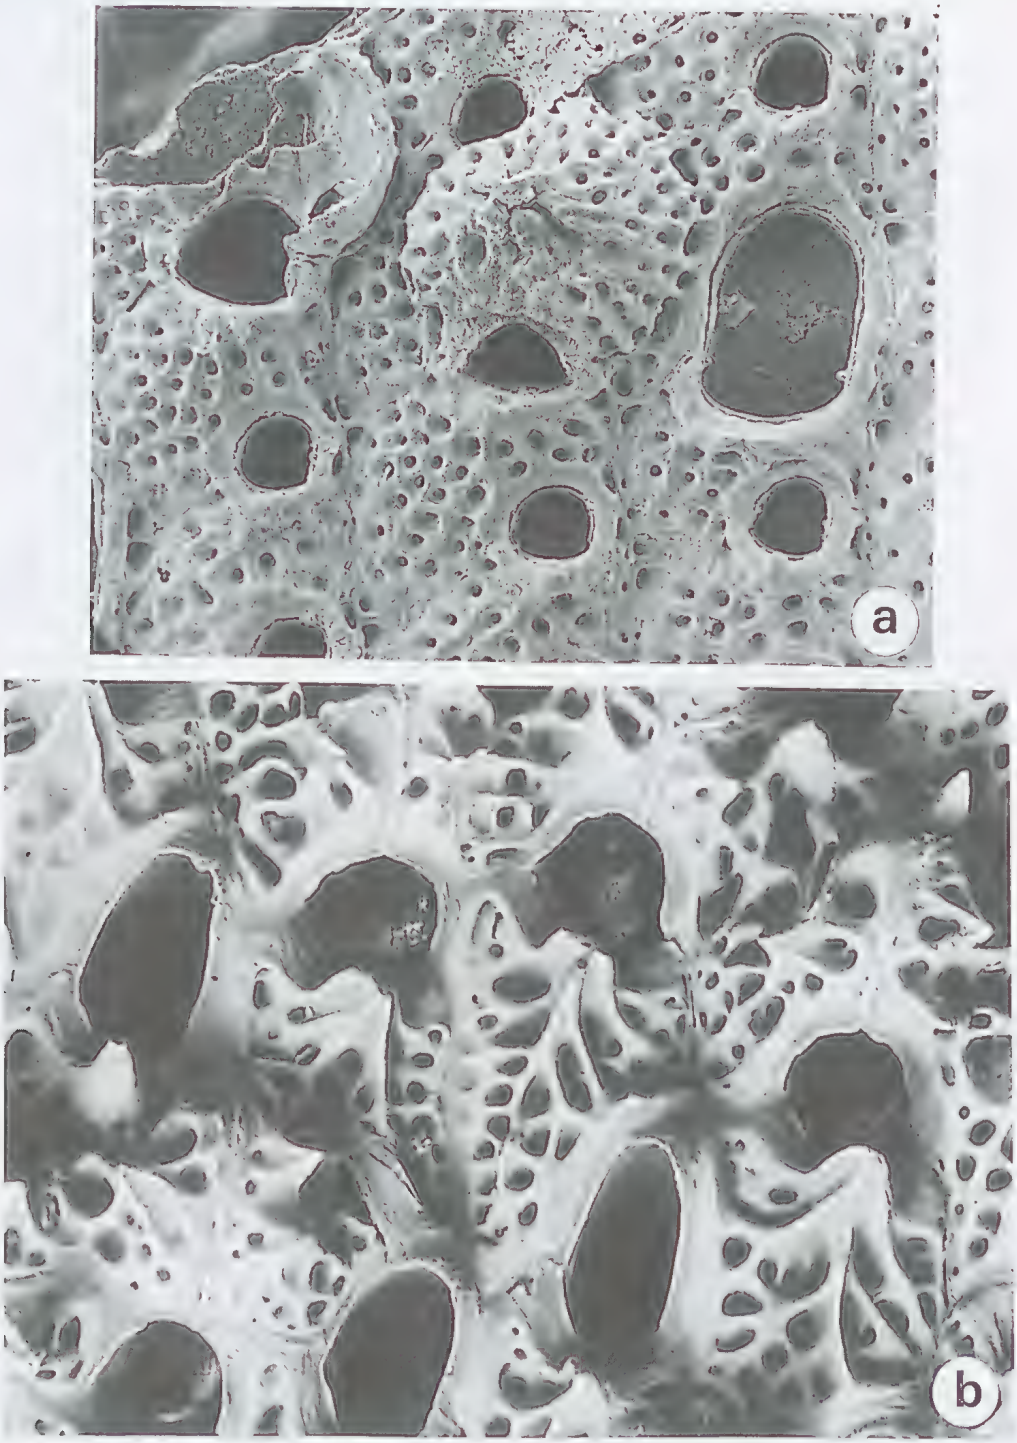

FIG. 2. a, *Parmularia occidenta*, Holothuria bank, autozooids, one brooding zooid and one vicarious avicularium, ×73. b, *Parmularia arnoldi*, Townsville, autozooids and brooding zooids with ovicells, ×85.

proximal sinus, illustrated by Livingstone (1926) are similar to those figured by Haswell (1880). Furthermore, both illustrations show similar ovicells and relatively little dimorphism of the brooding zooid orifices.

The BMNH 'Co-type' (1910.6.16.5) is a minute fragment comprising 8 zooids and 4 brooding zooids. It differs from Livingstone's figure in having larger autozooid orifices with subtriangular sinus and distinct condyles. No interzooidal avicularia are present. There is, however, some dimorphism of brooding zooid orifices. Harmer's figure (1957: pl. 66, fig. 18) shows autozooids with orifices resembling those figured by Haswell and Livingstone. However, the one brooding zooid orifice shown has a wide proximal curved edge with no sinus. Material from the same collection (Haddon) and locality (Torres Strait) in the BMNH (1935.2.22.1), which was also examined by Harmer, shows that the shape of the autozooid orifice may change with astogeny. The autozooids nearer the growing edge may have orifices with a wide subtriangular sinus. The brooding zooid orifices are larger and have a wider sinus which can be obscured by raised proximal calcification. The interzooidal avicularia resemble Livingstone's figure.

The specimen from Townsville (BMNH 1987.1.10.1, Fig. 1b) also has autozooid orifices with a subtriangular sinus, and a dimorphism of the brooding zooids is evident. The mandible of the interzooidal avicularia are proportionally much longer than those illustrated by Livingstone (1926: pl. 6, fig. 1) and by Harmer (1957: pl. 66, fig. 18). With this wide range of variability, *P. quadlingi* sensu lato may include the Siboga specimens from the Sulu Archipelago, which Harmer (1957) assigned to *P. cylindrica*. *P. cylindrica* Canu & Bassler (1929) was not described with interzooidal avicularia and none are present in the material examined (*P. cylindrica*, Bassler Collection BMNH 1931.12.30.153, Philippines). The interzooidal avicularia figured by Harmer seem to have had very short triangular mandibles and, like those of *P. quadlingi*, are narrower than those of *P. occidenta*.

P. quadlingi may prove to be a complex of more than one form or a single variable species. It appears to be confined to the coast of Queensland and the Torres and Makassar Straits.

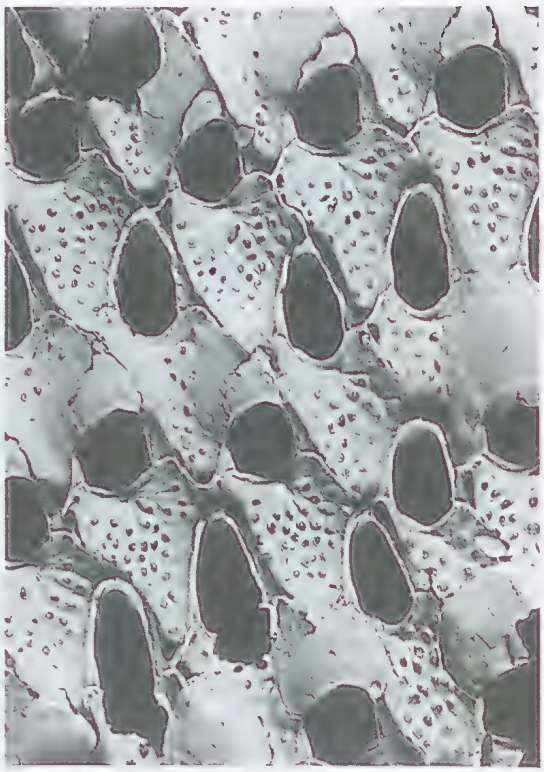

FIG. 3. *Parmularia arnoldi*, Townsville, autozooids and maternal brooding zooids with incipient ovicell development, ×48.

Parmularia occidenta sp.nov.
(Fig. 2a)

MATERIAL EXAMINED

HOLOTYPE: BMNH 1892.1.28.40A, Holothuria Bank, northwestern Australia, 27m.

PARATYPES: BMNH: 1892.1.28.40B, as for holotype; 1987.1.10.3, Holothuria Bank, 44-62m, (with *P. obliqua*.

ETYMOLOGY

Latin *occidentis*, west.

DESCRIPTION

Colonies lanceolate in early astogeny, becoming discoid or reniform, up to 2cm wide, with laterally directed zooidal series and zones of ovicells. Autozooid orifices somewhat elongated, curved, but not sinuate proximally, with small, spine-like, paired condyles near the proximal margin. Brooding zooid orifices wide, slightly curved proximally. During ontogenetic thickening a mucronate process develops proximally to the orifice and a similar mucro may appear on the

frontal surface of the ovicell. Interzooidal avicularia very large and wide, but with a short, narrow frontal shield that forms a raised shelf proximal to the mandible. Mandibles large, wide, rounded distally, with robust paired sclerites.

REMARKS

The holotype colony is dry but has a well developed extrazooidal calcification indicating that the rhizoid would have been 7mm wide at its origin. The accompanying paratype colony is only 1cm wide but has a rhizoid >1cm long and 2mm wide at its origin. The interzooidal avicularia often develop mandibles late in ontogeny and may be seen in a partially developed condition at some distance from the growing edge. *P. occidenta* resembles *P. mcneilli* Livingstone (1924: 194, pl. 24, figs 1,2, pl. 25, fig. 2), but differs by very large interzooidal avicularia. *P. occidenta* is known only from NW Australia.

Parmularia arnoldi sp.nov.
(Figs 2b, 3)

Parmularia sp. Cook & Chimonides, 1985:71, figs 2, 3A,B.

MATERIAL EXAMINED

HOLOTYPE: QM G21260, off Townsville, Queensland, 10-15m, large specimen 28mm in length with rootlet.

PARATYPES: QM: G21261, as for holotype colony fragements; G21259, Cleveland Bay, Queensland (19°13'S, 146°58'E), 23 August 1986, P.Arnold & A. Birtles, two colony fragment. BMNH: 1986.7.30.1, off Townsville, Queensland, 10-15m, numerous colony fragments, some with rootlets.

ETYMOLOGY

For Peter Arnold, Museum of Tropical Queensland.

DESCRIPTION

Early astogenetic stages lanceolate. Colonies becoming large, >4cm in diameter, discoid or reniform. Autozooid orifices very elongated, narrowing distally, deeply curved proximally, but without a distinct sinus; lateral condyles small. Distal rim of orifice raised, often with thin, crenulated processes overhanging the operculum. During ontogeny, a long mucronate process is developed proximally that obscures the secondary orifice. Brooding zooid orifices not elongated, slightly wider and proximally sinuate. Ovicells very large, with two or three suture lines, becoming tuberculate with large processes on the frontal surface. Avicularia absent.

REMARKS

The autozooid orifices distinguish this species from all others. The similarity between the autozooids of *P. arnoldi* and the avicularian zooids of *P. quadlingi* is striking (cf. Figs 1b, 2b). The raised distal process in *P. arnoldi* often overhangs the orifice and is reminiscent of the similar processes which occur in the dimorphic zooids of *Uscia mexicana* Banta (1969; see also Cook, 1979). The minute peg-like condyles are present in both autozooids and brooding zooids of *P. arnoldi*. Apart from not being as elongated, the brooding zooid orifices are not very dimorphic, being only slightly wider and having a shallow proximal sinus. Autozooids and brooding zooids frequently occur in sloping or horizontal series of alternating astogenetic generations (Fig. 2b). Each ovicell originates as a minute lamina growing distally from the maternal zooid orifice; this becomes the inner entooecial capsule. Simultaneous changes to the distal zooid or zooids include the obscuring of frontal pseudopores by secondary calcification and the gradual delineation of a circular distal depression (Fig. 3). This area marks the extent of the future ovicell and, later in ontogeny, the edges of the area (which is a frontal extension of the cryptocystal frontal shield of the distal zooids) become increasingly raised and eventually curve over and fuse medially, forming the ectooecium and enclosing the entooecial capsule contributed by the proximal maternal brooding zooid. Suture lines occur where more than one distal zooid has contributed to the ectooecial cover, and the ovicells become sunken as secondary calcification thickens the entire colony frontal. Large, irregular pores in the calcification are 'carried up' from the areolae above the marginal frontal septulae and these, together with the raised mucronate processes, give the colony an appearance unlike that of any other species (Fig. 2b).

Many colonies were collected alive from off Townsville in 1982. These possessed extensive, turgid rhizoid systems. Most of each rhizoid was buried in the muddy sand of the sea bottom, but supported the bilaminar 'head' of feeding zooids several centimetres above the surface of the substratum. The larval behaviour, the settlement and early astogeny of *P. arnoldi* have been described (as *Parmularia* sp.) by Cook & Chimonides (1985).

A small, worn fragment with zooids with similar, elongated orifices (BMNH 1882.2.23.498, Arafura Sea, off the Northern Territory, Australia, 68-72m) may belong to *P. arnoldi*. If con-

firmed by further specimens, this would extend its range across the northern coast of Australia.

ACKNOWLEDGEMENTS

We thank Dr P. Arnold (Museum of Tropical Queensland) and Dr A. Birtles (James Cook University of Northern Queensland) for their help in collecting and maintaining living colonies of *Parmularia*, and Dr J.D.D. Bishop (Port Erin Marine Laboratory, UK) for constructive criticism.

TWO BIVALVES FROM THE MIDDLE DEVONIAN BURDEKIN FORMATION, NORTH QUEENSLAND

ALEX G. COOK

Cook, A.G. 1993 06 30: Two bivalves from the Middle Devonian Burdekin Formation, north Queensland. *Memoirs of the Queensland Museum* 33(1): 49-53. Brisbane. ISSN 0079-8835.

The bivalves *Phenacocyclas pohli* LaRocque and *Modiomorpha mitchellae* sp.nov. are found within the Burdekin Formation, to the north of Charters Towers, north Queensland. They represent respectively the first lucinid and modiomorph described from these strata. *M. mitchellae* sp.nov. is characterised by its large size and elongate shape. □ *Mollusca, Bivalvia, Lucinidae, fossil, Phenacocyclas, Modiomorpha mitchellae, new species, Queensland, Middle Devonian, Burdekin Formation.*

Alex G. Cook, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; 14 August, 1992.

Collections of molluscs from the Middle Devonian (Givetian) Burdekin Formation have yielded two bivalve genera previously unreported from this formation, *Phenacocyclas pohli* LaRocque and *Modiomorpha mitchellae* sp.nov.

Stratigraphic nomenclature for the area is outlined in Wyatt & Jell (1980) and Lang et al. (1990). The Fanning River Group is divided into three formations— the Big Bend Arkose, mostly coarse grained siliciclastics is overlain by the Burdekin Formation, a dominantly limestone sequence, which in turn is overlain by the Cultivation Gully Formation, a predominantly siliciclastic unit. In the Burdekin Downs area (Fig. 1), the location of *Phenacocyclas pohli* LaRocque, the Burdekin Formation is about 90m thick and the Cultivation Gully Formation has been eroded. In the Paynes Lagoon area (Fig. 1), the locality of *Modiomorpha mitchellae* sp.nov., the only manifestation of the Burdekin Formation is a 2 to 5m thick molluscan shell bed that rests unconformably on Precambrian Basement.

In previous investigations of the molluscan fauna, Etheridge (1917) described a single gastropod from the Group and Heidecker (1959) described three gastropods and the two bivalve taxa from the Big Bend area: *Tanaodon louderbacki* Kirk and *Neoactinodonta amygdalina* Heidecker. Both Heidecker's species have been reassigned to *Tanaodon louderbacki* Kirk by Pojeta, Zhang & Yang (1986). Zhen (1990) reviewed the gastropod biofacies found at the base of the Fanning River Group, but did no further taxonomic investigations of the molluscan fauna. Cook (in press) describes a fourth genus of gastropod from the Big Bend Arkose and lower Burdekin Formation.

The Burdekin Formation has been assigned a late Eifelian to Givetian age based on limited conodont data, rugose coral associations, and the presence, in abundance, of *Stringocephalus* sp. No precise zonal ages for the localities given in this work are available but the coral fauna associated with both molluscs suggests a Givetian age (Zhen, 1990).

SYSTEMATIC PALAEONTOLOGY

Phylum MOLLUSCA
Class BIVALVIA Linné, 1758
Subclass HETERODONTA Neumayr, 1884
Order VENEROIDEA Adams and Adams, 1856
Superfamily LUCINICOIDEA Fleming, 1828
Family LUCINIDAE Fleming, 1828

Phenacocyclas LaRocque, 1950

TYPE SPECIES

Phenacocyclas pohli LaRocque by original designation from the Middle Devonian of Michigan.

DIAGNOSIS

Equivalved, irregularly rhomboidal lucinoideans with a prominent posterodorsal radial sulcus, slight anteroventral embayment and comarginal ornament. Hinge is straight and short with small umbones, narrow escutcheon and small lunule. Internal molds with posteroventral notch, two large elongate adductor scars and prominent irregular sigmoidal grooves. Posterior adductor deeper and narrower than anterior scar. Dentition small and poorly known: one probable small lateral tooth and probable small cardinal tooth.

REMARKS

Phenacocyclas, according to LaRocque (1950) is separated from *Paracyclas* Hall by the posterodorsal sulcus, the arrangement of the adductors, the presence of a strong posteroventral notch and

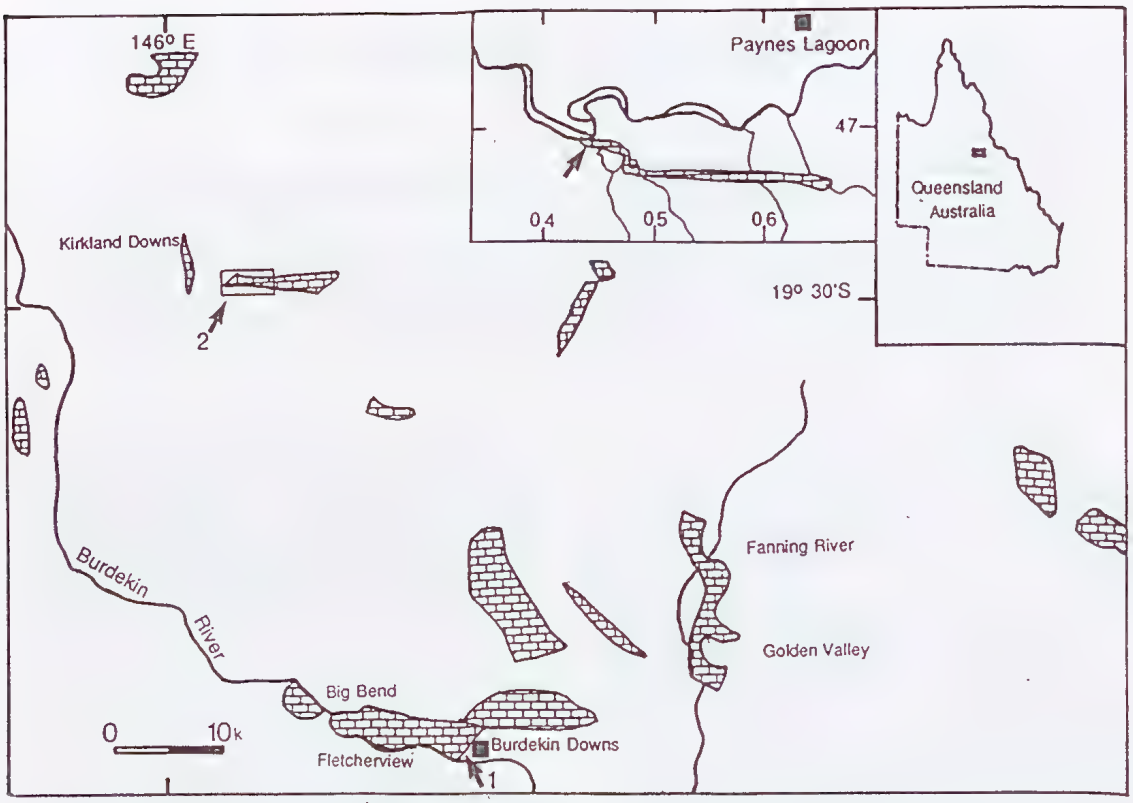

FIG. 1. Outcrop pattern for the Fanning River group within the Townsville Hinterland, showing collection localities (arrows) for *Phenacocylcas pohli* LaRocque (1) and *Modiomorpha mitchellae* sp.nov. (2).

the sigmoidal grooves on internal molds. It differs from *Crassatellopsis* Beushausen and *Montanaria* Spriestersbach on the basis of size of the dentition. The genus has been placed in the Lucinidae by Chavan (1969).

Phenacocyclas pohli LaRocque
(Fig. 2)

Material Examined
Nine conjoined specimens with shell intact and mostly free from host lithology of impure carbonate wackestone. Only 6 of the specimens are sufficiently complete to provide size data (Table 1). Material housed in Queensland Museum: QMF 22528, QMF 22529: James Cook University JCUF 11806-11812.

Age and Occurrence
Present Study: Middle Devonian (Givetian) Burdekin Formation, Fanning River Group. Collected from hill directly behind Burdekin Downs Homestead, NW of Charters Towers, north Queensland. Grid Reference Dotswood: DU 199 011. Middle Devonian Dundee Limestone and Rodgers City Limestone, Michigan, U.S.A.

Description
Medium to large equivalved rhomboidal shells ranging in height from 35-55mm, in length 42-56mm and width 19-25mm. Strong posterodorsal sulcus present. Slight embayment on the anteroventral margin. Thin shelled, with well developed comarginal ornament consisting of fine growth lines overprinted by coarser irregularly spaced rugations. Hinge and internal structures not seen.

Remarks
Burdekin material is only slightly larger than the type material illustrated by LaRocque (1950)

TABLE 1. Morphometric data for specimens of *Phenacocyclas pohli* from the Burdekin Formation. Measurements in mm.

SPECIMEN	HEIGHT	LENGTH	WIDTH
QMF 22528	43	46	24
QMF 22529	39	44	19
JCUF 11806	55	57	25

JCUF 11808	46	42	19
JCUF 11810	45	44	19

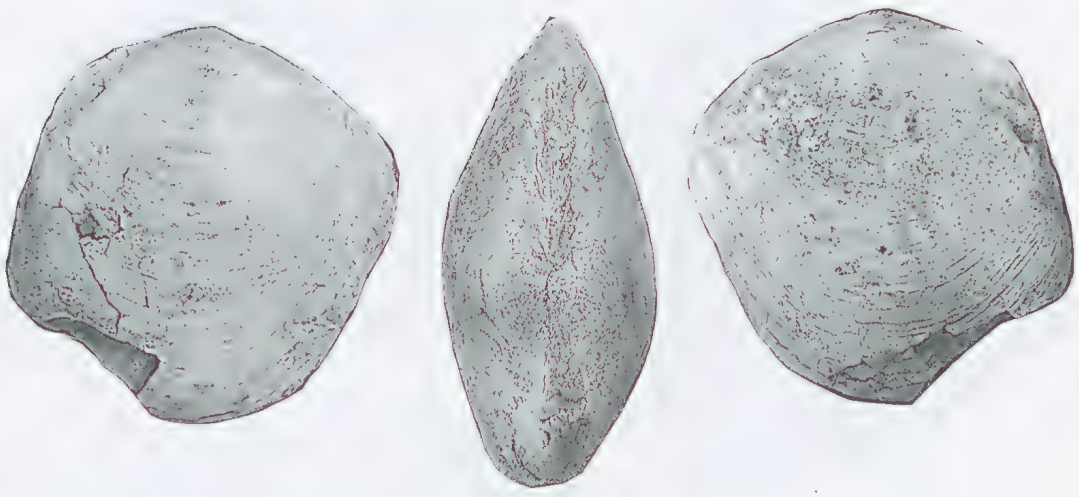

FIG. 2. a-c. *Phenacocyclas pohli* LaRocque JCUF 11806: a, right valve ×0.9; b, left valve ×0.9; c. dorsal view ×1.

and shows all of the external features described for *Phenacocyclas pohli*. Unfortunately the illustrated adult specimens are restricted to internal molds but juvenile material (LaRocque, 1950 pl. 15, figs 1-7) shows features found also in the Burdekin specimens.

Both LaRocque (1950) and Bailey (1983) suggested that *Paracyclas antiqua* (Goldfuss) may belong to *Phenacocyclas*. In particular *Paracyclas antiqua* (Goldfuss) of Beushausen (1895) shows many of the features of *Phenacocyclas*. The size of Beushausen's (1895) specimens, as given by Bailey (1983) is similar to that of *Phenacocyclas pohli* LaRocque. It is possible that the two are synonymous but determination of this awaits detailed examination of type material of *Paracyclas antiqua* (Goldfuss).

Subclass PALAEOHETERODONTA Newell, 1965
Order MODIOMORPHOIDA Newell, 1969
Superfamily MODIOMORPHACEA Miller, 1877
Family MODIOMORPHIDAE Miller, 1877

Modiomorpha Hall & Whitfield, 1869

TYPE SPECIES

Modiomorpha concentrica (Conrad, 1838)

DIAGNOSIS

Modioliform modiomorphids with large wedge-shaped cardinal tooth in left valve, socket in right valve, weak laterals, rugose growth increments.

Modiomorpha mitchellae sp.nov.
(Fig. 3)

MATERIAL EXAMINED

HOLOTYPE: JCUF 11823; internal mold.

PARATYPES: QMF 22684-85: well preserved internal molds, JCUF 11824-28, QMF 22686, 22687.

OCCURRENCE

Middle Devonian (Givetian), north Queensland Australia. Burdekin Formation, Paynes Lagoon Station, 80km W of Townsville.

DIAGNOSIS

Very large, elongate *Modiomorpha* with medium to coarse comarginal ornament.

DESCRIPTION

Large posteriorly elongate shells, modioliform in outline, up to 150mm long. Shell thick, especially anterodorsally, thinning posteroventrally. A break in shell slope, which runs from anterodorsal margin to posteroventral margin on the internal mold, is a weak ridge. Medium to coarse comarginal ornament preserved on JCUF 11824. Invagination along the hinge indicates large cardinal tooth and socket. Hinge plates relatively thick. Anterior adductor scar is small, subcircular. Quick and catch portions are easily discernible. Dorsally adjacent retractor scar is much smaller, subcircular. Posterior scar not preserved.

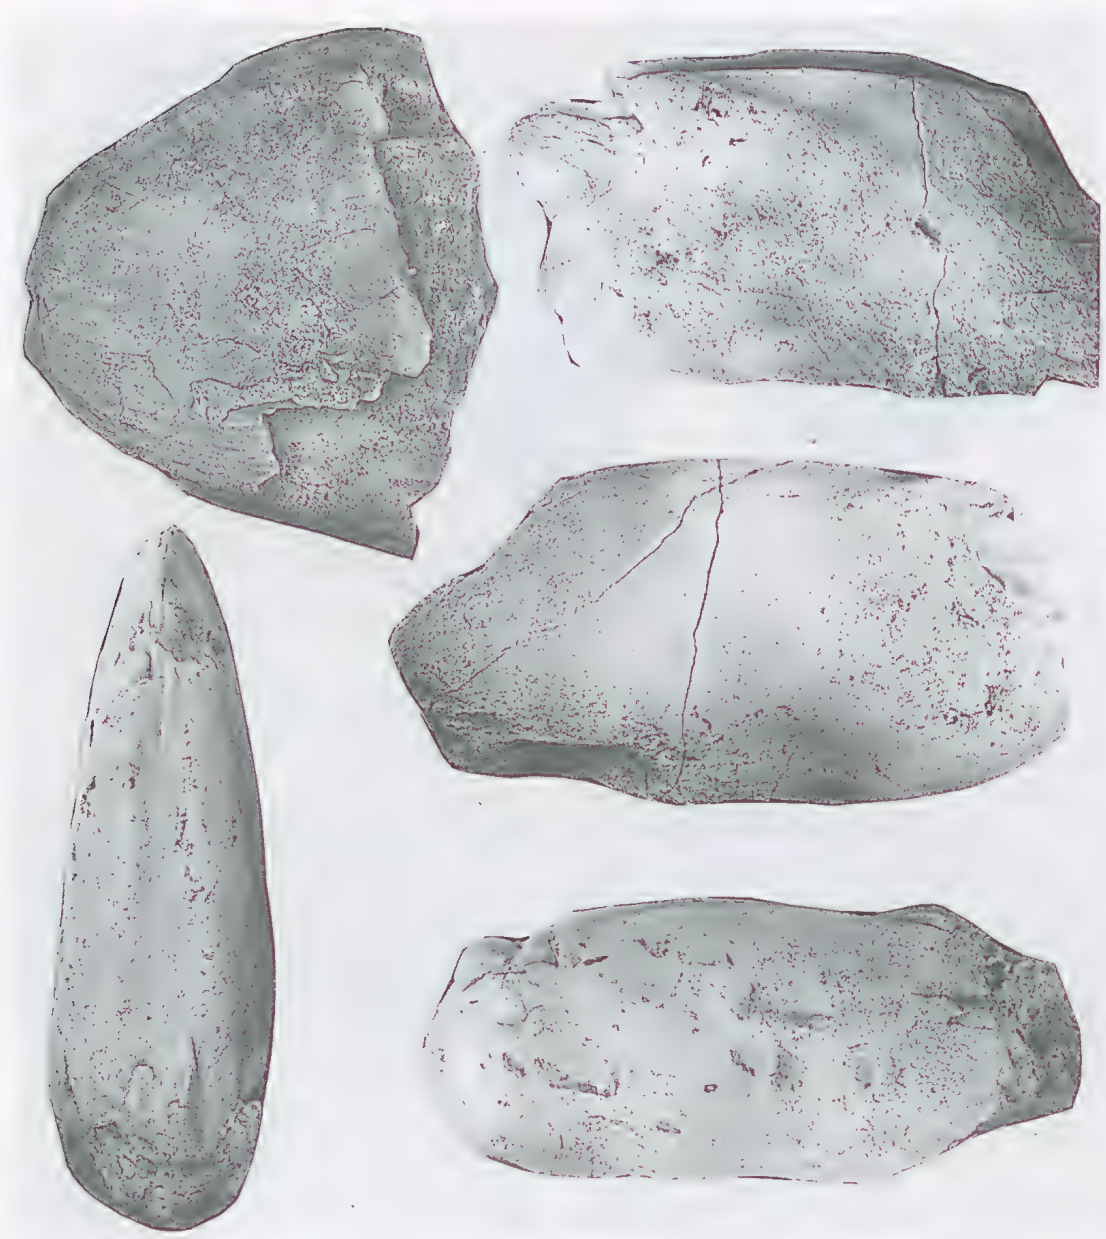

FIG. 3. a-e *Modiomorpha mitchellae* sp.nov: a, Paratype JCUF 11824, external of partial right valve, showing concentric ornament ×1.1; b, Holotype JCUF 11823, internal mold left valve ×1; c, Holotype JCUF 11823, internal mold right valve ×1; d, Paratype QMF 22684, dorsal view of articulated internal mold, showing invagination indicating large cardinal tooth ×1; e, Paratype QMF 22684, internal mold left valve, showing prominent anterior adductor ×1.

REMARKS

The characteristic musculature, dentition, shape and size ally the material to the genus *Modiomorpha*. It is distinguished by its size and rather elongate shape from other species of *Modiomorpha*. *M. concentrica* (Conrad) described by Bailey (1983), Pojeta, Zhang & Yang (1986) and *M. oblonga* Zhang 1977 are smaller despite Pojeta, Zhang & Yang's (1986) comment that *M. oblonga* is of large size. *M. herculi* Bradshaw 1991 (in Bradshaw & McCartin, 1991) is substantially smaller. *M. mytiloides* (Conrad, 1841; in Bailey, 1983) is also a small form. There is some disagreement concerning the systematic

position of *Modiomorpha* Hall & Whitfield. Newell's (1965) scheme is followed here, but Pojeta, Zhang & Yang (1986) express a different view.

ETYMOLOGY

Named for R. L. Mitchell for her contributions to the study of modern mollusca from the Townsville area.

ACKNOWLEDGEMENTS

R. A. Henderson is thanked for endless help and provision of specimens collected by D. H. Wyatt from Paynes Lagoon. JCU Merit grants in 1990 and 1992 contributed to this work, as did the Queensland Museum by the provision of services. M. Wade and P. A. Jell are thanked for their encouragement. The owners of Paynes Lagoon and Burdekin Downs are thanked for their hospitality.

A RECORD OF THE COMMON PLANIGALE AT MYORA SPRINGS: THE FIRST DASYURID FROM NORTH STRADBROKE ISLAND. *Memoirs of the Queensland Museum 33(1): 54. 1993:-* A Common Planigale (*Planigale maculata*) was captured at Myora Springs (153°25'E, 27°29'S), North Stradbroke Island on February 11, 1993. The animal was trapped during a survey by Griffith University staff and third-year students, conducted as part of a 'field ecology' course. The trapping effort at Myora Springs consisted of four pitfall traps (20 litre buckets c.38cm deep and 30cm diameter), each situated half-way along a 20m drift fence, as well as 40 small Elliott traps, all of which were set over four nights during February 9-12, 1993. The planigale was caught in one of the pitfall traps.

The Myora Springs region lies on the western edge of North Stradbroke Island, where Capembah Creek drains into the ocean. In this area there is a complex mixture of plant communities, including rainforest, *Melaleuca quinquenervia* forest and woodland, sedgeland, eucalypt forest and woodland, and disturbed areas. The habitat in which the traps were set was mapped by Coutts (1992) as partly disturbed closed forest, incorporating patches of simple notophyll vine forest dominated in part by *Melicope elleryana* with *Eucalyptus robusta* emergents and in part by *Callitris columellaris* with *Eucalyptus* spp. emergents; grading on its southern side into an open forest dominated by *Melaleuca quinquenervia* with *Eucalyptus robusta* emergents, and on the eastern side into open forest dominated by *E. pilularis*. The area of closed forest is not much more than one hectare, but is the only area of notophyll vine forest on North Stradbroke Island (Kikkawa, 1975).

The trapped specimen was a young male (testes clearly visible although not very large), of weight 6.0g, head and body length 59mm and tail length 48mm. After being caught it was retained in captivity for three days, during which period it was taken to the Queensland Museum where its identity was confirmed (S. Van Dyck) and it was photographed. It was then released on Stradbroke Island at the point of capture.

This specimen is significant because it is the first record of the family Dasyuridae from North Stradbroke Island. Three dasyurids (*Antechinus flavipes, Sminthopsis murina* and *Planigale maculata*) have been recorded from Fraser Island (Van Dyck, 1991), but none from either North Stradbroke or Moreton Islands, in spite of extensive survey effort on North Stradbroke Island (Martin, 1975; Barry & Campbell, 1977; Van Dyck, 1991). *Planigale maculata* was, however, recorded some time ago (1960) from nearby Russell Island (Van Dyck, 1983).

The present new record may be a consequence of using pitfall traps for sampling. Trapping with baited Elliott traps during the past ten years at Myora Springs during annual Griffith University field excursions (typically with 50-100 traps set over three nights each year) has usually yielded high capture rates of *Melomys* species (*M. burtoni* or *M. cervinipes*), moderate capture rates of *Rattus lutreolus*, and occasional captures of *Isoodon macrourus*. In 1993, *Mus musculus* was also captured in the area for the first time, probably a consequence of recent residential development nearby. Pitfall traps were set for the first time in 1993, and four pitfalls set over four nights caught one *Planigale maculata* and two juvenile *Melomys* sp.

The absence or relative scarcity of dasyurid marsupials on the large sand islands of Moreton Bay is a puzzling biogeographical pattern (see Barry & Campbell, 1977). The lack of dasyurids from these islands cannot be simply a consequence of lack of appropriate sampling, since *Antechinus* spp., if present, should have been caught using conventional baited traps. The distribution of habitat may also be a contributing factor: Stradbroke and Moreton Islands are dominated by 'dry' sclerophyll and heathland communities on soils very low in nutrients (see for example Clifford & Specht, 1979), whereas Fraser Island supports large areas of the moister forest types. Frequent fires on North Stradbroke Island have probably also influenced the habitat available to dasyurids (Martin, 1975). Further pitfall sampling in other parts of North Stradbroke Island would be required to determine whether *P. maculata* occurs throughout the island, or is localised within particular areas such as Myora Springs.

Acknowledgements

Thanks to Steve Van Dyck (Queensland Museum) for suggestions and encouragement and to all the staff and students of the 1993 Griffith University 'Field Ecology' course, in particular Nick Cilento, Jane Hughes and Stuart Bunn.

CHERAX CARTALACOOLAH, A NEW SPECIES OF FRESHWATER CRAYFISH (DECAPODA: PARASTACIDAE) FROM NORTHEAST AUSTRALIA

JOHN W. SHORT

Short J.W. 1993 06 30: *Cherax cartalacoolah*, a new species of freshwater crayfish (Decapoda: Parastacidae) from northeast Australia. *Memoirs of the Queensland Museum* **33**(1): 55-59. Brisbane. ISSN 0079-8835.

A new species of freshwater crayfish, *Cherax cartalacoolah*, from eastern Cape York Peninsula, Queensland is described and illustrated. The new species most closely resembles *C. robustus* Riek, 1951, which occurs in similar, sand dune habitats in southeast Queensland, and can be distinguished by the morphology of the carapace and first chelipeds. □ *Crustacea, Parastacidae, Cherax, new species, northeastern Australia, Cape York Peninsula, freshwater, taxonomy, biology.*

John W. Short, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; 3 March, 1993.

Australian species of *Cherax* Erichson were last revised by Riek (1969), who listed 27 species. Short (1991) described *C. nucifraga* from the Northern Territory.

Cherax cartalacoolah sp.nov. was brought to my attention in October 1991 by Mr Rolly McKay, Queensland Museum. Only two immature specimens and a number of carapace fragments and chelae were available but this was sufficient to establish that the species was new to science. A Queensland Museum expedition to the Cape Flattery area in November 1992 by Mr Peter Davie and myself, collected further material including mature adult specimens.

Abbreviations used in text: QM, Queensland Museum; CL, postorbital carapace length; T, thoracic sternite, T6, thoracic sternite six etc.

Cherax cartalacoolah sp.nov.

MATERIAL EXAMINED

HOLOTYPE: QM W18224, ♂ (30.3mm CL), Cape Flattery, second creek south of headland, 14°59.2'S, 145°20.2'E, supralittoral, in burrow amongst rushes fringing lagoon, peaty sand, freshwater, pH 5, hardness 40ppm, water temperature 33°C, dissolved oxygen 1.7ppm, altitude c.10m, 16/11/1992, J. Short, P. Davie.

ALLOTYPE: QM W18225, ♀ (23.6mm CL, right cheliped missing, left damaged at base of pollex), from same burrow as holotype.

PARATYPES: QM W17231, ♀ (14.4mm CL), Arnies Lake, Cape Flattery, 14°58'S, 145°19.5'E, 11/10/1991, R. McKay. QM W17234, ♂ (18.4mm CL), Windmill Lake, Cape Flattery, 14°58'S, 145°17.5'E, 13/09/1991, R. McKay. QM W18223, ♀ (16.2mm CL), Vince's Lake, Cape Flattery, 14°59'S, 145°16'E, supralittoral, burrow in bank of artificial drainage channel, peaty sand, altitude c.15m, 16/11/1992, J. Short, P. Davie. QM W18226, ♂ (13.7mm CL), 1 imm. (7.3mm CL), same locality and physiochemical data as holotype and allotype, in burrows along water line of lagoon. QM W18228, 4♂♂ (12.5-24.9mm CL), ♀ (19.8mm CL), Cape Flattery, 14°59.2'S, 145°18'E, 0.75m, artificial drainage channel, freshwater, peaty sand, water tannin-stained, fringing heathland/rushes, pH 5, hardness 80ppm, 17/11/1992, trapped, J. Short, P. Davie.

COMPARATIVE MATERIAL: *Cherax robustus* Riek, 1951 (from the vicinity of the type locality), QM W15312, 12♂♂ (17.0-30.4mm CL), 5♀♀ (17.9-25.2mm CL), Coomboo Lake, Fraser Is., 25°14'S, 153°10'E, in burrows around periphery of lake, 17/06/1987, S. Brooks, M. Tait.

DESCRIPTION OF HOLOTYPE

Rostrum triangular, dorsally flattened, slightly recurved distally, punctate proximally, glabrous to base of acumen; length c.1.3 × breadth (1.6-2.3 in allotype/paratypes), reaching penultimate segment of antennular peduncle (terminal segment in small paratypes); with moderately-developed lateral carinae, carinae commencing in line with postorbital processes, terminated at base of acumen by blunt process (spinate in several paratypes, particularly smaller specimens); ventrolateral margins setose; acumen blunt (acute in allotype/paratypes), setose.

Eyes with cornea large, globular, well pigmented, eyestalks slightly concealed by rostrum. Antennula without unique features. Scaphocerite short, length c.1.9×breadth (2.0-2.4 in allotype/paratypes), reaching end of rostrum (slightly exceeding rostrum in allotype/paratypes), broad-

est at mid-length; lamina broadly rounded mesially, lateral margin terminating in well developed spine. Antennal peduncle setose ventrally, coxocerite acute anteriorly (spinate in allotype/paratypes), basicerite laterally spinate.

Carapace punctate, breadth c.0.6×CL, depth c.0.6 × CL; postorbital carinae poorly developed, excavated with interconnected punctations, forming irregular sulcus, armed with blunt process anteriorly (spinate in allotype/paratypes), diverging posteriorly, length c.1/3 cephalon length; cephalon with few tubercles ventrally (absent in small paratypes); branchiostegites slightly inflated, with few indistinct tubercles along cervical groove (spines on allotype/paratypes), granulose anteriorly (non-granulose in smaller paratypes); branchiocardiac grooves distinct (indistinct or absent in paratypes).

FIG.1. *Cherax cartalacoolah* sp.nov., holotype ♂ (30.3mm CL), QM W18224, dorsal view.

FIG.2. *Cherax cartalacoolah* sp.nov., holotype ♂ (30.3mm CL), QM W18224, ventral view.

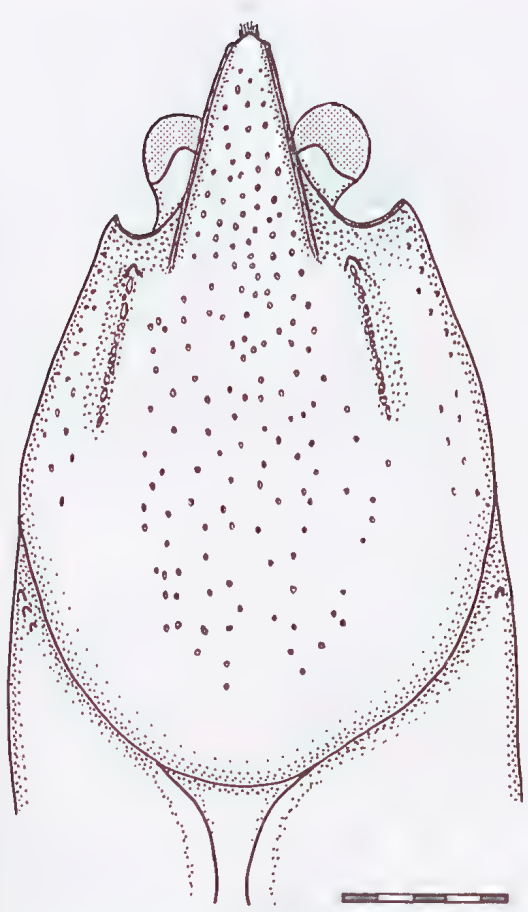

FIG.3. *Cherax cartalacoolah* sp.nov., holotype ♂, QM W18224, anterior carapace and rostrum. Scale divisions in mm.

Epistome slightly concave, sparsely setose, without obvious tubercles, lateral margins entire, slightly crenulate. Mouthparts without unique features. Branchial formula typical for genus (cf. Holthuis, 1949), with posterior arthrobranch above fourth pereiopod reduced.

First chelipeds large, subequal (isomorphic in paratypes), distal merus reaching end of scaphocerite (carpus in allotype/paratypes); outer margin of chelae moderately convex; fingers without obvious gape, opposing edges densely setose, bearing low rounded teeth; pollex broad basally; dactylus equal to manus in length; manus moderately broad, breadth equal to length (less than length in paratypes), dorsum moderately-convex longitudinally (slightly convex in allotype/paratypes), strongly convex laterally, mesial margin serrations restricted to proximal half; carpus c.0.3 chela length, bearing large, uncinate mesial spine, blunt process at anteroventral condyle (acute in paratypes), similar process at ventromesial angle followed by two or three tubercles posteromesially, anteromesial angle with dense pubescence of long setae; merus of typical shape, c.0.6 chela length, dorsal carina armed with blunt process (spinate in allotype/paratypes) followed by series of tubercles, ventral surface with pubescence of setae and numerous strong cuticular processes, two or three larger than rest (spinate in allotype/paratypes).

Sternal keel sharp, without spines, lateral processes juxtaposed on T7 and T8, bearing conspicuous pores on T6 and T7. Abdomen punctate, somite 2 pleurae with deep concavity.

COLOURATION

Body colour varying from rusty brown to bluish-grey, ventral manus of first chelipeds magenta to cyanine blue, articular membrane between merus and carpus geranium red.

BIOLOGY

Freshwater, fossorial, burrows terminating slightly below level of water table, supralittoral to shallow littoral areas around perch lakes and along creek banks. Collected from low altitude <15m, peaty sand areas within sand dune formations, generally amongst rushes, fringing heathland. Recorded physiochemical tolerances: pH 5, hardness 40-80ppm, water temperature 33°C, dissolved oxygen 1.7ppm.

DISTRIBUTION

Cape Flattery, northeast Queensland. It is likely, with further collecting, that the range of this species will be extended into other sand dune areas between Cape Bedford and Lookout Point.

ETYMOLOGY

An aboriginal word meaning 'a water hole between two sandhills' (cf. Reed, 1970), which is an accurate description of the type locality. The specific name is to be treated as a noun in apposition.

SYSTEMATIC POSITION

The new species most closely resembles *C. robustus* Riek, 1951, from southeast Queensland, which also occurs in acidic, peaty-sand habitats and has similar colouration. The following morphological features can be used to distinguish the two species:

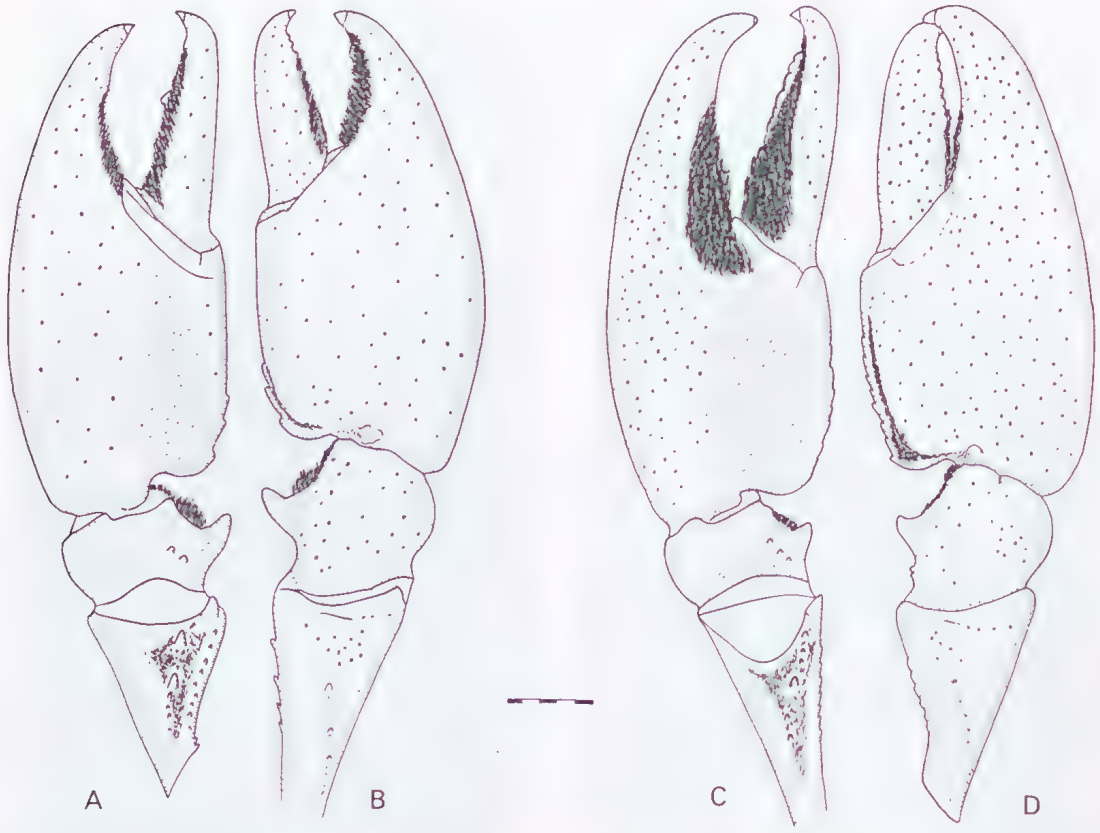

FIG.4. *Cherax cartalacoolah* sp.nov., holotype ♂, QM W18224: A, ventral view of right first cheliped; B, dorsal view of right first cheliped. *Cherax robustus* Riek, 1951, ♂ (30.2mm CL), QM W15312: C, ventral view of right cheliped; D, dorsal view of right cheliped. Scale divisions in mm.

1. The mesial carpal spine on the first chelipeds is much stouter in *C. robustus* and is usually followed by one or more tubercles. In the present species there are no tubercles behind the spine.

2. The ventral setation on the pollex of the first chelipeds continues for some distance onto the manus in *C. robustus*. In the present species the setation is restricted to the opposing edge of the pollex and does not continue onto the manus.

3. The mesial serrations on the manus of the first chelae continue over about two thirds of the mesial margin length in *C. robustus* whereas in the present species they are restricted to the proximal half.

4. Large adults of the new species have well-developed, branchiocardiac grooves which are lacking in *C. robustus*.

5. The punctations along the postorbital carinae form an irregular sulcus in the present species. In *C. robustus* the punctations sometimes connect anteriorly, but are otherwise well separated.

C. cartalacoolah can easily be separated from nominal species of the *'depressus'* group (sensu Riek 1969), which also occur east of the Great Dividing Range in northeast Queensland, by the presence of setal pubescences on the mesial carpus and ventral merus of the first chelipeds.

C. rhynchotus Riek, 1951, which occurs in similar habitats to the new species on northern Cape York Peninsula and Badu Is., Torres Strait, is not a closely allied species and belongs instead to the *'quadricarinatus'* species-group (cf. Short, 1991).

ACKNOWLEDGEMENTS

I am grateful to Rolly McKay for bringing this crayfish to my attention. Peter Davie is thanked for allocating QM resources towards the collection of further material, and for his expertise in the field. Des Bolton, Natural Resource Assessments Pty Ltd, kindly organised the assistance of

Cape Flattery Silica Mines Pty Ltd and the Hopevale Aboriginal Community preceding the 1992 collecting trip to Cape Flattery. I am also indebted to John Benfield, Cape Flattery Silica Mines Pty Ltd, for the use of facilities and the assistance of his staff. In particular, Paul Miller provided support and local knowledge during the collecting effort. Mr Steve Brooks donated specimens of *C. robustus* to the QM. Jeffery Wright printed the photographs.

A RECORD OF COMMUNAL EGG-LAYING IN THE SKINK *CARLIA TETRADACTYLA*. *Memoirs of the Queensland Museum 33: 60. 1993:-* During a visit to the Oakey area, southeast Queensland on 25 November 1992, a communal nest of 25 skink eggs was located. The site — a disused railway line — was approximately 8km NW of Oakey township and consisted of a relatively continuous row of wooden sleepers.

The nest was located beneath a single sleeper, which was lying on an approximate north-south axis, at its northern end. The whole sleeper was also angled slightly to the west. The eggs varied little in size. All were partially buried in the soil. The eggs were not measured at the time, but their size suggested they could belong to *Carlia tetradactyla*, a very common species at the site. Considering the paucity of records of communal nesting for *Carlia*, one egg was retained by one of us (RP) for artificial incubation to confirm its identification.

On return to Brisbane the egg was transferred to a small plastic container with a little soil from beneath the sleeper and sprayed lightly with water. Access to an incubator was not possible immediately, so the container was maintained between 25-30°C near a 60 watt incandescent light bulb. After two days, the egg had shrivelled markedly and the upper surface had turned a tea-brown colour. However, after a liberal spraying, it almost regained its original shape, though some small wrinkles remained until hatching. After five days the egg was placed in an incubator maintained at 29.5-30.5°C.

On the 3 December 1992, the container was removed from the incubator for the purpose of taking measurements of the egg. However, on opening, it was found the egg had already hatched. Even so, approximate measurements were taken of the empty egg-shell (15.8 × 10mm). The hatchling was tentatively identified as *C. tetradactyla* and a snout-vent measurement was taken (27.6mm). It was then transferred to a small holding container where it thrived and began feeding on hatchling locusts within 4-5 days. The specimen was later taken to the Queensland Museum, where its identification was confirmed (P. Couper). It was subsequently lodged as Queensland Museum specimen number J56882.

Considering the consistent clutch size of two eggs for *C. tetradactyla* (Greer, 1989), the large number of eggs found by us indicates the use of the nesting site by some 13 individual females (or a smaller number of animals laying multiple clutches). Greer states that the communal nests of two genera, *Lampropholis* and *Saproscincus*, usually contain eggs laid almost simultaneously, or at least within a few of hours. He also notes that (at least with the above two genera) nests always consist of eggs from only one species. Thus it seems fair to assume that all 25 eggs belong to *C. tetradactyla*, especially as there were no other abundant, similarly-sized species observed in the vicinity.

Greer (1989) cites only one reference (Wilhoft, 1963) for communal nesting in the genus *Carlia*, *C. rhomboidalis* (= *C. rubrigularis* Ingram & Covacevich, 1989). Thus our record is the second instance of such behaviour in *Carlia*.

It is not known what stimulates several female lizards to lay in the same site. At the nest discovered by us, there did not appear to be any old shells to indicate past use as a favoured nesting site. It is also interesting to speculate why this particular sleeper was chosen amongst hundreds of others. Perhaps it had special features attractive to gravid females, or it may simply have been a choice by one female that, in turn, stimulated several others to lay, possibly by some olfactory cue.

OCEANAPIA SAGITTARIA FROM THE GULF OF THAILAND

JOHN N.A. HOOPER, MICHELLE KELLY-BORGES AND MARTIN RIDDLE

Hooper, J.N.A., Kelly-Borges, M. & Riddle, M. 1993 06 30: *Oceanapia sagittaria* from the gulf of Thailand. *Memoirs of the Queensland Museum* **33**(1): 61-72. Brisbane. ISSN 0079-8835.

Oceanapia sagittaria (Sollas) is redescribed from shallow water, soft benthic communities surrounding the limestone islands of Ko Samui, southwest Gulf of Thailand, with additional new records from southern Papua New Guinea. Morphological redescription is based on live material, highlighting in particular a unique, tentacle-like, dendritic series of exhalant canals with its complex of oscules on the apex of the primary (open) fistule. Evidence is presented to suggest that this capitate structure serves as both a complex series of exhalant pores and canals, and an asexual dispersal propagule. Scanning electron microscope studies also detected an additional morphology of toxa microscleres, not previously recorded for the species, and studies of skeletal structure indicate that the species is more appropriately included in the family Oceanapiidae (Porifera, Demospongiae, Haplosclerida), being the sixth member of the 'biminia' group of *Oceanapia* species. The distribution and comparative morphology of this species group are discussed. □ *Oceanapia sagittaria, Porifera, Demospongiae, Haplosclerida, Oceanapiidae, Gulf of Thailand, oscular structure, asexual propagule, taxonomy.*

John N.A. Hooper, Queensland Museum, PO Box 3300, South Brisbane, Queensland, 4101, Australia; Michelle Kelly-Borges, Division of Biomedical Marine Research, Harbor Branch Oceanographic Institute Inc., 5600 North U.S.1 Highway, Fort Pierce, Florida, 34946, USA; Martin Riddle, Australian Institute of Marine Science, PMB 3, Townsville MC, Queensland, 4810, Australia, Present address: Water Board of Sydney, E.M.U., PO Box A53, South Sydney, NSW, 2000, Australia; 10 February, 1993.

Species of *Oceanapia* are common, with more than 50 nominal species recorded for the Indo-west Pacific region alone, relatively abundant in both soft and hard substrates, and widely distributed (known throughout the world's oceans: Antarctic, amphi-Atlantic, Mediterranean, Red Sea, western and eastern Indian Ocean, Indo-Malay archipelago, Indo-west Pacific, Japan, New Zealand and eastern Pacific Ocean). However, many of these species are poorly known: most *Oceanapia* species have been described only from preserved material; in many cases they have been described only once; in several instances species descriptions are based solely on incomplete individuals (e.g. fistules); and in some cases species were created on the basis of only minor differences in spicule morphometrics from their siblings. These problems are common to many groups of sponges, but possibly they are most apparent in the relatively morphologically depauperate Haplosclerida, including *Oceanapia*. Whilst reexamination of the type material for many of these species is usually necessary (the original descriptions being very brief and/or very poor), generally this process does no more than confirm or refute those characters already described for the species. Consequently, *Oceanapia* appears to contain many species differing from each other only slightly in any of their major characters (growth form, spicule morphology, spicule size, skeletal structure), whereas in situ observations of live populations are much more informative in discriminating sibling species. In this present paper we redescribe *Oceanapia sagittaria* (Sollas) from live populations in the Gulf of Thailand, including in situ observations of intact capitate, oscular structures peculiar to this species, whereas the species had previously been described only from preserved material (Sollas, 1902; Burton, 1934; Bergquist, 1965), virtually all fragmented. We also describe some observations of populations from southern Papua New Guinea.

METHODS

Preparation of material for light microscopy and scanning electron microscopy (SEM) is described elsewhere (Hooper, 1991). The descriptive language system DELTA was used to prepare the taxonomic description (Dalwitz & Paine, 1986). Abbreviations used in the text are as follows: BMNH, Natural History Museum, London; NCI Q66C-, US National Cancer Institute shal-

low water collection program (Australian Institute of Marine Science, Townsville, contract) – primary material now in Smithsonian Institution, NTM and QM; NMV, Museum of Victoria, Melbourne; NTM, Northern Territory Museum, Darwin; PMBC, Phuket Marine Biology Center, Phuket, Thailand; QM, Queensland Museum, Brisbane; ZMA, Zoological Museum, Amsterdam.

SYSTEMATICS

Family OCEANAPIIDAE van Soest
Oceanapia Norman, 1869

Oceanapia Norman, 1869 [type species: *Desmacidon jeffreysii* Bowerbank, 1866 (= *D. robusta* Bowerbank, 1866 (Carter, 1882))].
Rhizochalina Schmidt, 1870 [type species: *Rhizochalina oleracea* Schmidt, 1870].
Phloeodictyon Carter, 1882 [type species: *Phloeodictyon isodictyiforme* Carter, 1882].
Biminia Wiedenmayer, 1977 [type species: *Oceanapia toxophila* Dendy, 1922].

Diagnosis

Haplosclerida, predominantly fistulose, with a unispicular, tangential, subisotropic ectosomal skeleton, often detachable, and an irregular, longitudinal and/or transverse system of multispicular tracts with a subisotropic reticulation of single spicules dispersed between forming the choanosomal skeleton; microscleres may include sigmas and toxas (modified from de Weerdt, 1985).

Remarks

The genus, its contents, generic synonymy and relationships with other oceanapiids have been discussed at length by several contemporary authors (Bergquist & Warne, 1980; van Soest, 1980; de Weerdt, 1985; Wiedenmayer, 1989; Fromont, 1991). The synonymy cited above is now generally accepted, although de Weerdt and van Soest (1986) also note that *Rhizochalina* and *Oceanapia* s.s. could be considered two 'convenient' subgenera, differentiated by their consistency and development of their spongin fibre skeletons; the first having strongly developed spongin fibres and the second with a pulpy choanosomal skeleton. However, these apparent differences are not clear-cut for all species (i.e. several species in both nominal genera have intermediate character states), and formal recognition of these 'convenient' subgenera may not be fully justified. In fact, there is equal justification for recognising alternative 'convenient' subgenera within *Oceanapia*, based on microsclere diversity for example (e.g. *Biminia* with toxas and sigmas, *Oceanapia* (s.s.) with only sigmas, and *Phloeodictyon* (s.s.) without microscleres), but this system also lacks a sound phylogenetic basis (de Weerdt and van Soest, 1986).

Material Examined

NTM Z3679, QM G301346, QM G300640, PMBC 9210: E side of northern island, Ko Wao Yai Group Marine National Park, NW of Ko Samui, S Gulf of Thailand, 9°47.0'N, 99°41.0'E, 6 June 1990, 12.5m depth, coll. M. Riddle, S. Sorokin, J.N.A. Hooper, SCUBA (stn JH-90-016). Unregistered material: Motupore I., southern Papua New Guinea, various dates 1987, coll. M. Kelly-Borges.

Distribution, Substrate and Depth Range

This species is only recorded from Kepulauan Bidang, north of Penang, Andaman Sea (Sollas, 1902), Ko Samui, southern Gulf of Thailand and Motupore Island, southern Papua New Guinea (present study), Koror I., Palau Islands, central western Pacific (Bergquist, 1965), and the Low Isles, Great Barrier Reef (Burton, 1934). It is probably a widely distributed Indo-Malay species, but because of its small, relatively cryptic, burrowing habit the extent of its distribution is still not fully known. The recorded depth distribution is from shallow subtidal waters to approximately 14m. The Thailand collection site – located 50m from shore, at 12m depth on sand and coral rubble slope, rising to coral dominated slope and *Porites* heads, at base of limestone cliffs rising to greater than 70m altitude – contained a population of this species with many specimens, although the species was not seen in any other sites in this region. In southern Papua New Guinea the species is also relatively abundant, found in muddy silt substrates.

Description

Shape. Sponge burrowing into soft sediments; slightly enlarged basal root submerged completely below substrate, with one or more fistules protruding above surface (Fig.1). Basal root (or 'body' of sponge) expanded, bulbous, subspheri-

FIG. 1. *Oceanapia sagittaria* (specimen NTM Z3679) in situ (photo M.Riddle).

cal, more-or-less solid, attached to detritus in soft sediments (Fig. 6). All collected specimens consisted only of single primary fistules, with or without smaller, vestigial, secondary (blind) fistules, erect on single basal roots; primary fistule cylindrical, tubular, hollow, with cavernous central lumen, widest at base, tapering to constriction below apex; fistules simple-flagelliform, flexible, fleshy, mucous-covered in life, although more fragile, thin-walled when preserved. Apex of primary fistule with unusual capitate structure (= capitum), which in life is extremely fragile, subspherical, membraneous on its exterior surface, completely translucent, clearly showing dendritic fibre and canal system within (Fig. 1); membraneous capitum collapses upon collection, leaving only dendritic fibres and spicule tracts, tapering at their ends (Figs 7,8). Dimensions: basal root 11-23mm diameter; primary (open) fistule 33-54mm long, 2-4.5mm external diameter, 1.5-4.0mm internal diameter; secondary (blind) fistules 8-18mm long, up to 2.5mm external diameter; capitum (in life, when intact) approximately 20mm diameter, when preserved (i.e. dendritic fibres situated on apex of fistule) 7-11mm long, 4-10mm wide. Growth form consistent for all known specimens.

Colour. Live colouration of basal root dark brown or black; fistules dark red-brown (Munsell 5R 4/10); fibre bundles inside translucent capitum pale red in life (2.5R 6/10) (Fig. 1). Live colouration relatively consistent. Colour of specimens in ethanol grey-brown.

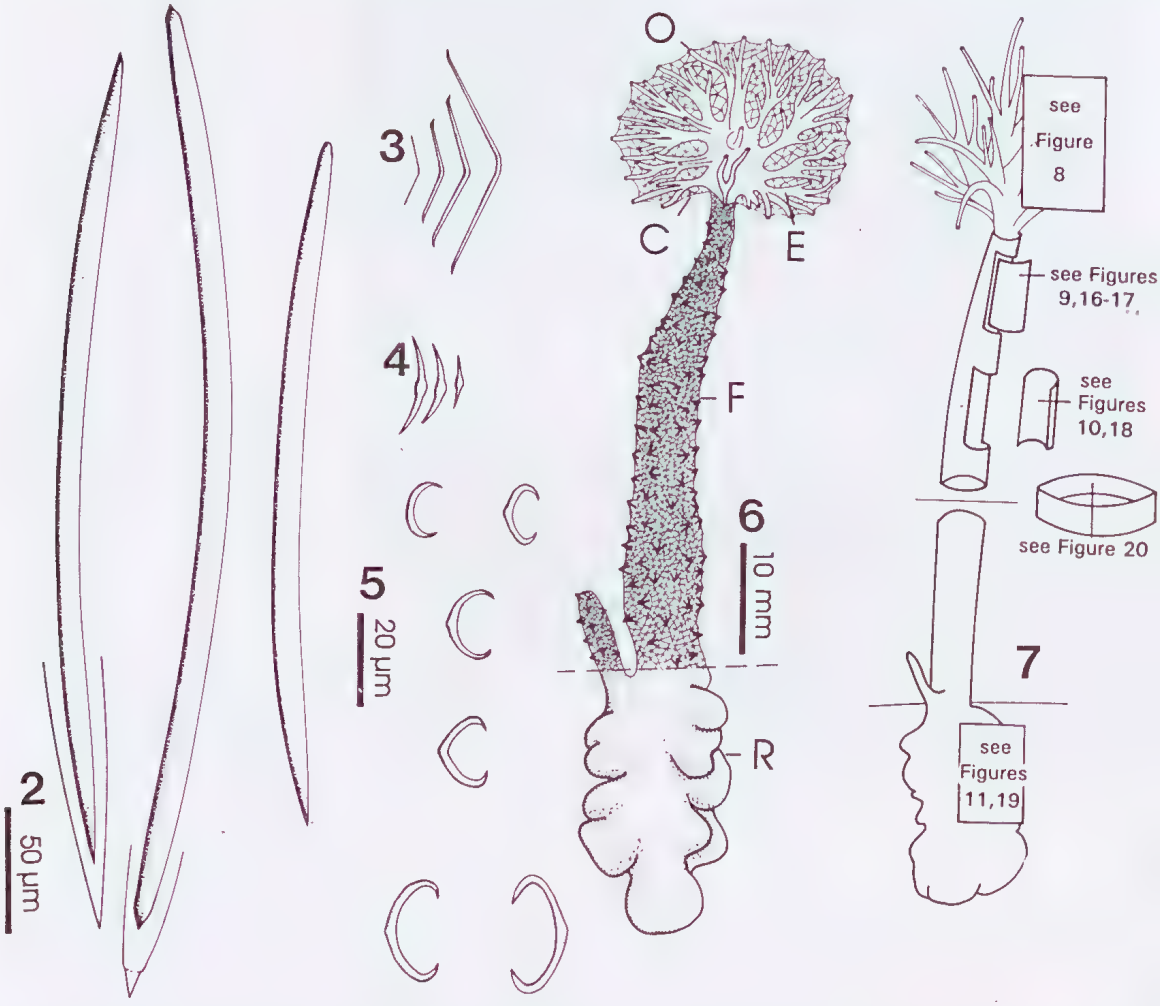
Oscules. Oscules confined to distinct areas on membraneous capitum at apex of sponge; terminal, situated at the ends of dendritic fibre bundles (which probably surround/support exhalant canals), protruding from apex of sponge (Fig. 6); primary fibre bundles thickest at centre of capitum, bifurcating only once or twice within membraneous capitum, with each exhalant canal slightly swollen at apex, and each bearing a single oscule; oscules more-or-less evenly distributed

over entire capitum, minute, 0.2-0.5mm diameter, but not observable in preserved material (i.e. capitum collapses). Inhalant pores not seen.

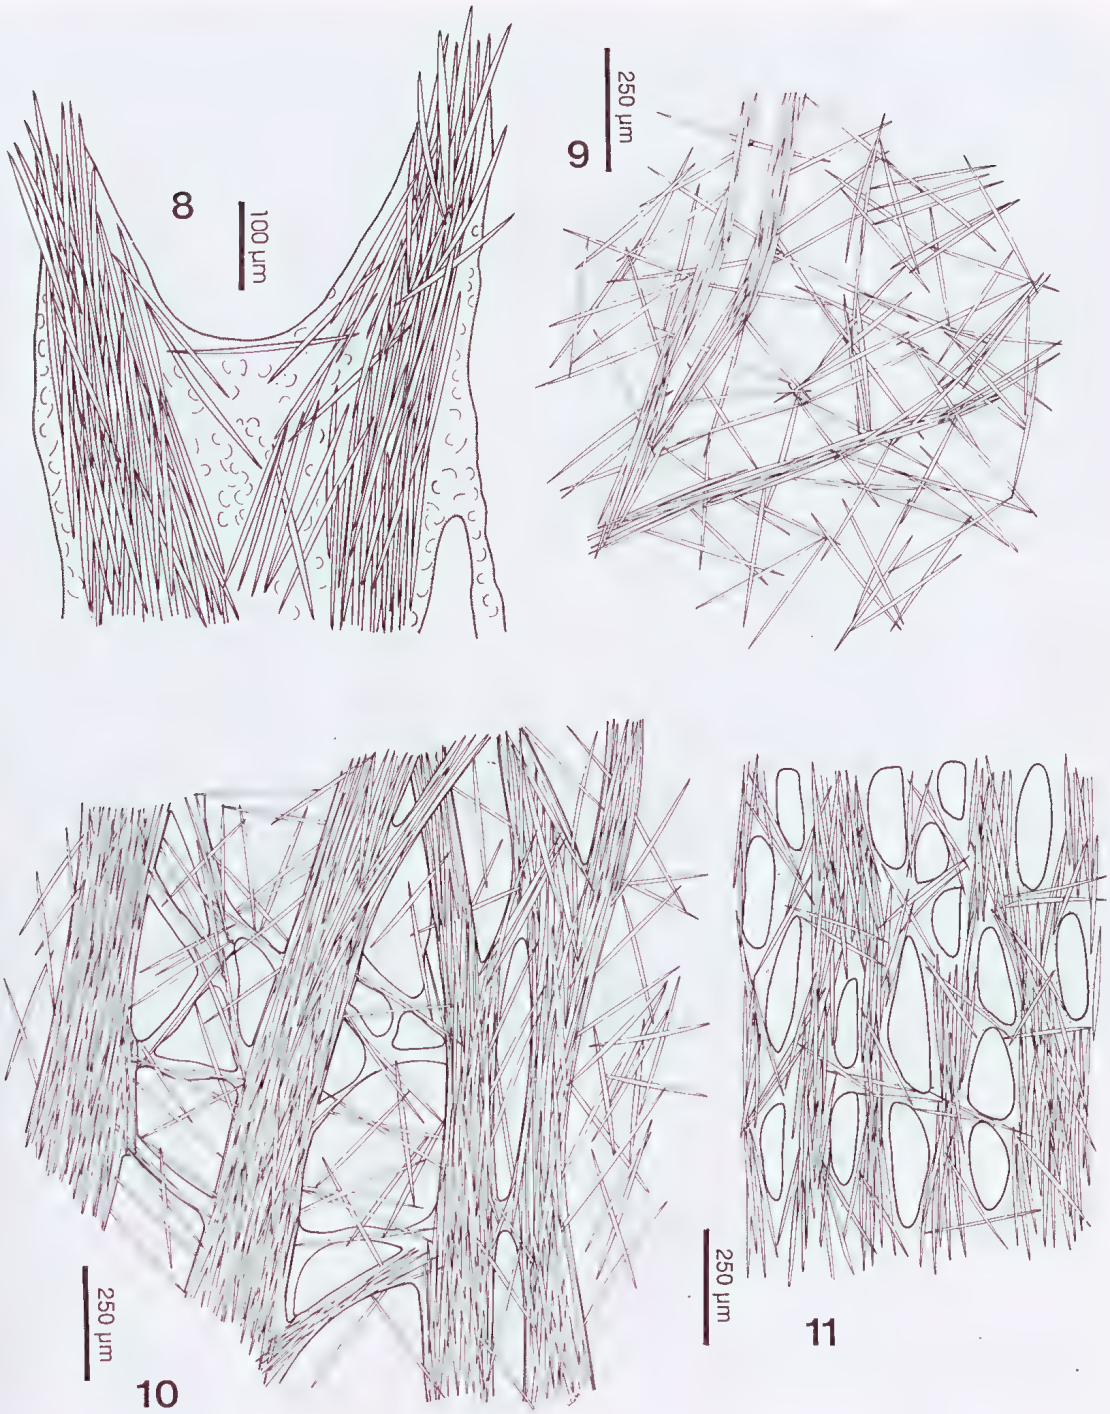
Texture. Fistule soft, elastic, flexible, fragile, easily torn both in life and when preserved; basal root solid, woody, inflexible, easily crumbled.

Surface characteristics. Fistule fleshy, collagenous, pigmented, microconulose, prominently sculptured in life (Fig. 6), with prominent tangential spicule skeleton forming a microscopic, triangular, cobweb-like network (Figs 9,16-17), although appearing more shaggy when preserved. Membraneous capitum skin-like, glabrous in life, with faint, fragile, irregularly isodictyal, tangential spicule skeleton; capitum is translucent in life and choanosomal fibres clearly visible through membraneous surface. Basal root dense, spiculose, heavily pigmented, with smooth surface, and loose, irregular, tangential spicule skeleton, although the latter is not a prominent feature.

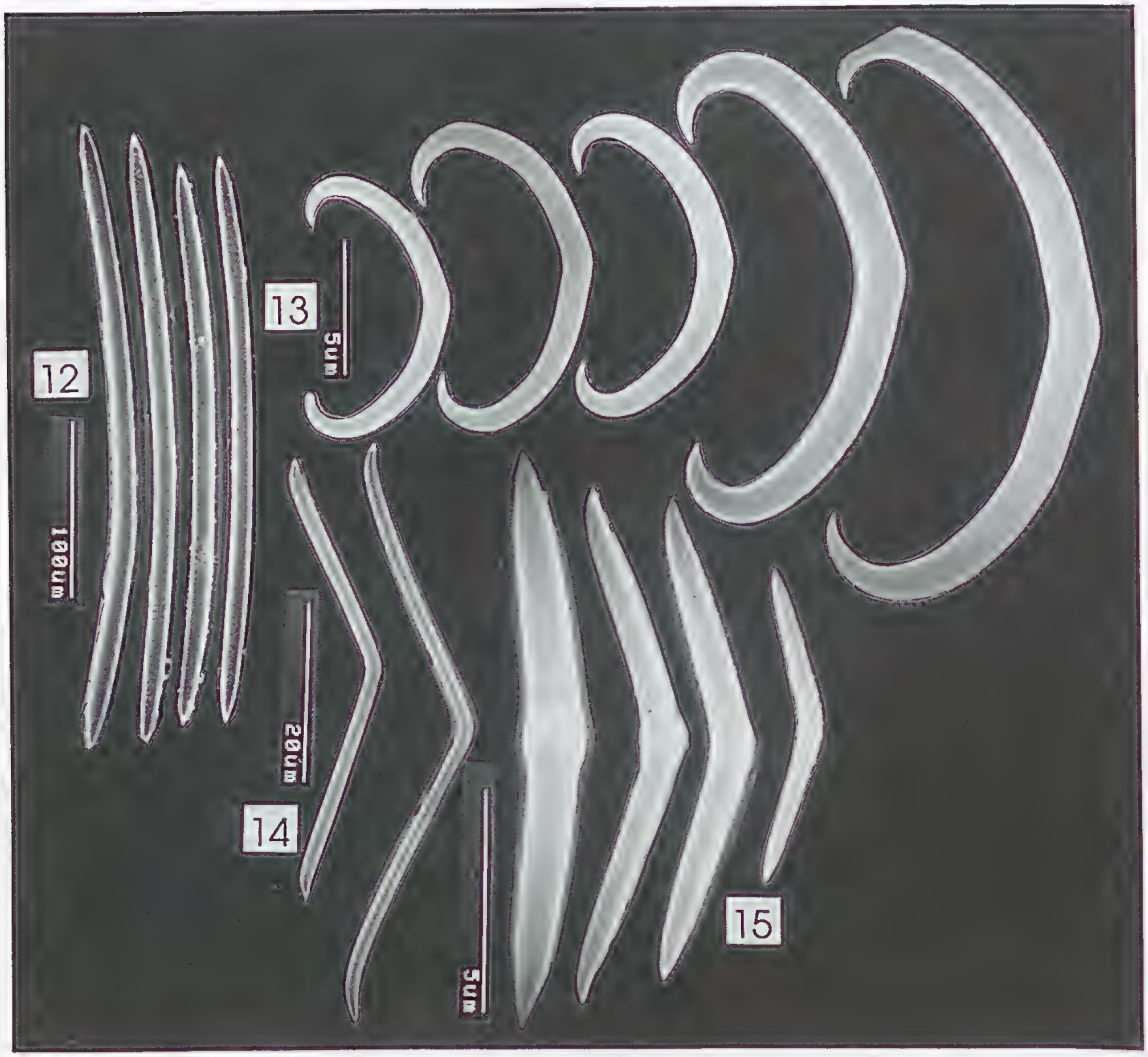
Ectosome and subectosome. Ectosomal skeleton with both unispicular and paucispicular tangential tracts of oxeas (Figs 9,17). Capitum, when intact, with unispicular, subisodictyal, tangential ectosomal tracts, without any support underlying



FIGS 2-7. *Oceanapia sagittaria*, spiculation and morphology. 2, oxeas (and rare anisoxeas). 3, long toxas. 4, robust, centrangulate toxas. 5, centrangulate sigmas. 6-7, interpretation of live, whole specimen (from Fig.1), with stippled basal region indicated below substrate. 7, guide to location of sections depicted in figures 8-20. F=tubular fistule, C=membraneous capitum, R=basal root, with woody exterior and pulpy interior, O=oscule, E=exhalant canal.



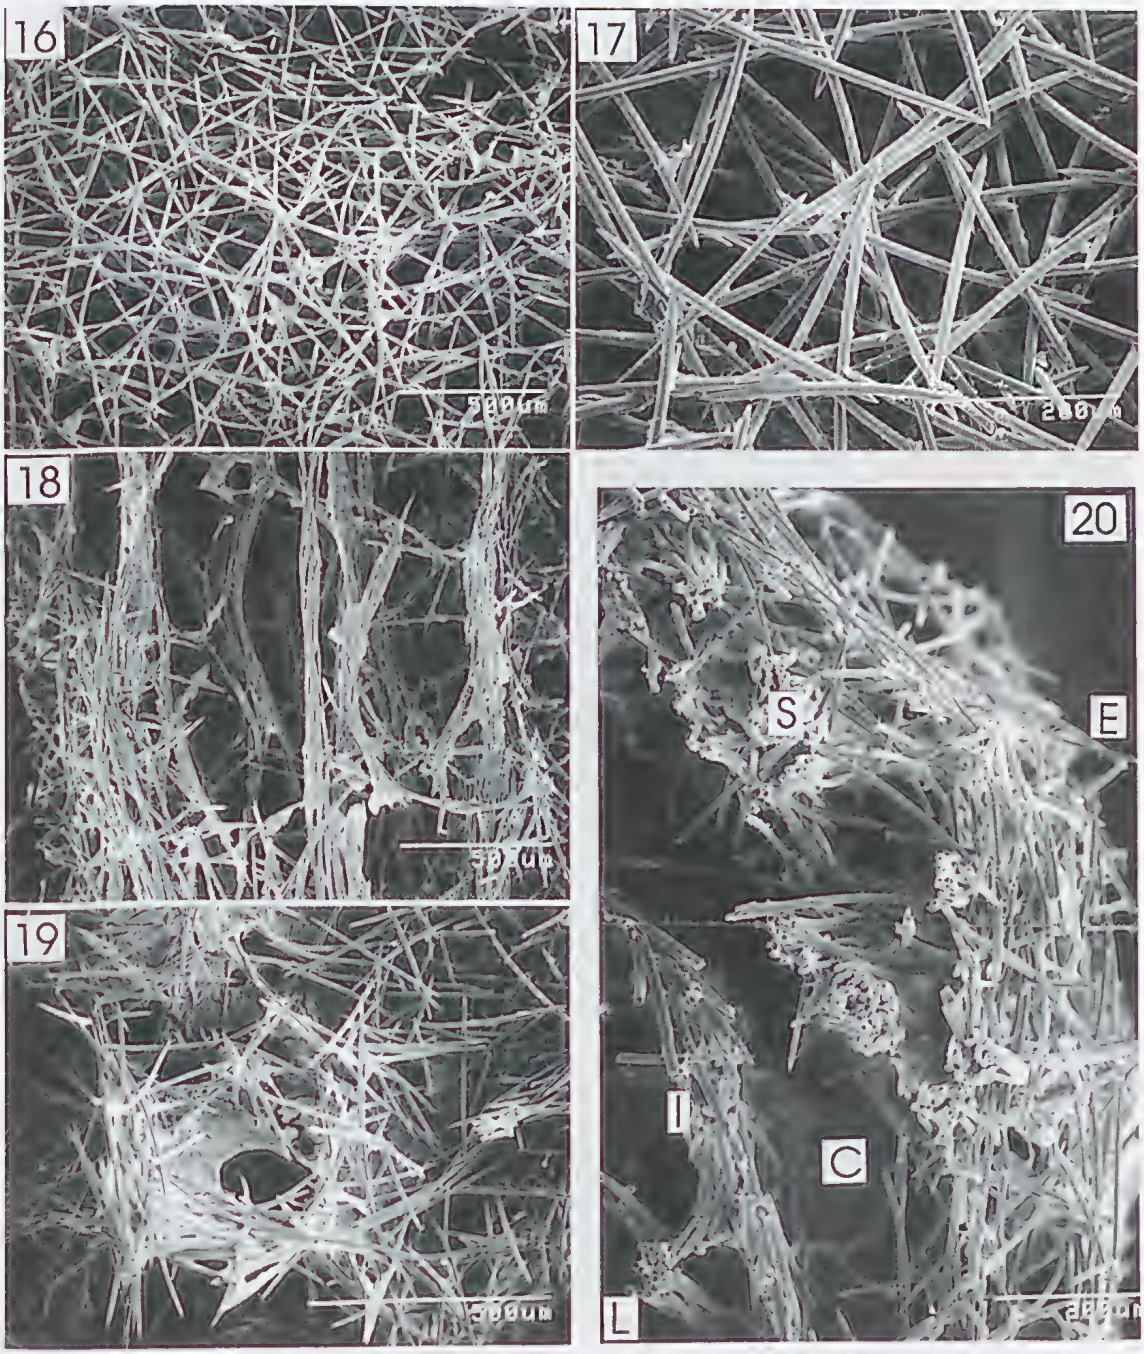
FIGS 8-11. *Oceanapia sagittaria*, interpretation of regional skeletal structures. 8, tip of capitum in preserved condition, showing ascending spicule bundles supporting individual exhalant canals (oscules collapsed). 9, external wall of fistule, showing unispicular, isotropic overlying skeleton and multispicular supporting tracts of subectosome. 10, internal wall of fistule, showing multispicular choanosomal tracts, interdispersed with unispicular, isotropic spicules. 11, section through basal root (or 'body' of sponge, burrowing into substrate), with reticulate, pulpy architecture.



FIGS 12-15. *Oceanapia sagittaria*, scanning electron micrographs of spicules. 12, oxeas. 13, centrangulate sigmas. 14, long toxas. 15, robust, centrangulate toxas.

ectosomal skeleton (unlike most other parts of the skeleton). Fistule with both uni- and paucispicular tracts of oxeas tangential to surface, with multispicular tracts visible just below surface (Fig. 9), and a prominent cavernous area between ectosomal (unispicular and paucispicular) and choanosomal (multispicular) regions (Fig. 20). Basal root with dense, disorganised, unispicular, tangential tracts and dense, multispicular, tracts below the ectosome (Fig. 19), both close to surface. Extra-fibre spicules (i.e. those not associated with the tangential unispicular ectosomal or multispicular subectosomal skeletons) lie in sparse, single or paucispicular subisodictyal tracts throughout the skeleton (Fig. 10).

Choanosome. Choanosomal skeletal structure reticulate, composed of relatively homogenous, dense spicule tracts differentiated into primary (longitudinal) and secondary (transverse) skeletal lines. Primary tracts long, multispicular, 70-160μm diameter, joined by shorter pauci- or multispicular secondary tracts, 30-50μm diameter, together forming irregular elongate or eliptical meshes, 450-1500μm long, 120-250μm wide. Extra-fibre spicules scattered between choanosomal meshes, in unispicular, subisodictyal tracts. Basal root ('body' of sponge), pulpy, occupying most of 'body' diameter, with central lumen of fistules extending several millimetres into 'body', and with large, cavernous meshes pro-



FIGS 16-20. *Oceanapia sagittaria*, scanning electron micrographs of skeletal structure (see Fig. 7 for location of sections). 16, tangential, unispicular, isotropic reticulation of ectosome, exterior wall of fistule. 17, close-up of same. 18, multispicular, mostly longitudinal reticulation of interior wall of fistule. 19, cavernous, pulpy choanosomal skeleton of basal root ('body' of sponge). 20, cross-section through fistule wall, showing exterior unispicular tracts (E), with subectosomal support (S), a cavernous region in between (C), interior multispicular tracts of choanosome (I) lining lumen of fistule (L).

duced by reticulation of longitudinal and transverse skeletal tracts, up to 0.5mm diameter (Figs 11,19). Fistules with greatly compressed choanosomal skeleton, attached directly to the interior of fistule walls (Figs 10,18). Spongin fibre skeleton greatly reduced; spongin fibres typically very light (Figs 10,11), whereas spicules between major tracts (i.e. forming the subisodictyal skeleton) usually bound together by sparse, granular, lightly pigmented collagen. Collagen in mesohyl abundant, darkly pigmented, dispersed evenly throughout, slightly granular, packed with microscleres. Choanocyte chambers minute, ovoid, 12-26μm diameter, lined by sigma and toxa microscleres.

Megascleres. Relatively long, thin, smooth oxeas (Figs 2,12), slightly curved, with fusiform points or occasionally slightly constricted near apex and bearing a sharp, mucronate, abrupt point; very homogenous in size throughout skeleton (length 329-363.4-393μm; width 9-10.8-12μm).

Microscleres. Two categories of microscleres present, both very abundant. C-sigmas (Figs 5,13), of a single size class, varying only slightly in size, usually very small, thin, typically centrangulate, never s-shaped or contort, completely smooth (length 8-12.6-22μm, width 0.5-1.2-2μm).

Toxas include two morphs, the larger more common: (i) long, thin, v-shaped toxas (Figs 3,14), with wide angular central curvature, and reflexed points (at extremities only) (length 28-41.9-68μm; width 0.5-1.2-2.5μm); (ii) short, thin, robust toxas (Figs 4,15), with only slight angular central curvature and slightly swollen (centrangulate) at centre, and with straight (unreflexed) points (length 8-13.7-23μm; width 0.5-0.9-1.5μm).

In situ observations. Field and laboratory observations were made over a period of several weeks in 1987 (M.K-B.). In the field, the capitum is easily dislodged from the apex of the fistule with only moderate movement of the water column above the specimen. Several dislodged capitate structures were observed lying on sand, in coral reef interstices and seagrass beds in the vicinity of Motupore Island. Laboratory observations on several intact specimens suggest that the capitum may have an asexual reproductive function. Several observations were made: 1, several capitate structures were carefully detached from transplanted aquarium specimens, through gentle movement of the water column directly above specimens. After detachment, capitate structures rolled over the aquarium floor until they became wedged in substrate; 2, after 24 hours of resting on the substrate the dendritic exhalant canal tubes, easily visible within the capitum (Fig. 1), extended towards and became attached to the substrate, forming a plate-like, basal, anchoring structure; 3, 36-48 hours after detachment these spherical capitate structures deflated, slightly flattened at the apex, and spread laterally into a thickened plate with single apical oscule.

Field observations in the Gulf of Thailand (J.N.A.H. and M.R.) also noted that these capitate structures are elaborate exhalant devices. Small particles of silt and other detritus were observed to be periodically expelled from the small oscules scattered over the capitum. Ostia (inhalant pores) were not seen.

Remarks

Oceanapia sagittaria is unique amongst all oceanapiids (in fact, as far as known, amongst all sponges), in having the peculiar capitate structure on the apex of its primary fistule. Bergquist (1965: 155) first hypothesised that these 'terminal caps', apparently observed free floating in the Palau Islands, might be asexual dispersal mechanisms. We confirm this idea in the present study, and suggest that this structure is the first documented case of a specialised asexual propagule recorded for the Haplosclerida, although many cases of 'unspecialised' surface and basal buds are known for several Hadromerida (e.g. *Polymastia* (Battershill & Bergquist, 1990), *Tethya* (Bergquist & Kelly-Borges, 1991), *Aaptos* (Bergquist, 1968)).

The holotype of *O. sagittaria* was apparently originally deposited in the Zoological Museum at Cambridge University, but this material has not been mentioned since Sollas's (1902) publication and it is unknown if it still survives. A spicule preparation of the holotype is also apparently located in the Natural History Museum, London (BMNH 1938.8.7.3), but this preparation contains no details of skeletal structure (F. Wiedenmayer, pers.comm.). Although *O. sagittaria* has now been described from three separate collections, only the description of Bergquist (1965), based on preserved material, is adequate by modern standards. Sollas (1902) provided an extremely brief description, essentially only describing spicule shape and size, without any useful information on skeletal structure. Oxeas were cited as 300-350×10-13μm, sigmas 12-16μm long, and toxas were 49μm long. Burton (1934) did not provide any details of the Great

Barrier Reef material, but merely compared his and Sollas's fragments. Bergquist's (1965) more detailed description of Palau Islands specimens gave spicule measurements as: oxeas (325-375× 5.5-10μm), centrangulate sigmas (10.5-20.5μm long), and toxas (36-50μm long). These dimensions, compared to those seen in the Gulf of Thailand specimens, indicate that the species is relatively homogeneous across its range, although live colouration differs slightly: Burton (1934) reported that Great Barrier Reef material was magenta and ultramarine, whereas both the present specimens and those described by Bergquist (1965) were simply red-brown or bright red, respectively.

Oceanapia sagittaria has been previously included with the family Chalinidae Gray (or its synonym Adociidae de Laubenfels), whereas it is clearly a member of the Oceanapiidae and consequently defined in this family in the present study. The Chalinidae have a more-or-less regular, unilayered, unispicular, isotropic, tangential ectosomal skeleton, with three-sided spicule meshes. In *Oceanapia* this peripheral skeleton may also be regular, isodictyal, with vaguely triangular meshes, but the tangential layer of spicules is substantially more dense and the nodal spongin, prominent in many species of Chalinidae, is usually absent (Fig. 16). Similarly, choanosomal structure in the Chalinidae is ladder-like, with uni-, pauci- or multispicular tracts, whereas in *Oceanapia* primary ascending fibres are multispicular, supporting the dense tangential ectosomal skeleton, and supplemented by a secondary (isotropic) reticulation of single spicules lying between the main fibres (Figs 10,11,18) (de Weerdt, 1985).

In the strict sense, the present species belongs to the nominal genus *Biminia*, in having both centrangulate sigmas and toxa microscleres in a fistulose, reinforced oceanapiid skeleton. However, de Weerdt (1985) and de Weerdt & van Soest (1986) argue that these microscleres may represent the retention of a primitive character and hence not valid at the generic level. They suggest that the genus should be dropped into synonymy with *Oceanapia* as the two nominal genera are virtually identical in all other respects. Several other haplosclerids have both sigma and toxa microscleres, including species of Chalinidae (e.g. *Orina*) and Callyspongiidae (e.g. *Callyspongia*). *Orina* lacks the disctinctive pulpy, reinforced, multispicular choanosomal skeleton of *Oceanapia*, having instead a unispicular, isotropic choanosome, and *Callyspongia* has a distinctive network of tangential primary, secondary, and occasionally tertiary fibres in the ectosomal skeleton, and typically regularly reticulate, wide-meshed, choanosomal fibres cored by single or few spicules. Both Burton (1934) and Wiedenmayer (1977) discuss examples of this convergence between *Oceanapia* (as *Biminia*), *Orina* and *Callyspongia* further.

An alternative point of view, offered by de Weerdt & van Soest (1986), is that the distribution of 'biminias' may reflect a possible Tethyan distribution of their common ancestor, although they are sceptical about whether this combination of characters is an apomorphy for *Oceanapia* [as inferred by Wiedenmayer (1977) and Hooper (1984)], or whether it is a synplesiomorphy and thus contains no phylogenetic information [as proposed by van Soest (1980)]. Further analysis of this possibly ancestral, possibly Tethyan distribution should be made by comparing the distributions of both the 'biminia' and non-biminid groups of *Oceanapia*, and the comparative distributions of the *Orina* and *Reniera* groups of Chalinidae. However, much of the type material relevant to this analysis, presently unavailable, firstly requires re-examination.

In addition to *O. sagittaria* there are five other species of *Oceanapia* that fit in the 'biminia' group: *Oceanapia toxophila* Dendy, 1922:45 from Providence I., Seychelles Is, western Indian Ocean (holotype BMNH 1921.11.7.37 re-examined); *O. stalagmitis* (Wiedenmayer, 1977:124) from the Bahamas; *O. ooita* (Hoshino, 1981:122) from Japan; *O. macrotoxa* (Hooper, 1984:55) from the Timor and Arafura Seas, northwest Australia (holotype NMV F51373); and *O. cancap* de Weerdt & van Soest, 1986:39 from the Madiera region, West Africa, southeast North Atlantic. In addition to these taxa, re-examination of Ridley's (1884:424) material of '*Gellius fibulatus*' from Torres Strait, Qld (BMNH 1822.2.23.281) found that it is neither a chalinid nor conspecific with *Reniera fibulata* Schmidt, 1862, but belongs to Oceanapiidae and furthermore appears to be identical to *O. macrotoxa*. The identity of an Indonesian specimen collected by the *Siboga* expedition (ZMA POR 1709), cited as *O. toxophila* by de Weerdt (1985:81), is not certain, but it too is possibly conspecific with *O. macrotoxa*. An alternative point of view is that these three nominal Indo-west Pacific 'biminia' species, *O. toxophila*, *O. macrotoxa* and *O. ooita*, may be geographic variants of a single, widely distributed species, extending from the Seychelles Islands to Japan, Indonesia, northwest and northeast Australia.

Apart from the peculiar capitum seen in *O. sagittaria*, there are few major differences between any of the 'biminia' species in external morphology, skeletal structure, spicule geometry or spicule size (as noted by Hooper, 1984: table 1). Thus, it would be equally justifiable to synonymise all six known 'biminia' species as it would be to combine the three Indo-west Pacific species on the basis of these conventional morphometric characters. For the present we maintain all these species in the 'biminia' group, but recognise that only more comprehensive collections of *Oceanapia* throughout the Indo-Pacific may discover material with intermediate characteristics, resolving present doubts.

Apart from the peculiar capitum, *O. sagittaria* is most similar to *O. toxophila*. However, oxeas are sharply pointed, fusiform, or occasionally mucronate in the present species, whereas in *O. toxophila* they are hastate or rounded; oxea size is relatively homogeneous within both species but substantially larger in *O. sagittaria*; microsclere dimensions are similar in both species (see dimensions below for *O. toxophila*), although *O. toxophila* has both c-shaped and contort sigmas, and *O. sagittaria* was discovered to have a morphologically distinct, smaller category of centrangulate, robust toxas, not previously described for the species. Although these differences in spicule size and geometry could be construed as being relatively trivial, they are certainly as substantial as any of the differences between all other 'biminia' species.

Morphological characteristics of other 'biminia' species are as follows. *Oceanapia toxophila* Dendy has a tubular, burrowing, globular, simple base, with very thin, single fistules on each end of the body (the larger, open fistule is apical, the smaller, blind fistule is a basal rootlet); fistules up to 50mm long, 5mm diameter; ectosomal skeleton is a detachable, thin, unispicular, subisodictyal crust; choanosomal skeleton contains both reticulate, multispicular bands and a dense feltwork of subisodictyal spicules; oxeas hastate or rounded, mostly blunt (265-315×5-12μm); microscleres are only moderately common; sigmas very small, c-shaped or contort (12-26×0.5-1.5μm); toxas sharply angular at centre, straight arms, slightly reflexed points (12-55×0.5-2.5μm) (redesribed from the holotype BMNH 1921.11.7.37 (RN XX.2) and Dendy (1922) in part).

Oceanapia stalagmitis (Wiedenmayer) has a semi-incrusting, burrowing, massive base, with multiple, short, open and blind fistules on upper surface, rhizome-like blind fistules on under surface; fistules up to 17mm long, 10mm diameter; ectosomal skeleton a dense, subisodictyal, unispicular layer over a denser detachable crust; choanosomal skeleton an irregular reticulation of both stout and thin fibres, with unispicular subisodictyal spicules dispersed between; oxeas usually sharply pointed, fusiform (100-155×3.5-5μm); microscleres abundant; sigmas centrangulate, c-shaped (11-32×0.5-1μm); toxas small, slight central curvature, straight arms, very slightly reflexed points (10-32×0.5-1μm) (Wiedenmayer, 1977).

Oceanapia ooita (Hoshino) has a massive, subspherical, burrowing base, with numerous, open, wide fistules on upper surface, and rhizome-like, blind fistules on under surface; fistules up to 40mm long, 8mm diameter; ectosomal skeleton dense, unispicular, subisodictyal; choanosomal skeleton with densely packed, longitudinal spicule tracts, interdispersed with subisodictyal single spicules; oxeas homogenous, abruptly pointed, hastate (180-218×7-9μm); microscleres abundant; sigmas c-shaped, centrangulate (14-35xup to 1μm); toxas slightly curved at centre, straight arms, straight points (up to 45μm, thin) (Hoshino, 1981).

Oceanapia macrotoxa (Hooper) has a burrowing, massive, subspherical base with many long, thin, open and blind fistules on the upper surface, and smaller, thinner, rhizome-like blind fistules (rootlets) on the under surface; fistules are up to 60mm long, 8mm diameter; ectosomal skeleton is a thick, detachable, unispicular, subisodictyal crust; choanosomal skeleton with multispicular tracts, some ascending as well as uni- or paucispicular, subisodictyal tracts dispersed between; oxeas are divided into two indistinct size classes, fusiform to subhastate, mostly sharply pointed (94-260×1.5-7μm, 171-279×6-11μm); microscleres abundant; sigmas are small, centrangulate, c-shaped (9-35×0.5-2.0μm); toxas have angular central curves, straight arms and reflexed points (8-82×0.4-3.5μm) (Hooper, 1984).

Oceanapia cancap de Weerdt and van Soest is burrowing, fistulose, although the base is unknown; fistules are open, single or bifurcate, up to 80mm long, (?) 50mm diameter; ectosomal skeleton unispicular, tangential, subisodictyal; choanosomal skeleton (only known for fistule walls) is longitudinal, branching and anastomosing, multispicular tracts with interdispersed subisodictyal single spicules; oxeas fusiform, sharply pointed (up to 320×8μm); sigmas c-

shaped, centrangulate (20μm, thin); toxas with slight central curvature, straight arms, slightly reflexed points (50-75μm, thin) (de Weerdt and van Soest, 1986).

ACKNOWLEDGEMENTS

We are most grateful to Wallie de Weerdt and Jane Fromont, both of who provided invaluable comments and greatly improved our interpretation of this species. We also thank Peter Murphy (AIMS, Townsville) for providing the opportunity for J.N.A.H. and M.R. to travel to and collect from the Thai region; Motupore Island Research Station, University of Papua New Guinea, for providing facilities for M.K-B.; Shirley Stone (BMNH, London) for assisting the senior author in locating particular sponges amongst the vast BMNH collections; and Leonie Hooper for patiently inking all the line drawings.

A NEW SPECIES OF *NYCTIMYSTES* (ANURA: HYLIDAE) FROM THE STAR MOUNTAINS, PAPUA NEW GUINEA

STEPHEN J. RICHARDS AND GREGORY R. JOHNSTON

Richards, S.J. & Johnston, G.R. 1993 06 30: A new species of *Nyctimystes* (Anura: Hylidae) from the Star Mountains, Papua New Guinea. *Memoirs of the Queensland Museum* **33**(1): 73-76. Brisbane. ISSN 0079-8835.

Nyctimystes oktediensis sp.nov. is a member of the *N. papua* group. Morphologically, it is similar to *N. disrupta* from which it can be distinguished by its brown iris, reduced finger webbing, and palpebral venation of vertical to oblique lines over most of the eyelid. *N. oktediensis* is a stream-dwelling species inhabiting lower montane rainforests in the rugged Ok Tedi headwaters region of western Papua New Guinea. □ *Hylidae, Nyctimystes oktediensis, new species, Papua New Guinea.*

Stephen Richards, Zoology Department, James Cook University, Townsville, Queensland 4811, Australia; Greg Johnston, School of Biological Sciences, Flinders University, Bedford Park, South Australia 5042, Australia; 5 November, 1992.

The montane hylid genus *Nyctimystes* is characterised by the presence of vertical pupils and palpebral venation (Zweifel, 1958). Twenty-three species are presently known, with 21 from the island of New Guinea (Zweifel, 1958; 1983), one species in northern Queensland, Australia (Czechura, Ingram & Liem, 1987) and another in the Moluccas.

Within *Nyctimystes* a distinctive, and presumably monophyletic, group of species has been referred to as the *N. papua* species group (Zweifel, 1983). Members of this group are moderate to large in size, have sparse or much reduced palpebral venation, lack a vocal sac in males, have short, high, rounded snouts, and the outer fingers are no more than one half webbed. Although Zweifel (1983) recognised only four species in the group, he was aware of several specimens that could not be allocated to any known species.

In November 1991, we surveyed the frog fauna of the upper Ok Tedi drainage basin on the southern slopes of the Star Mountains, central New Guinea. We collected 36 species, of which almost one half could not be allocated to any known taxon. The only *Nyctimystes* that we encountered was an undescribed member of the *N. papua* group. Our specimens were most similar morphologically to *N. disrupta* but had a brown iris, reduced webbing between the fingers, and less disrupted palpebral venation.

Measurements and terminology follow Zweifel (1983). Abbreviations used in the text are: SV, body length from snout to vent; TL, tibia length; FT, foot length; HD, hand length; EN, eye to naris distance; IN, internarial distance; SN, snout to naris distance; HW, head width; EY, eye diameter.

Specimens are housed in the Queensland Museum (QM), South Australian Museum (SAM), Biology Department, University of Papua New Guinea (UP) and the American Museum of Natural History (AMNH).

Nyctimystes oktediensis sp.nov.
(Figs 1-3)

MATERIAL EXAMINED

HOLOTYPE: QM J56896 adult male with nuptial pads, collected by S.J. Richards & G.R. Johnston at 1625m, 23 November 1991 on the southeastern slopes of Mt Akrik, Star Mountains, Western Province, Papua New Guinea (5°10'S, 141°10'E).

PARATYPES: QM J56897-8, SAM R40771 three adult males with nuptial pads, same data as holotype but collected on November 24, 1991; UP 5137-9, three adult males with nuptial pads collected by D. Hyndman, 16 February 1975, from a stream adjacent to the Bleil Bil hunting lodge at Kamfon (2200m), Kam Valley, Star Mountains, Western Province, Papua New Guinea.

DIAGNOSIS

Nyctimystes oktediensis is distinguished from its congeners by a combination of the following characters: palpebral pigmentation relatively sparse; males without vocal sac; iris brown in life; fingers less than half webbed; tympanum indistinct but visible; moderately large size (males 60.8-67.2mm SV).

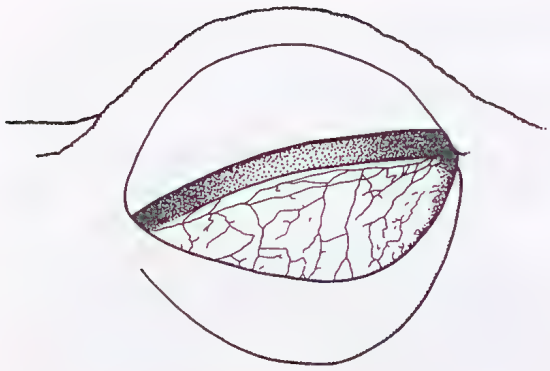

FIG. 1. Right eye of *Nyctimystes oktediensis* (holotype) showing palpebral venation.

DESCRIPTION OF HOLOTYPE

Adult male with the following measurements and proportions: SV 60.8; TL 35.8; HW 21.8; EY 7.8; EN 5.0; IN 6.5; SN 3.5; HD 24.0; FT 32.1; width of third finger disc 4.4, width of third penultimate phalanx 2.7; width of fourth toe disc 3.8, width of fourth penultimate phalanx 3.0; TL/SV 0.588; HW/SV O.358; EN/SV 0.082; EY/SV 0.128; IN/SV 0.106; EN/IN 0.769.

Snout short, high, rounded in dorsal view, almost vertical in lateral view; canthus rostralis distinct, slightly curved; loreal region steep, slightly concave; nostrils directed laterally (quite evident in dorsal aspect), internarial distance distinctly greater than distance from eye to naris (EN/IN 0.769). Pupil vertical. Palpebral pigmentation of vertical to oblique lines over entire eyelid, with few broken, interconnecting horizontal lines, slightly weaker posteriorly (Fig. 1). Tympanum indistinct but visible, dorsal one quarter of tympanic annulus hidden by postocular fold. Vocal sac absent. Vomerine teeth in two transverse rows between the internal nares.

Relative lengths of fingers 3>4>2>1; scanty webbing between third and fourth fingers, reaching halfway to distal subarticular tubercle on fourth, and to proximal tubercle on third; subarticular tubercles single; disc of third finger more than half eye diameter. A finely granular nuptial rugosity on inside of first finger. Relative lengths of toes 4>5=3>2>1, webbing almost to discs on all toes except fourth, fourth toe webbed to just short of distal subarticular tubercle; subarticular tubercles rounded, single; a low, oval inner metatarsal tubercle but no outer one (Fig. 2).

Dorsal surfaces slightly rugose, without conical asperities. A strong fold from posterior corner of eye to above arm insertion. Ventral surfaces granular. No heel lappet. Dorsally olive green. Lateral surfaces mottled olive gold and dark brown. Limbs and back (posteriorly) with a mozaic of olive green patches edged with dark brown, and interspersed with olive gold tending to form bands across the limbs. Venter speckled with cream and grey, iris brown (Fig. 3).

VARIATION

The smallest specimen, the holotype, has more widely spaced nares than the paratypes (EN/IN 0.769 vs 0.800-1.00). While the palpebral venation is similar in all of the type series, there is some variation in the degree to which the oblique lines are interconnected horizontally, and the venation of one specimen (QM J56898) is scarcely detectable on the posterior one quarter of the right eyelid (clearly visible on left eyelid). Proportions of the paratypes are as follows: TL/SV 0.583-0.627; HW/SV 0.342-0.356; EN/SV 0.080-0.087; EY/SV 0.110-0.127; IN/SV 0.082-0.100; EN/IN 0.800-1.00.

COMPARISON WITH OTHER SPECIES

The reduced palpebral venation, lack of a vocal sac, snout shape, basal finger webbing and size of *N. oktediensis* show that it is a member of the *papua* group defined by Zweifel (1983). However, *N. papua* is a much smaller species, with females smaller or about the same size as male *N. oktediensis*, and has only a few flecks of black pigment in the anterior corner of the lower eyelid (Menzies, 1975; Zweifel, 1983). Even allowing for greater variation when additional specimens are collected (see Zweifel, 1983), palpebral venation of this species is unlikely to approach the state of *N. oktediensis*. *N. trachydermis* is larger than *N. oktediensis* (smallest male *N. trachyder-*

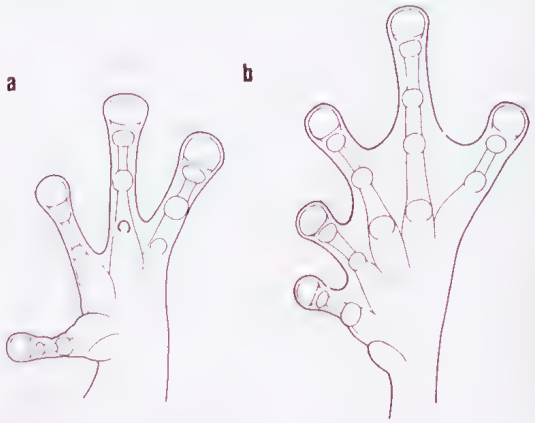

FIG. 2. Left hand (a) and foot (b) of *Nyctimystes oktediensis* (holotype) in palmar and plantar view respectively.

FIG. 3. Holotype of *Nyctimystes oktediensis* in life.

mis 71.6mm), has conical asperities on the dorsum, and a completely concealed tympanum. The sole specimen of *N. tyleri* (a male) is also much larger (78mm), and had a bright yellow iris (brown in *N. oktediensis*) in life (Zweifel, 1983). *N. disrupta* is similar in size to *N. oktediensis* but has a green iris in life, more extensive webbing between the fingers, and palpebral venation of very fine, disrupted lines (Zweifel, 1983).

Habits and Habitat

The Mt Akrik specimens were collected at night from branches overhanging the Ok Kun, a steep rainforest stream draining into the Ok Tedi. None was heard calling, and additional observations are required to determine whether this species can vocalise. At least four species of suctorial tadpoles were collected at this site, but we are unable to associate any of these positively with *N. oktediensis*.

Distribution

Currently known only from the Star Mountains in central New Guinea.

Etymology

Named for the rugged upper Ok Tedi drainage basin where all of the types were collected.

REMARKS

Zweifel (1983) discussed several samples of *N. disrupta*- like specimens that he was unwilling to assign to any known taxon. All of these have finger webbing typical of *N. oktediensis* but most show characters distinguishing them from this species. Two specimens from Irian Jaya (AMNH 49671, 49674) are quite distorted, making accurate measurements impossible, and we are unwilling to assign these to *N. oktediensis* without fresh material. An adult male from Telefomin (AMNH 114817) agrees well with the type series, although the colour of the iris in life is unknown, and we tentatively assign this specimen to *N. oktediensis*. Specimens from Okefomin (AMNH 11485-6), Ialibu (AMNH 81025-6), and Wagau (AMNH 74816-7) have much less palpebral venation than *N. oktediensis*. A series of adult males from Nipa, Southern Highlands (AMNH 103184-8) are large (to 72mm), extremely rugose dorsally (but without conical asperities), and have a completely hidden tympanum. They clearly represent a species distinct from *N. oktediensis* and all other described *Nyctimystes*.

Hyndman & Menzies (1990) list two unassigned species of the *Nyctimystes papua* group from the Ok Tedi region. Their *N.*(?) *papua* (UP 6719) possesses a vocal sac and thus is not a member of this group. The specimens listed as *N.* cf *disrupta* (UP5137-9) agree with *N. oktediensis* in all respects, and are included in the type series.

ACKNOWLEDGEMENTS

Field work in Papua New Guinea was funded by a grant from the Peter Rankin Trust Fund for Herpetology and a James Cook University Research Grant (to SJR). Ok Tedi Mining Limited provided invaluable support in and around Tabubil. We particularly thank Murray Eagles and Ross Smith of the OTML Environment Department, and Bob Murphy of the OTML Geology Department, for transport, food and accomodation during our field work. The Gregory Family and Rob Lachlan provided generous hospitality and logistical support in Tabubil, and Mr James Menzies helped in numerous ways during our stay in Port Moresby. Roselyn Busasa of the Institute of PNG Studies and Guy Kula of the Department of Environment and Conservation greatly facilitated the processing of research visas and export permits respectively. James Menzies (UP), Darryl Frost (AMNH) and M. Hutchinson (SAM) provided access to specimens in their care, and R.G. Zweifel kindly commented on the manuscript.

THE TAXONOMY AND DISTRIBUTION OF *PETAURUS GRACILIS* (MARSUPIALIA: PETAURIDAE), WITH NOTES ON ITS ECOLOGY AND CONSERVATION STATUS

STEVE VAN DYCK

Van Dyck, S. 1993 06 30: The taxonomy and distribution of *Petaurus gracilis* (Marsupialia: Petauridae), with notes on its ecology and conservation status. *Memoirs of the Queensland Museum* 33(1): 77-122. Brisbane. ISSN 0079-8835.

Petaurus gracilis is morphologically and biochemically distinct from *P. norfolcensis* from which it is geographically isolated. Since its description in 1883, *P. gracilis* has been recorded from 22 localities between Ingham and Tully (80km) in coastal lowland woodland below the 90m contour. Its restricted distribution is determined by very high seasonal rainfall, a mean dry quarter precipitation usually greater than 100mm and a woodland blend of vegetation that is shaped and maintained by fire. The presence of one of the northern bloodwoods (*Eucalyptus intermedia*, *E. clarksoniana* or *E. dolichocarpa*) and an accompanying species of 'bird-syndrome' arillate *Acacia* are suggested as a minimal basis for suitable habitat. Among exudivores, *Petaurus gracilis* appears to be more a dietary opportunist, feeding on nectar, pollen, arthropods, *Acacia* exudates, lerp, and honeydew when these items become seasonally available. More notable dietary items include *Acacia* arils, *Xanthorrhoea* scape exudates and sap (or kino) of *E. intermedia*. Interpretation of its socioecology was impeded by small sample size but home range size for an adult female was determined at 23ha and a quasi-polygynous mating system was suggested. *Petaurus gracilis* is endangered throughout its range by habitat destruction, fragmentation and changes in local fire regimes that together have resulted in an 80% loss of its preferred habitat. □ *Petaurus gracilis, Petaurus norfolcensis, Petauridae, taxonomy, distribution, conservation, Queensland, Australia, Mahogany Glider, habitat, ecology, tropical woodland, diet, behaviour.*

Steve Van Dyck, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; 21 February, 1993

Since its description in 1883 by Charles de Vis, the taxonomic status and distribution of *Petaurus gracilis* has been a matter for conjecture. De Vis failed to designate a holotype and no specimens are referred to in the literature or known from collections outside the Queensland Museum. Five years after its description, Thomas (1888) synonymized *P. gracilis* with *P. norfolcensis* (then *Petaurus sciureus*) and Mackay (1988) dealt with it similarly. Other references to the name *P. gracilis* deal with it as a northern subspecies of *P. norfolcensis* (Iredale & Troughton, 1934; Troughton, 1941; Tate, 1945; Fleay, 1947; 1954; Marlow, 1962; Suckling ,1983; Alexander, 1981; Colgan & Flannery, 1992). Given the lack of *P. gracilis* specimens in collections, and the subsequent anonymity of the species, it is probable that its synonymy has resulted from a broad interpretation of de Vis's brief description rather than from a physical examination of the few *P. gracilis* specimens. Also, the assigning of *P. norfolcensis gracilis* to a wide range of Queensland examples of *P. norfolcensis* has resulted from too broad an interpretation of de Vis's loose reference to its collection locality, 'North of Cardwell' (de Vis, 1883: 620).

In 1990 I reported three previously unregistered museum specimens, whose large size, long, thin, short-haired tails, pattern of fur colouration and measurements agreed closely with de Vis's description of *P. gracilis* (Van Dyck, 1990). These skins had been collected by Kendall Broadbent in 1886, from somewhere on, or near Mt Echo, 18km SW Cardwell. At the time of that report, given the faded, deteriorated quality of the skins, the fragmentary nature of cranial and dental material extracted from them, and inexplicable inconsistencies between the de Vis description and data associated with old identification tags attached to the skins, it was concluded that until additional material came to hand, *P. gracilis* should remain a junior synonym of *P. norfolcensis*. However, I also concluded that it was inappropriate to continue the use of *P. norfolcensis gracilis* in respect of all northeastern and mideastern Queensland examples of *P. norfolcensis* as they were indistinguishable from their more southern conspecifics.

In December 1989, living representatives of *P.*

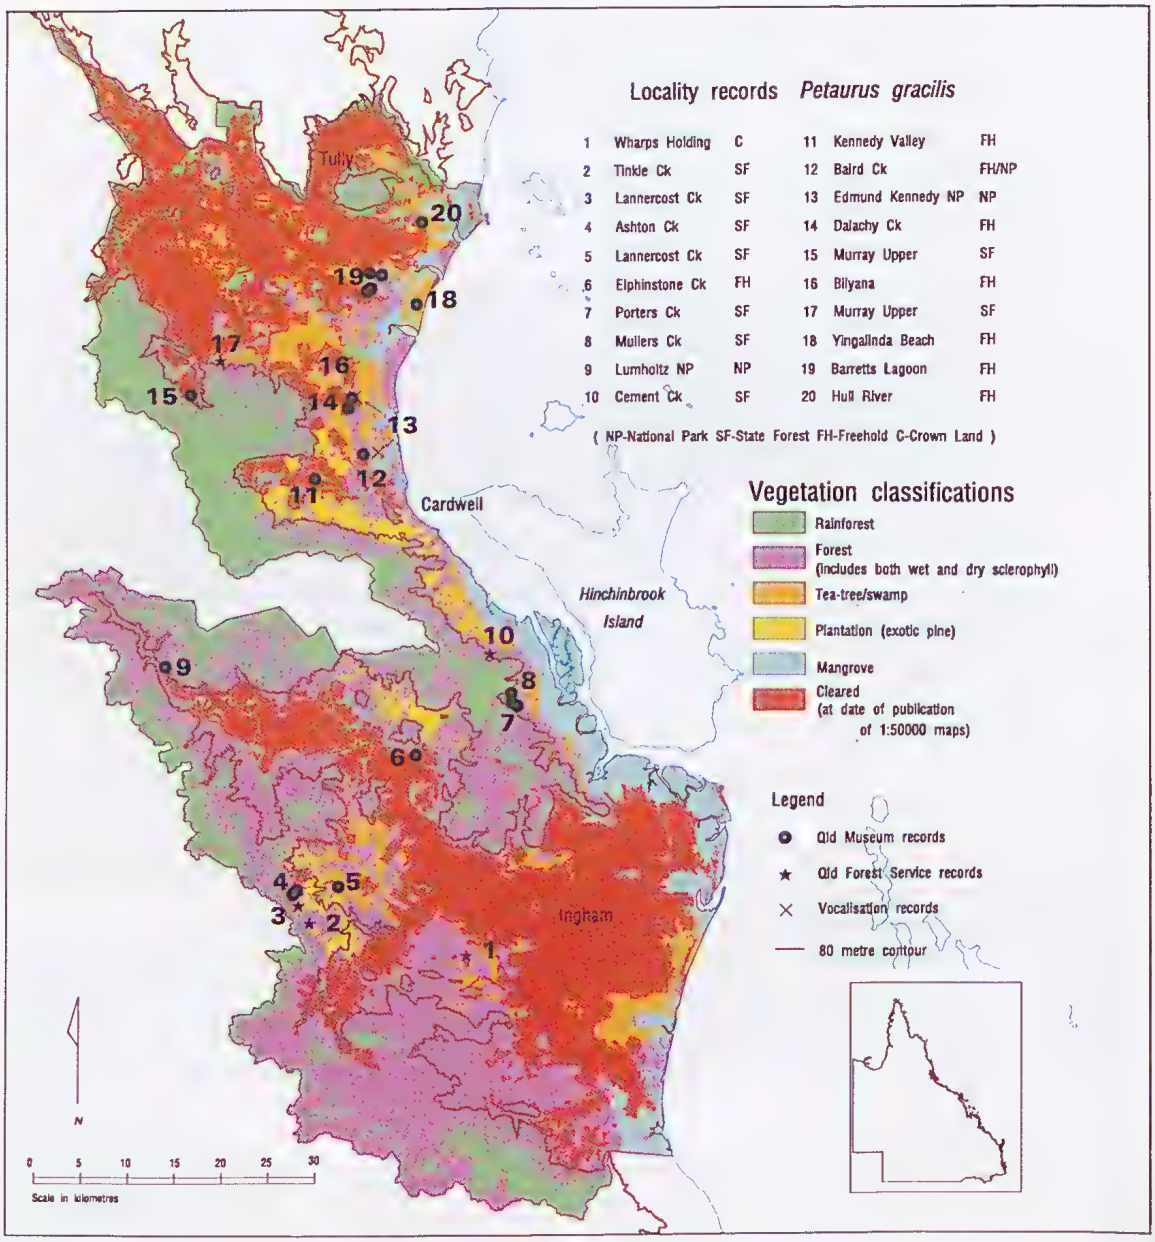

FIG. 1. Locality records for *Petaurus gracilis* (see Table 1 for details).

gracilis were located on freehold land at Barretts Lagoon (18°02'S, 145° 58'E), 14km SE of Tully. At that time, one specimen (JM7605) was collected for museum accession. In January 1990 the collection site was cleared for cultivation of bananas and pineapples. In February 1991 an adult female was captured nearby, photographed (Fig. 2) and subsequently (May) released at the site of capture (Van Dyck, 1992a). Further surveys conducted during 1991-2 extended and refined the range of the species and provided data suggesting that the long-term conservation of the species could be a matter of grave concern.

The aim of the present study was to: 1, clarify the taxonomic status of *P. gracilis* with respect to *P. norfolcensis* (in particular) and other members

of the genus; 2, provide preliminary data on the distribution, habitat requirements, diet and socioecology of *P. gracilis*; and 3, assess the conservation status of the species.

METHODS

Systematics

Nomenclature for molar tooth structure follows Woodburn et al. (1987), and cheek tooth number follows Archer (1978) (see explanation in Marshall, 1987). Dental and cranial measurements were made after the method shown in Fig. 3. Specimens were measured to the nearest 0.01mm using NSK electronic digital calipers. Specimens compared in diagnoses were adults with fully erupted fifth molars. T-tests were used to test for statistical significance.

Specimens from the following institutions were examined: Queensland Museum (specimens refered to in text prefixed by J or JM); Australian Museum, Sydney (specimens prefixed by M); Australian National Wildlife Collection, Division of Wildlife Research, Canberra; Bishop Museum, Honolulu; British Museum (Natural History), London; American Museum of Natural History, New York; Museum of Victoria, Melbourne. Maximum numbers of individuals included in statistical analyses were: *P. norfolcensis* 70, *P. breviceps* 21, *P. australis* 11, *P. abidi* 5 and *P. gracilis* 11. Old skins (JM5521, JM5522, JM5523) were omitted from statistical analyses.

Field Surveys

Field observations and surveys were made during the following periods: 1-13 Dec 1989, 9-24 Feb 1991, 9-24 May 1991, 2-16 Aug 1991, 23-29 Nov 1991, 29 Feb-13 Mar 1992, 13-14 May 1992, 24 May-6 June 1992, 26 Sept-11 Oct 1992, 24-26 Nov 1992. Fieldwork during 1989 and 1991 concentrated on capture and radiotelemetry of individuals at Barretts Lagoon, while 1992 fieldwork was concerned with an assessment of distribution outside the immediate area of the lagoon.

Capture Techniques

Wire cage and aluminium live traps were set 2-7m above the ground. Traps included Elliott aluminium (460×160×150mm and 330×95×100mm) Mascot wire (560×205×215mm),

FIG. 2. Adult female *Petaurus gracilis* T4026, caught Barretts Lagoon 22 Feb 1991, released 11 May 1991.

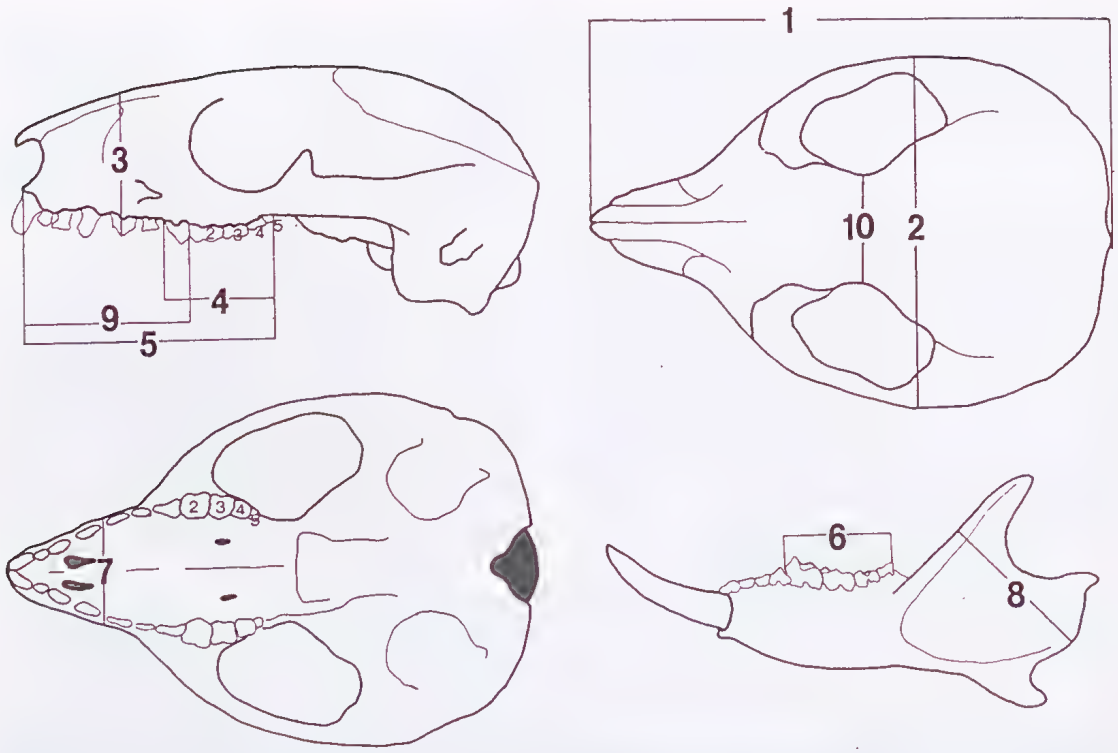

FIG. 3. Method used in skull and tooth measurement: 1, maximum skull length; 2, zygomatic width; 3, rostrum height; 4, upper molar row length; 5, upper tooth row length; 6, lower molar row length; 7, rostral width between upper canines; 8, width of ascending ramus; 9, upper incisor-premolar row; 10, interorbital width.

Tamohawk wire (400×140×140mm) and Acme wire (440×200×180mm). Traps were protected by plastic bag weather shields and supported on horizontal ply baseboards screwed to right-angle iron brackets which were nailed to tree trunks. Baits consisted of a sugar/honey toffee or a mixture of honey and sweetened condensed milk. Additional attractants of diluted honey, sugar water or raspberry cordial were sprayed on tree trunks near trap entrances to lure gliders into the traps. Traps were laid along transects on trunks of living and dead trees, or arranged in groups of up to 12 among flowering *Xanthorrhoea johnsonii* chosen for signs of *P. gracilis* visitation by way of footprinted flower stalks. Trapping was carried out during the following periods: 1-13 Dec 1989 (205 trap nights); 9-24 Feb 1991 (230 trap nights); 9-24 May 1991 (110 trap nights); 29 Feb-13 Mar 1992 (176 trap nights). Trap-nights totalled 721 and covered 10 sites at Barretts Lagoon and one at Edmund Kennedy National Park, Cardwell.

At the beginning of the survey (Feb and May 1991), 48 artificial nesting hollows were installed and left for between 16-19 months at 2 sites at Barretts Lagoon to act as a back-up should the trapping program fail. Of these, 34 were attached to tree trunks (Feb 21) at the Barretts Lagoon 'Rice Fields' (18°01'S, 145°58'E) where an adult female had been caught (19 Feb). This 200-400m wide strip of woodland was bordered to the west by Barretts Lagoon Road and to the east by natural treeless swales (Fig. 19). Given the irregular shape of the site, the 34 hollows were arranged in a grid of six rows (1 row of 7 hollows, 2 of 6, 3 of 5) with minimum spacings of approximately 50m. On 17 May 1991, 14 additional artificial nests were installed further east (18°01'S, 145°59'E) and set along 700m of north-south track and spaced at 50m. The choice of 'nest' design was based roughly on the trap of Mawbey, (1989) which was shown to be highly effective for catching sugar gliders *P. breviceps* in the field. The artificial nesting hollows used in my study were of 160mm (diameter) PVC sewer pipe cut to 500mm lengths, capped at either end and

FIG. 4. One of 48 PVC artificial nest hollows used in the survey. Each was strapped onto a trunk with fencing wire.

drilled with a 65mm (diameter) entrance hole 120mm from the top of the tube (tube vertical). These hollows were furnished internally with a 280mm 'ladder' of roughened timber screwed directly below the entrance hole while the floor was perforated for drainage. All tubes were painted a dull brown-green, numbered and strapped vertically to trunks at heights of 3-7m using fencing wire (Fig. 4). All tubes were inspected at least once per survey period and all but one (occupied by a family of *P. breviceps*) were removed from the two sites by 8 Sept 1992.

One *P. gracilis* (Fig.2) was captured in a mist-net enclosure constructed around the outside of its den in a hollow Swamp Mahogany trunk (see Van Dyck, 1992a). Two were captured by 'port-holing' hollow trunks of known nest trees. This practice involved cutting a rectangular hole (approx 120mm × 180mm) into the den and extracting the glider(s) by hand. The 'port-hole' was then plugged with a hardwood block which was wired for later access. One individual was caught by shaking it from a small tree (see Van Dyck, 1992b).

Handling and Radio-tracking Procedures

Captured individuals were weighed, measured, sexed, assigned to an age category from the condition of wear of the first upper incisors (Suckling, 1980; Alexander, 1981), tagged on one ear with a numbered (T40_ _) fingerling ear-tag ('FF', Salt Lake Stamp Co., Utah) and (where possible) released back into the den from which they were taken. Gliders used in radio tracking were fitted with a Titley (Ballina, NSW) 'Microlite', two-stage transmitter either attached to a soft leather collar with a protruding 15cm whip antenna or epoxy-potted into a small disc (diameter 26mm × 10mm high) with a protruding 28cm antenna. The ventral surface of the epoxy disc transmitter was glued to the animals mid-back (Selleys Supa Glue) after a circle of fur approximating the diameter of the disc had been cropped close to the glider's skin. The short hair stubble that remained, provided a rough bonding surface for the glue on the transmitter and at the same time protected the animal's skin from contact with the adhesive. Long hair surrounding the positioned disc was then glued over the dorsal surface of the transmitter, in effect hiding it and leaving only the whip antenna exposed. The total weight of the transmitter package was approximately 11g. A 2000 channel 'Regal 2000' (Titley) portable receiver operating on the 150.000-151.999mHz band, and a 2 element hand-held H-frame antenna were used to locate animals.

Home Range Determination

Preliminary home range estimates were determined for one adult female (T4026) and two sub-adult female gliders (T4027 and T4028, presumed to be the offspring of T4026). During the course of the study only one male (T4030) was captured and radio-tagged. This male dislodged its transmitter on the third day and only den site data was recorded. Although gliders were strictly nocturnal, a morning (0600hrs) and afternoon (1600hrs) den fix was usually taken for each tagged animal. Because animals proved difficult to catch and visits to the area were irregular (and often 3-4 months apart), animals were radio-tracked both continuously and randomly during each visit. Direct observation was used to maximise return of information other than that associated solely with home range. Trees visited on a

glider's traversed route were marked with flagging tape and surveyed during the day.

It is acknowledged that direct observation through continuous tracking may have led to an underestimation of home range size through loss of independence of fixes (Swihart & Slade, 1985). To overcome this problem, where continuous tracking was employed, 30 minute fixes were extracted from examination of each route plotted through time. Quin et al. (1992) considered that 30min radio fixes for fast moving mammals such as species of *Petaurus* were adequate to assume independence of data points. Fixes were taken from adult female T4026 over a period of 4 full nights and 13 partial nights (including den fixes) during May, August and November 1991 (110 fixes), while those from sub-adult female T4028 were taken over a period of 1 full night and 9 partial nights (including den fixes) during May 1991 (36). Fixes from sub-adult female T4027 were taken over a period of 1 full night and 6 partial nights (including den fixes) during May 1991 (36 fixes). Estimates of home range area were generated using the harmonic mean distance minimum (HM) using 95% isopleths (see Dixon & Chapman, 1980) and the minimum convex polygon (MCP: Mohr 1974). The utility and appropriateness of the HM for describing home ranges of animals such as sugar gliders was demonstrated by Quin et al. (1992). Estimates were generated with the RANGES IVm software package (R. E. Kenward; Institute of Terrestrial Ecology, Furzebrook Research Station, Wareham, United Kingdom).

Spotlighting

12 volt, 150mm and 230mm 'Powa Beam Spotlights' (Byron Bay, NSW) were used from a vehicle, the 230mm (9") 'Powa-lite' (1 million CP, quartz halogen) being particularly efficient. 150mm, 12V spotlights powered by wet cell motorbike batteries were used for on-foot surveys. 3 and 4 'D'cell 'Mag-Lite' torches (Mag Instruments - Ontario, Calif) were used to observe radio-tagged animals. The expanding beam of these torches greatly facilitated detection of gliders leaping from treetops. A total of 1334 manhours were spent spotlighting for *P.gracilis* (Table 3). *Petaurus gracilis* was consistently difficult to locate (see Davey, 1984; Menkhorst et al., 1988 for similar problems with *P. norfolcensis*). It was practically silent, evasive in spotlights and its eyes reflected poorly (dull red). Animals attracted by playback recordings of *P. norfolcensis* or *P. gracilis* vocalisations (see Kavanagh & Rohan-Jones, 1982) or by imitated calls aborted their approach if a light was turned on. In approximately 877 manhours of non-telemetry spotlighting (547 hours from a vehicle, 330 on foot), 22 of the 28 animals located by this method were first observed from a vehicle.

Palynological Analysis

Pollen analysis was undertaken by M. Dettmann (University of Qld) on five faecal samples collected between Feb and Nov 1991 from Barretts Lagoon. Two strew slides were prepared from each sample. One, contained crushed but otherwise untreated faecal material mounted in glycerine jelly under a glass coverslip. The second slide contained faecal material treated with warm 5% KOH for 5min, then washed thoroughly under distilled water and sieved through a 240μ mesh screen prior to mounting in glycerine jelly. The untreated slides were examined to estimate relative proportions of pollen, other plant tissue and insect fragments in each sample, and to estimate the proportion of pollen with their contents (intine) in place. Qualitative and quantitative analyses of the pollen assemblages represented in each sample were determined from the treated slide.

Vegetation Analyses

At each site where a glider had been observed (Table 1) the vegetation was assessed visually and classified into one of the vegetation types of Tracey (1982). A vegetation proforma was prepared by W. Lavarack and R. Cummings (Queensland Department of Environment and Heritage) for each site. Trees, shrubs and grasses were recorded in terms of their relative abundance (A-abundant, C-common, O-occasional, U-uncommon). An estimate was made of projective foliage cover (% of the sample site occupied by the vertical projection of foliage only, see McDonald et al., 1984) and the soil type noted. Nest sites of four individuals were described in more detail by P. Stumkat and I after the manner of Menkhorst et al. (1988). A square quadrat, centered on a frequently used denning tree, was defined with its apicies 30m to the N, S, E, and W (total area 1800m^2). Densities of trees were then presented as mean number of trees per 1000m^2. Within each quadrat all trees and shrubs

TABLE 1. Site and record details for *P. gracilis* sorted from the south by latitude. Age as adult (A) or juvenile (J). Sex as male (M) or female (F). Tenure includes National Park (N.P.)3 and State Forest (S.F.) +Site inside (east of) NP fence, but fence west of gazetted park boundary. * Record courtesy of J. Kehl, QFS.

FIG. 5. Comparison of size in four species of *Petaurus*. L to R, *P. gracilis* (adult male JM9014, Dalachy Creek), *P. abidi* (adult female M21664, Wilbeite, Papua New Guinea), *P. norfolcensis* (adult female J11514 Warwick), *P. breviceps* (adult female JM7396, Barretts Lagoon). Scale divisions in cm.

taller than 3m were identified, counted and their height and circumference-at-breast-height measured (Table 4).

Biochemical analysis

Frozen tissues of adult female JM8459 (Kennedy Valley) were the subject of electrophoretic allozymic analysis as described by Colgan & Flannery (1992).

SYSTEMATICS

Petaurus gracilis (de Vis, 1883)

Diagnosis

Petaurus gracilis is distinguished from *P. norfolcensis* by its larger size, reflected in the following measurements (in mm) for which respective values show no overlap:

Maximum skull length: mean 51.14, R= 49.80-52.60, N=7, SD=0.95 vs 45.33, R=40.96-49.05, N= 68, SD= 1.80.

Zygomatic width: mean 34.14, R=32.90-35.08, N=7, SD= 0.71 vs 30.15, R= 27.81-32.59, SD= 1.19.

Rostrum height: mean 14.02, R= 13.00-15.93, N= 9, SD= 0.84 vs 11.54, R= 9.89-12.68, SD= 0.62.

Tail-vent length: mean 353.50, R= 300-390, N= 10, SD=25.76 vs 239.43, R= 195-290, N= 30, SD=22.06.

P. gracilis has a significantly (P<0.001) narrower interorbital width than *P. norfolcensis*: mean 8.59, R= 7.30-9.82, N=9, SD= 0.95 vs 9.60, R= 7.97-11.73, N= 69, SD= 0.70.

P. gracilis is significantly (P<0.001) larger than *P. norfolcensis* in the following measures (Fig. 5):

Head-body length: mean 247.45, R= 215-265, N= 11, SD= 15.86 vs 200.72, R= 165-232, N= 29, SD= 17.17.

Hind foot length: mean 39.61, R= 37-43, N= 11, SD= 2.00 vs 32.03, R= 24-38, N= 29, SD= 3.01.

Weight: mean 349.45, R=255-410, N= 11, SD=39.69 vs 170.47, R= 110-301, N= 30, SD= 43.57.

Upper molar row length: mean 8.68, R=8.30-9.00, N= 9, SD= 0.21 vs 8.06, R= 7.37-8.90, N= 70, SD= 0.34.

Upper tooth row length: mean 23.90, R= 23.00-24.80, N=9, SD=0.51 vs 21.78, R= 19.76-23.51, N=69, SD= 0.84.

Lower molar row length: mean 9.43, R=9.00-9.91 N= 9, SD= 0.28 vs 8.73, R= 7.73-9.50, N= 69, SD= 0.34.

Upper incisor-premolar row length: mean 16.03, R= 15.47-16.59, N= 9, SD= 0.34 vs 14.46, R= 12.95-15.99, N= 69, SD= 0.69.

Rostral width between upper canines: mean 9.69, R= 9.10-10.30, N= 9, SD= 0.29 vs 8.67, R= 7.60-10.00, N= 69, SD= 0.46.

Width of ascending ramus: mean 13.13, R= 12.09-13.70, N= 9, SD= 0.32 vs 11.15, R= 9.93-12.50, N= 69, SD= 0.59.

Figs 6, 7 and 8 demonstrate the relationship between *P. gracilis* and *P. norfolcensis* for some of the measures refered to above.

Petaurus gracilis is distinguished from *P. breviceps* by its much larger size, reflected in the following measurements for which respective values show no overlap:

Maximum skull length: mean 51.14 vs 36.07, R= 33.17-37.91, N= 17, SD= 1.23.

Zygomatic width: mean 34.14 vs 24.79, R= 22.53-26.53, N=16, SD= 1.20.

Rostrum height: mean 14.02 vs 8.92, R= 8.29-9.55, N= 19, SD= 0.36.

Width of ascending ramus: mean 13.13 vs 8.18, R= 7.28-9.49, N= 20, SD= 0.56.

Tail-vent length: mean 353.50 vs 192.92, R= 159-235, N= 13, SD= 19.62.

Weight: mean 349.45 vs 93.09, R= 59-118, N= 11, SD= 19.19.

Upper molar row length: mean 8.68 vs 6.37, R= 6.05-7.75, N= 21, SD= 0.20.

TABLE 2. Queensland Museum specimens (prefixed JM) and tagged individuals caught and released (prefixed T). Age as adult (A), sub-adult (SA) or juvenile (J). Sex as male (M) or female (F). Measurements in mm, weight in g. Tail damaged as (d).

Rostral width between upper canines: mean 9.69 vs 6.79, R= 6.29-7.30, N= 20, SD= 0.31.

Petaurus gracilis is immediately distinguished from *P. abidi* by the atrophied condition of P^2 in *gracilis*, but which, in *abidi*, is well developed and subequal in crown height to both P^1 and P^3. *P. gracilis* is further distinguished by its reduction in buccal ectoloph enamel on M^2 and M^3 and by the reduction in the paracone relative to the metaconule (the posterolingual cusp previously and commonly termed the hypocone; see Woodburn et al., 1987: 641 for discussion) in M^2. *P. gracilis* is also distinguished from *P. abidi* by its smaller dimensions in the following measurements for which respective values show no overlap:

Interorbital width: mean 8.59 vs 10.42, R=9.70-11.50, N= 3, SD= 0.78.

Upper molar row length: mean 8.68 vs 9.50, R= 9.30-9.70, N= 2, SD= 0.21.

Petaurus gracilis is distinguished from *P. australis* by its smaller size, reflected in the following measurements (for which respective values show no overlap:

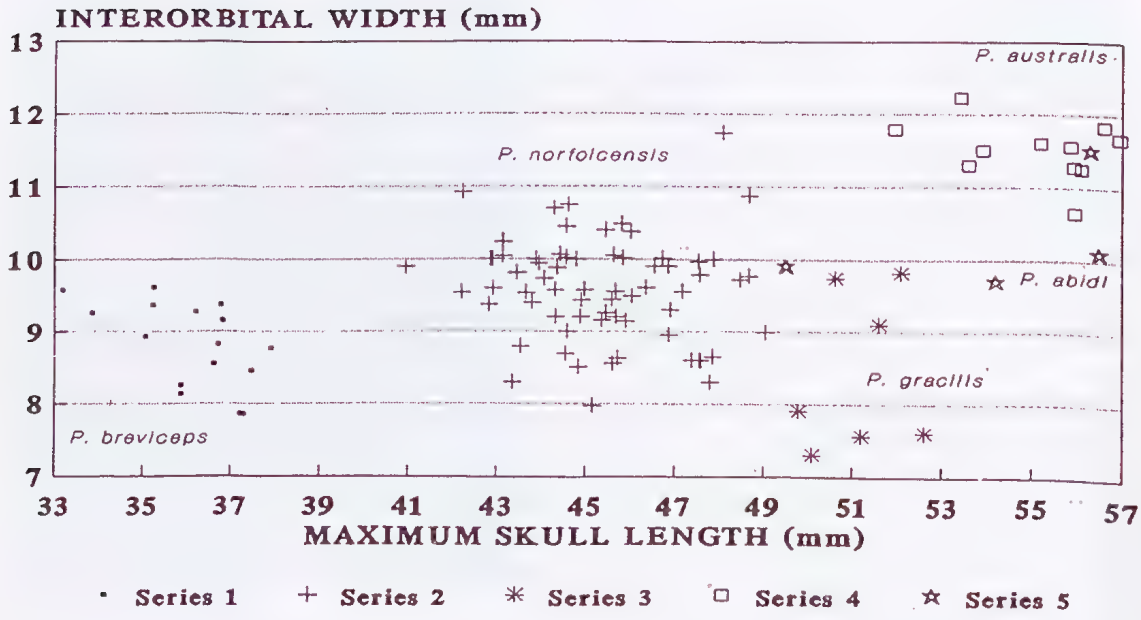
Zygomatic width: mean 34.14 vs 37.38, R= 34.98-39.70, N= 10, SD= 1.45.

Tail-vent length: mean 353.50 vs 433, R= 410-460, N= 6, SD= 17.88.

Interorbital width: mean 8.59 vs 11.51, R= 10.65-12.22, N= 11, SD= 0.38.

Rostral width between upper canines: mean 9.69 vs 12.00, R= 11.06-12.70, N= 11, SD= 0.53.

Ear length: mean 31.96, R= 27-36, N= 10, SD= 2.85 vs 51.40, R= 46-56, N= 5, SD= 3.88.



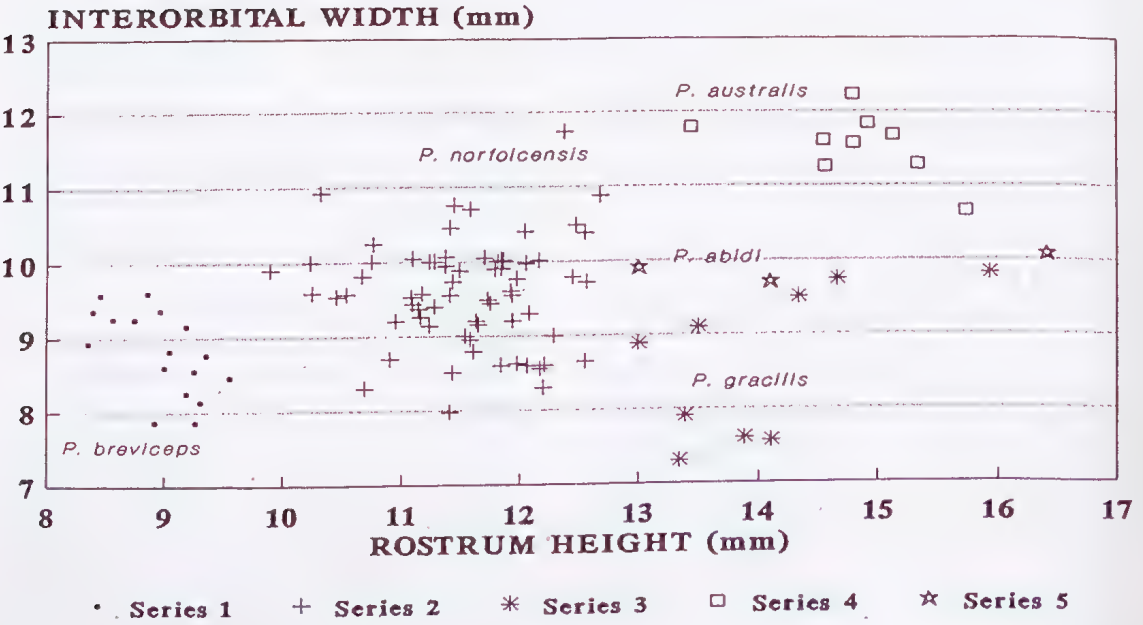


FIG. 6. Bivariate plots of interorbital width against rostrum height and maximum skull length. Series 1= *P. breviceps*, Series 2= *P. norfolcensis*, Series 3= *P. gracilis*, Series 4= *P. australis*, Series 5= *P. abidi*.

FIG. 9. Dorsal perspective of three colour morphs in *P. gracilis*. L to R, dark phase (adult male JM9014), buff phase (adult female JM9015), aberrant phase (adult female JM9016).

DESCRIPTION

Externally, this species of *Petaurus* is distinctive for its large size, long, relatively short-haired tail and buff to mahogany-brown belly (Figs 5, 9, 10). There is considerable variation in the depth of both dorsal and ventral tonings and the band of fur along the lateral anterior edge of the gliding membrane may be buff, rich orange or deep mahogany. Ventral fur (adult and sub-adult of both sexes) may be either buff, honey-yellow or deep mahogany (Figs 9, 10; Table 2).

Pelage: Colours (where capitalised after Ridgway, 1912) of the buff phase (example used JM7400) are as follows: Fuscous-Black mid-dorsal head-and-body stripe variable in width (partially depending on the 'lie' of the body fur) commencing at a point between the anterior edge of the eyes and extending posteriorly to the rump. It is 12mm wide between the ears, 5.6mm at mid-neck, 17mm at mid-shoulder blades and fading away over the rump. Fur of the mid-back (16.3mm long) with basal 14.4mm Smoke Gray, median 1.4mm either Pale Smoke Gray (off-white) or Chamois (brown-yellow), apical 0.5mm Fuscous-Black. The back therefore appears overall a patchy wash of smoky grey (Smoke Grey) and yellowish-brown. The yellowish patches are most pronounced over the shoulders, along the flanks and over the rump. Medially thickened Fuscous-Black-tipped guard hairs are interspersed very sparsely through the fur and are 20.4mm on the mid-back and reduce to 3.6mm on the tip of the snout where they are entirely Fuscous-Black. Fur on either side of the head-stripe is Pale Smoke Gray with a yellowish-buff wash. A ring of Fuscous-Black fur encircles the eye, and fur below the eye-ring to the corner of the mouth is Pale Olive-Buff. Muzzle (delineated by the presence of mystacial vibrissae) a weak Fuscous-Black. Fuscous-Black fur encircles the dorsal posterior and ventral base of the pinna, extending forward and down to slightly posterior of the genal vibrissae. Directly anterior to the ear and posterior to the genal vibrissae, is a patch of anteriorly-directed Pale Olive-Buff fur. The pinna is virtually naked on the inner surface, and on the distal 11mm of the outer surface. The pinnae of living animals are a pink-bronze. A patch of pale Olive-Buff fur (hairs up to 8mm long) on the posterior external edge of the pinna forms a conspicuous tuft.

Dorsally, the patagium is fringed along its length by a thickly-furred band of Cream-Buff fur (hairs 3mm long). Midway between the wrist and digit 5, the apex of a triangular patch of striking Chamois-coloured fur extends in a narrowing band (to 5mm wide) posteriorly along the inner side of the outermost Cream-Buff band. More mesially, and slightly overlaying the Chamois band the patagium is coloured Sepia in a hard line 6mm wide and extending posteriorly from the wrist to the ankle. Sepia fur sparsely covers the rest of the patagium.

Ventrally, the patagium is fringed in a 5mm wide band of Clay coloured fur from the claw of digit 5 to the ankle. More mesially this band is partly overlaid by another 5mm wide band of Sepia which extends from 20mm posterior of the digit 5 claw to the ankle where its colour fades. The bulk of the patagium is then sparsely covered with 15mm long Honey-Yellow fur.

The soft ventral fur (18mm long on the belly) is Cream-Buff to Honey Yellow, but is suffused with Smoke Gray hairs on either side of the neck and around the muzzle.

Forefeet digits are thinly covered with Smoke Gray hairs. Hindfeet are more thickly covered with slightly lighter Pale Olive-Buff which contrasts with a 'mitten' of Smoke Gray over the metatarsals extending up to the inner posterior region of the thigh in a triangular stripe 23mm at

TABLE 3. Localities surveyed, spotlight effort and arboreal mammals recorded. Mammals are grouped by locality, not by date. Fruit bat presence not recorded.*Observed on dry *E. acmemoides* ridge. # Observed at approx. 610 m. a.s.l. ▲ Site cleared Feb 1990.

			TOTAL	1334	

its widest point almost to the base of the tail. A similar, but darker forearm 'stripe' (Fuscous Black) extends from the base of digit 1 along the antero-mesial region of the forearm to terminate in a 20mm wide patch at the base of the forearm.

The tail is thinly haired and approximately one-and-a-half times longer (average 147%) than the head and body length. Near its base (40mm from the body) the fur is slightly shorter dorsally (25mm) and ventrally (17mm) than laterally (33mm). 40mm from the tip of the tail the fur is even in length and slightly shorter (24mm). The distal one-third of the tail is Fuscous Black changing reasonably abruptly to honey-grey (basal 20mm Smoke Gray, apical 13mm Chamois).

Males exhibit naked, ovoid glandular patches on the crown of the head within the black head-stripe (gland approx. 9mm × 5mm) and at the base of the throat (approx. 9mm × 7mm).

Vibrissae: Approximately 16 relatively short Fuscous Black mystacial vibrissae occur on each side and measure up to 19mm long; supra-orbital vibrissae (Fuscous Black) number approx. 2 each side, genals number 2-3 (Fuscous Black) and metatarsals number 4 (Chamois).

Claws of fore and hind feet are relatively large with maximum chord length of digit 4 and 5 claws approx 9mm. Digit 4 is the longest digit of manus or pes and digit 4>5>3>2>1.

In the dark phase (Figs 9, 10), white and buff colours are replaced with deep gingers, browns or Fuscous-Black. The pattern of body stripes, tail and limb 'pennants' is as in the buff form but the median section of mid-back varies from Tawny Olive to Deep Mouse Gray (not Pale Smoke-Gray), the head may be Tawny Olive to Pale Olive Gray, the cheeks and flanks Honey Yellow to Dark Olive-Gray (not Pale Olive-Buff), and the dorsal anterior flange of the patagium Honey Yellow to Deep Olive Yellow (not Chamois). The dorsal surface of the patagium is Deep Mouse Gray, its external margin Deep Olive-Gray, ventrally the patagium is fringed in a 5mm wide band of Deep Olive-Gray fur tipped with buff (the apical 1mm) from the claw of digit 5 to the ankle. More mesially this band is partly overlaid by another 5mm wide band of Fuscous-Black which extends from 20mm posterior of the digit 5 claw to the ankle where its colour fades. The bulk of the patagium is then sparsely covered with Deep

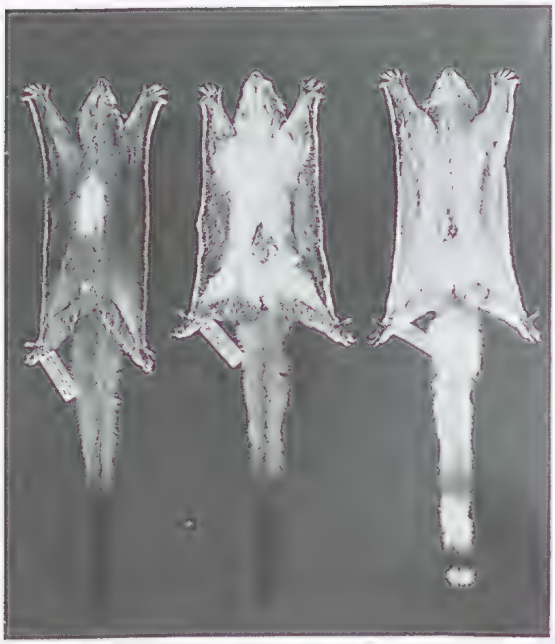

FIG. 10. Ventral perspective of three colour morphs in *P. gracilis*. L to R, dark phase (adult male JM9014), buff phase (adult female JM9015), aberrant phase (adult female JM9016).

Olive-Gray fur. Fur encircling the dorsal posterior and ventral base of the pinna, extending forward and down to slightly posterior of the genal vibrissae is Fuscous-Black. The ventral surface from throat to sternum is a Grayish Olive to Tawny Olive darkening to Sepia or Dark Olive near the belly. A small spot or streak of white fur may be present on the belly, sternum or slightly anterior to the pouch. The scrotum is buff-coloured, and hair inside the pouch Warm Sepia.

Aberrant form (Figs 9,10): JM9016 may represent an aberrant form where the ventral surface is more richly coloured with Clay Colour (orange-ochre) fur which extends around the forefeet up to the elbows, around the hind feet as far as the knees, and over the patagial edges to end along the animal's flanks . A small white patch of fur is present in the head-and-body stripe just posterior the ears. The tail is banded as follows (from the base), 11mm white, 14mm Mineral Gray, 50mm Tilleul Buff, 36mm Mineral Gray, 40mm Tilleul Buff, 57mm Mineral Gray, 26mm Fuscous (marking the proximal extent of a normal black tail-tip), 64mm Pale Olive-Buff, 40mm Fuscous-Black. Alexander (1981) illustrated an aberrant specimen, M8134, from Grafton, New South Wales similar to JM9016. He commented on the possibility of M8134 being 'some sort of hybrid' between *P. breviceps* and *P. norfolcensis*. Given the size disparity between *P. breviceps* and *P. gracilis* and the observed intolerance of *P. gracilis* toward *P.breviceps* in the field, the likelihood of JM9016 representing a hybrid is probably remote.

Cranium and dentition: Essentially similar to *P. norfolcensis* except skull longer and much broader, with a much higher rostrum and wider ascending ramus. In spite of such consistently high values in *P. gracilis*, upper molar row lengths are not significantly longer than those of large examples of *P. norfolcensis*, and interorbital length in *P. gracilis* is significantly narrower than *P. norfolcensis* of all sizes (Figs 6-8).

Biochemical analysis: Electrophoretic allozymic analysis conducted by Colgan and Flannery (1992) showed *P. gracilis* to be genetically distinct (three fixed differences; adenylate kinase (1), glycerophosphate dehydrogenate and phosphoglucomutase in 21 loci) from *P. norfolcensis norfolcensis* (Limeburners Creek, NSW).

DISTRIBUTION

P. gracilis has been recorded only from a narrow band of medium to low woodland on Quaternary coastal alluvium and granite north of Wharps Holding (S of Herbert River, Ingham) to the Hull River, a latitudinal range of almost 80km (Fig. 1). In this band, *P. gracilis* has been found at altitudes below 90m a.s.l. with most records from between the 0-20m contours (Tables 1 and 2).

RESULTS

HABITAT

Vegetation associated with *P. gracilis* included Vegetation Types 15a (Medium Open-forest i.e. paperbark swamp), 17 (Coastal Beach Ridges and Swales), 19 (Coastal Floodplains and Piedmont slopes), 20 (Texture-contrast Soils with Impeded Drainage on Coastal Plains) and 24 (Cleared) of Tracey (1982). The appropriate Tracey vegetation type (TVT) appears with each site vegetation proforma below. The following abbreviations were used to describe the relative abundance of plant species (A-abundant, C-common, O-occasional, U-uncommon).

Sites marked thus * indicate records supplied courtesy of Queensland Forest Service. Tracey (1982) provides an overview of climate, physiography, geography and soils of the area. The Quaternary lowland coastal plains and extensive

beach ridges which typify the distribution of *P. gracilis* occur in narrow corridors up to 10km wide and 50km long between the steep ranges near the coast and the main scarp further upland. Soil types are determined by drainage; on the better-drained levees yellow friable loams predominate, and there is a progression to gleyed podzolic soils, humic gleys and acid peats as the site drainage becomes poorer. Calcareous or siliceous sands are found on the younger near-coastal ridges and podzols occur on the older ridges.

Annual rainfall is high, but widely different rainfall regimes operate and vary considerably over short distances because of local topographic changes which include the height and orientation of mountain ranges and the direction of the coastline with respect to the prevailing south-east air stream. The wide coastal plains and beach ridges show dramatic drops in rainfall from coast to foothills, e.g. Halifax 2127mm west to Upper Stone 1533mm in 45km. The relative dryness of foothills and eastern slopes may account for the apparent restriction of the glider to areas of very low elevation (below 90m a.s.l.). While foothills may receive only slightly less summer rainfall than coastal plains (Rollingstone, 19°03'S 146°24'E, Dec 220mm, Jan 416mm, Feb 344mm compared with coastal plain Euramo, 18°00'S 145°56'E Dec 167mm, Jan 597mm, Feb 652mm), dry season rainfall in foothills may be inordinately low (Rollingstone Jun 15mm, Jul 11mm, Aug 18mm, Sept 25mm contrasted with Euramo Jun 132mm, Jul 93mm, Aug 67mm, Sept 99mm). Latitudinal variation in rainfall may also be dramatic over short distances, e.g. Tully 4188mm south to Cardwell 2132mm in 40km.

SITE RECORDS (see Table 1)

Two historic records exist for which there can be no precise fix:

i. 'North of Cardwell' (de Vis 1883). No habitat information is included in the original description, and to date no Broadbent diary has been found for that period. The Edmund Kennedy National Park (NP 771) now accounts for approximately 6200ha of largely unaltered lowland coastal land immediately north of Cardwell (to the Murray River). The park contains a variety of lowland vegetation communities (all below 20m elevation) from mangroves, bulkuru swamps, paperbark forest and dry eucalypt woodland through to rainforest. Approximately 30% of this park could be considered possible habitat for *P. gracilis* (open sclerophyll forest with shrubby understorey), approximately 1% could be considered optimal habitat. The glider has recently been recorded within the park boundary. For more detailed floristics see habitat data (for sites 13 and 14) below.

ii. 'Mt Echo' (locality information on tags attached to skins JM5521, JM5522, JM5523). No specific vegetation or elevation information is available with this record and although the 1886 diary of Kendall Broadbent documents his camp on the Herbert River and his collecting efforts on the steep slopes and summit of Mt Echo, no details are given concerning where gliders were collected. The problem is further compounded by Broadbent's various references to vernaculars such as 'small flying squirrels', 'flying squirrels', and a 'large flying squirrel' in lieu of specific titles for collected examples of *Petaurus breviceps*, *P. gracilis* and *Petauroides volans*. Vegetation of the dry slopes of Mt Echo beside the Herbert R has probably changed little since Broadbent's day. At one site (18°24'52"S 145°46'13"E) the dominant species in the upper canopy (23m with 30% cover) were *Eucalyptus tereticornis* (C), *Lophostemon suaveolens* (A), *E. clarksoniana* (O) and *E. tessellaris* (O). Understorey (<5% cover) species comprised *Planchonia careya* (O) and *Pandanus* sp. (O). Ground layer (100% cover) consisted of *Imperata cylindrica*, *Mnesithea rottboellioides* (A), *Trumfetta rhomboidea* (C) and *Panicum maximum* (O). Soil was rocky, brown sandy loam, TVT 19.

Contemporary records for which more precise fixes are available (Fig. 1):

1. ***Wharps Holding** (18°41'18"S 146°04'25"E). Dominant species of the upper stratum (25m with <45% cover), *E. platyphylla* (U) and *Melaleuca dealbata* (A). Understorey (20% cover) composed of *L. suaveolens* (C) and *Pandanus* sp. (U). Ground layer (50% cover and heavily grazed) probably *I. cylindrica* and other grasses. This area was notable for its coarse mosaic of single species associations. Isolated clumping of single species included *M. dealbata*, *L. suaveolens*, *E. tessellaris* and *Acacia crassicarpa* with *E. platyphylla* scattered throughout. This area is renown for its protracted periods of extensive inundation during the wet season. Soil, grey loam, TVT approaching 16p. A second glider observation was made nearby (100m N) on a gently sloped rocky ridge (40m a.s.l.) where dominant species of the upper stratum (18m with <30% cover) included *E. platyphylla* (O), *L. suaveolens* (A), *E. tessellaris* (O) and *E. dolichocarpa*. The understorey (<1% cover) was com-

Additional notes on nest sites of Table 4.
Understorey.

Site 1 (Fig. 11): Dry low woodland between swales with groundcover species homogeneous throughout site. 70-95% cover and dominated by *Themeda triandra* and *Leptocarpus ramosus* (both about 1 m) with smaller representation (< 10 specimens) by *Lomandra longifolia*, *Dianella caerulea*, *Melastoma affine*, *Banksia integrifolia* var. *aquilina*, *Dipodium ensifolium*, *Schoenus sparteus* and *Lindsaea ensifolia*. Regrowth (< 3 m) with 10-20% cover by *Acacia mangium*, *A. crassicarpa*, *Lophostemon suaveolens*, *E. pellita*, *M. viridiflora* and *A. pubirhachis*. Of *X. johnsonii*, (tallest 800mm), 32 with green scapes (7 with *P. gracilis* foot prints, 2 with gouges), 130 with dry seeded scapes. Site 1 sufficiently elevated to escape inundation in wet season.

Site 2 (Fig. 12): Tall teatree-razorgrass swamp with eastern edge encroaching swale and dominated by dense groundcover (90%) of *Leptocarpus ramosus*, *Blechnum indicum*, *Scleria ciliaris*, *Baumea* sp., and *Ischaemum australe* var. *villosum*. Sparce cover of *M. affine*. Southern and western quarters dominated by *S. ciliaris* and *B. indicum* to 1400mm (70-90%), *Baumea* sp. (approx 2%) and *Dichranopteris linearis* (approx 5%). The drier, more elevated western quarter dominated by *I. australe* var. *villosum* and *L. ramosus* at 400mm (approx 50%) with *Gahnia sieberiana* at 1.2m (10%), *D. linearis* at 600mm (5%) and stunted *M. quinquenervia* (2%) with *L. ramosus* at 600mm and *Erocaulon australe* at 300mm in the swale. Sparse (<1%) regenerating vegetation comprised *M. quinquenervia* in western, southern and eastern quarters with *A.crassicarpa, A.flavescens* and *L. suaveolens* (total 2%) in the north. *X. johnsonii* showed 4 green scapes, 4 dry seeded scapes, 1 with foot prints and 0 scarred.

Site 3 (Fig. 13): Swale and medium to low woodland. Southern half (swale) dominated by dense groundcover (75% cover) of stunted *M. quinquenervia* (5-6%) at 0.5m, *M. viridiflora* (30 specimens all < 3 m), *I. australe* var. *villosum* (80%) at 1.1 m, *Themeda triandra* (1-5%), *Leptocarpus ramosus* (5%), *Scleria polycarpa* (5%) and *Eriachne triseta* (5%). Northern half (woodland) densely covered (100%) with *I. australe* var. *villosum*, *T. triandra* and *Lomandra longifolia*, *Smilax australis* abundant and up to 4 m, *L. ensifolia* common in localised clumps, *M. affine* sparse, *D. caerulea* common, *Planchonia careya* common and up to 3 m, *M. affine* to 2m but uncommon, *Schoenus calostachyus* common. Revegetation dominated by *A. flavescens* to 3m and spaced at approximately 2 m, *A.crassicarpa* to 3m but less common. *X. johnsonii* showed 41 green scapes, 58 dry seeded scapes, 11 with foot prints and 5 scarred.

Site 4 (Fig. 14): Groundcover homogeneous throughout with *Smilax australis* rampant and up to 6 m. *L. ensifolia* common throughout, *H. actuigluma* sparse, *D. caerulea* common, *Pteridium esculentum*, *T. triandra*, *P. careya*, *Schizaea dichotoma* sparse, *Eustrephus latifolius*, *L. longifolia* common, *Clerodendrum longiflorum* var. *cunninghamii* common to 2m and often dense. *M. affine* forming clumps up to 2m high by 12m wide, *Alphatonia excelsa* sparse. Regenerating *A. flavescens* and *A. crassicarpa* to 3m common and forming 20% cover. Many dead acacias 8-10 m. *X. johnsonii* showed 80 green scapes, 131 dry seeded scapes, 51 with foot prints and 23 scarred

posed of *Planchonia careya* (O) and the ground layer (50% cover and heavily grazed) of probably *I. cylindrica* and other grasses.

2 & 3. ***Tinkle Creek** (18°39'20"S, 145°54' 55"E) and ***Lannercost Creek** (18° 38'20"S, 145°54'15"E). Dominant species in the upper canopy (22m with 30% cover), *E. platyphylla* (C), *E. clarksoniana* (C), *E. tessellaris* (C) and *E. drepanophylla* (C). Understorey (30% cover) composed of *P. careya* (C) and *Xylomelum scollianum*. Ground layer (50% cover and grazed) of *Cajanus reticulata* and *Heteropogon contortus*. Soil, coarse pale sand and rocks, TVT 16p. Foothills with a gentle slope (1:10).

4. **Ashton Creek** (18°37'41"S, 145°53'57"E). Glider not seen feeding. Dominant species in the upper canopy (24m with 35% cover), *E. tereticornis* (C), *E. platyphylla* (C), *E. clarksoniana* (C) and *E. tessellaris* (C). Understorey (20% cover) composed of *P. careya* (C), *A. crassicarpa* (O), *A. mangium* (O), *L. suaveolens* (O), *Albizia canescens* (U) and *Timonius timon* (U). Ground layer (50% cover and grazed) of *Hyptis capitata, I. cylindrica* and other grasses. Soil, brown sandy loam, TVT 20.

18° 37'26"S 145° 54'12"E. Gliders feeding in flowering *E. tereticornis*. Dominant species in the upper canopy (20m with 35% cover), *E. tereticornis* (C), *L. suaveolens* (A), *E. clarksoniana* (O), *E. tessellaris* (O), *A. crassicarpa* (O) and *Acacia mangium* (O). Understorey (<5% cover) of *P. careya* (O). Ground layer (30% cover and heavily grazed) of unidentified grasses. Soil, grey-brown sandy loam, TVT 20.

5. **Lannercost Creek** (18°37'13"S, 145°56' 44"E) (tongue of natural vegetation between exotic pine plantation and creek). Glider not seen feeding. Dominant species in the upper canopy (30m with 30% cover), *E. drepanophylla* (C), *E. dolichocarpa* (O), *L. suaveolens* (O), *E. tessellaris* (O), *E. platyphylla* (U) and *M. leucadendron* (C) on the creek. Understorey (10% cover) composed of *P. careya*, *Acacia crassicarpa*, *A. mangium* (creek), *Carallia brachiata* and *Dillenia alata*. Ground layer (60% cover and heavily grazed) of probably *I. cylindrica* and other un-

identified grasses. Soil, grey-brown loam, TVT 20.

6. **Elphinstone Creek** (18°29'42"S, 146°01' 26"E) (isolated *E. clarksoniana* on edge of cane field with remnant creek vegetation). Glider feeding on *E. clarksoniana* blossom. Dominant species in the upper canopy (20m with 30% cover), *L. suaveolens* (C), *E. platyphylla* (C) and *E. clarksoniana* (C). Understorey (<10% cover) composed of *P. careya* (C) and *A. crassicarpa* (C). Ground layer (80% cover) of *I. cylindrica* and *Themeda triandra*. Soil, grey-brown sandy loam, TVT 19.

7. **Porters Creek** (18°26'57"S, 146°07'35"E). Glider feeding on blossom of *E. pellita*. Gully with 20m buffer zone, bordered both sides by exotic pine plantation. Dominant species of the upper stratum (25m with 50% cover), *E. intermedia*, *E. pellita*. Understorey (30% cover) composed of *Casuarina torulosa* (C, almost forming canopy), *A. flavescens* (C), *A. crassicarpa* (O), *X. scottianum* (O), *A. mangium* (O), *P. careya* (C) and *Persoonia falcata* (O). Ground layer (60% cover) of *T. triandra*, *Pteridium esculentum*, *Lomandra longifolia* (C), *Mnesithea rottboellioides* (C). Soil, brown, sandy loam, TVT 16f (without *Syncarpia glomulifera* and *Banksia compar*).

18°26'47"S, 146°07'17"E. Glider not seen feeding. Dominant species of the upper stratum (25m with 50% cover), *E. clarksoniana* (C), *E. platyphylla* (C) and *Lophostemon suaveolens* (C). Understorey (20% cover) composed of *A. flavescens* (A) and *A. mangium* (O). Ground layer (60% cover) of *H. triticeus* (O), *T. triandra* (C) and *I. cylindrica* (A). Soil, grey-brown, sandy loam, TVT 19.

8. **Mullers Creek** (18°26'13"S, 146°07'15"E). Gliders not seen feeding, site logged and thinned out. Dominant species of the upper stratum (20m with 30% cover), *E. clarksoniana* (C), *E. platyphylla* (C) *L. suaveolens* (C), *E. tessellaris* (O), *Melaleuca dealbata* (O), and *Albizia canescens* (O). Understorey (<5% cover) composed of young *M. dealbata*. Ground layer (80% cover) of *T. triandra* (C) and *I. cylindrica* (A). Soil, grey-brown loam, TVT 19.

9. **Lumholtz National Park** (18°24'30"S, 145° 46'10"E (rainforest transition site by the Herbert R). Glider feeding on *Melicope elleryana* blossom. Dominant species in the upper canopy (22m with 50% cover), *E. tereticornis* (C), *M. elleryana* (O), *L. suaveolens* (C), *Aleurites moluccana* (O), Lauraceae sp. (O), and *E. torelliana*.

Understorey (40% cover) composed of *Mallotus philippinensis* (O), *Macaranga tanarius* (O), *Aphananthe philippinensis* (O), and *Lantana camara* (O). Ground layer (10% cover) of *Calamus caryotoides* and *Triumfetta rhomboidea*. Soil, brown sandy loam, TVT 19.

10. ***Cement Creek** (18°23'55"S, 146°05' 57"E). Site not surveyed.

11. **Kennedy Valley** (18°13'31"S, 145°55' 23"E). Site presumed. Closest woodland stand to location of specimen snared on barbed-wire fence. Dominant species of the upper stratum (22m with 40% cover), *E. tereticornis* (C), *E. pellita* (C), *E. drepanophylla* (C), *E. clarksoniana* (O), *Acacia mangium* (C) and *E. tessellaris* (U). Understorey (30% cover) composed of *A. flavescens* (C), *Pandanus* sp.(O), *Guioa acutifolia* (O), *Breynia cernua* (O) and *L. camara* (C). Ground layer (40% cover) of *T. triandra* (C) and *I. cylindrica* (A). Soil, brown loam, TVT 20.

12. **Baird Creek** (18°12'11"S, 145°58'17"E). Glider feeding on *E. tereticornis* blossom. Dominant species of the upper canopy (25m with 40% cover), *E. tereticornis* (C), *E. clarksoniana* (C),

FIG. 11. Vegetation surrounding Nest Site 1 (of Table 4), Barretts Lagoon. Den tree is arrowed.

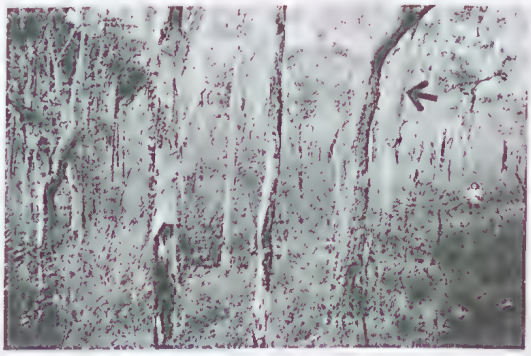

FIG 12. Vegetation surrounding Nest Site 2 (of Table 4), Barretts Lagoon. Den tree is arrowed.

A. mangium (C), *E. tessellaris* (O), *Melaleuca dealbata* (O) and *Melicope elleryana* (O). Understorey (50% cover) composed of *Alphitonia excelsa* (C), *Glochidion ?lobocarpum* (C), *B. cernua* (C), *Acacia flavescens* (C), *Polyscias elegans* (C) and *Planchonia careya* (O). Ground layer (<5% cover) of *Alpinia caerulea* (U) and *I. cylindrica* (U). Soil, grey-brown loam, TVT 19.

13. **Edmund Kennedy National Park** (18° 12'04"S, 145°59'14"E). Glider not seen, call only recorded. Dominant species of the upper canopy (25m with 45% cover), *E. tereticornis* (C), *Acacia mangium* (C), *Lophostemon suaveolens* (C), *E. tessellaris* (U), *Melaleuca dealbata* (O) and *E. intermedia* (O). Understorey (30% cover) composed of *Alphitonia excelsa* (O), *G. ?lobocarpum* (C), *A. crassicarpa* (C), *P. elegans* (C), *D. alata* (C) and *Pandanus* sp.(O). Ground layer (30% cover) of *I. cylindrica* (A), *Pteridium esculentum* (O), *T. triandra* (O), *Cycas media* (U), *Heteropogon ?triticeus*, with *Cymbidium madidum*, *Platycorys hillii* and *Smilax australis* (C). Soil, grey sand, TVT 19.

18°08'43"S, 145°57'50"E. Although this glider was recorded east of (and hence inside) the Edmund Kennedy National Park fence line, the site does not actually occur within the National Park. The fence does not accurately reflect the gazetted east-west boundary. Glider not seen, call only recorded. Dominant species of the upper canopy (20m with 35% cover), *E. pellita* (A), *E. intermedia* (C), *L. suaveolens* (O) and *Deplanchea tetraphylla* (U). Understorey (30% cover) composed of *A. flavescens* (C), *A. crassicarpa* (C) and *Dillenia alata* (O). Ground layer (40% cover) of *Melastoma affine* (C), *Gahnia sieberiana* (O) and *Scleria ciliaris* (A). Soil, grey sandy loam, TVT 19.

Glider moved from this site into adjacent tea-tree swamp where the dominant species of the upper canopy (15m with 50% cover) was *Melaleuca quinquenervia.* Ground layer (95% cover) of *Melastoma affine* (C), *G. sieberiana* (O), *A. pubirhachis* (C), *Rhynchospora* sp. (C), *Schoenus ?melanocephalus* (C), *Lycopodium cernuum* (O), *Leptocarpus ramosus* (A), *Eriocaulon* sp. (A), *Ischmaeum* sp. (C) with *Drosera spathulata*, *Myrmecodia beccarii* and *Dischidia nummularia*. Soil, grey sandy loam, TVT 15a.

14. **Dalachy Creek** (18°09'26"S, 145°57' 26"E). Glider feeding on flowering *E.clarksoniana* in cleared paddock. Vegetation proforma of closest adjacent site (creek community). Dominant species of the upper canopy (20m with 80% cover), *A.mangium* (C), *A. aulacocarpa* (C), *Lophostemon suaveolens* (C), *Tristaniopsis exiliflora* (C), *Eucalyptus intermedia* (U). Understorey (30% cover) composed of *Alstonia muelleri*, *Polyscias elegans* and *P. australiana.* Ground layer (<1% cover) of *Piper novaehollandiae*, *Lygerdum* sp., *Tetracera nordtiana* and *Lomandra hystrix.* Soil, brown loam, TVT 24 (cleared near TVT 1a).

18°08'51"S, 145°57'40"E. Glider feeding on flowering *E. pellita.* Dominant species of the upper canopy (20m with 30% cover), *E. pellita* (C). Understorey (40% cover) composed of *Lophostemon suaveolens* (C), *Acacia flavescens* (C), *A. crassicarpa* (C), *Dillenia alata* (O), *Pandanus* sp. (C) and *Melaleuca quinquenervia* (C). Ground layer (30% cover) of *Scleria ciliaris* (A) and *Blechnum indicum* with *Dendrobium smilliae* and *Drynaria rigidula.* Soil, grey-brown sandy loam, TVT 19.

15. **Murray Upper** (18°08'38"S, 145°47' 54"E). Rainforest transition site, gully with 20m buffer zone, bordered both sides by pine plantations, glider not recorded feeding. Dominant species in the upper canopy (20m with 40% cover), *E. pellita* (C), *E. clarksoniana* (C), *A. mangium* (C), *E. tessellaris* (C) and *L. suaveolens* (C). Understorey (70% cover) composed of *A. flavescens* (C), *Guioa acutifolia* (O), *Scolopia braunii* (C), *Timonius timon* (C), *Dillenia alata* (C), *Rubus moluccanus* (C) and *Polyscias australiana* (C). Ground layer (<2% cover) of *Smilax australis* (C), *Hysperpalaurina* sp. (C) and *Lomandra longifolia.* Soil, brown sand, TVT 19 .

16. **Bilyana** (18°07'S, 145°56'E). Mounted specimen in private collection of T. Marsilio for which the only collection details (from card attached to specimen) are as follows: 'Fly Squerrel was killid in falling tree in front of Joe Ottone while Alec was clearing line for El. Power. at Bilianna on Bluff Road. 15 ?years ago'. TVT 24 with remnants of 19.

17. ***Murray Upper** (18°06'30"S, 145°49' 40"E). Dominant species of the upper canopy (25m with 40%cover), *E. tereticornis* (C), *A. mangium* (C), *E. tessellaris* (O), *M. dealbata* (O), *E. clarksoniana* (C) and *Melicope elleryana* (O). Understorey (50% cover) composed of *Alphitonia excelsa* (C), *Glochidion ?lobocarpum* (C), *A. flavescens* (C), *Polyscias elegans* (C), *Breynia cernua* (C) and *Planchonia careya.* Ground layer (<5% cover) of *I. cylindrica* (U) and *Alpinia caerulea* (U). Soil, grey-brown sand, TVT 19.

18. **Yingalinda Beach** (18°03'18"S, 146°01' 37"E). Glider recorded in *E. intermedia.* Dominant species in the upper canopy (35m with 35%

cover), *E. intermedia* (C) and *L. suaveolens* (C). Understorey (40% cover) composed of *A. flavescens* (A), *A. crassicarpa* (A), *Polyscias elegans* (O), *Alstonia muelleri* (O), *Canarium australiana* (O), *Deplanchea tetraphylla* (O) and *Planchonia careya*. Ground layer (20% cover) of *Scleria sphaolata* (C), *Pteridium esculentum* (C), *I. cylindrica* (C) and *Xanthorrhoea johnsonii* (O) with *Smilax australis*, *Eria fitzalanii*, *Dendrobium smilliae* and *Cymbidium madidum*. Soil, grey sand, TVT 17.

19. **Barretts Lagoon**. (i) South western bank (18° 02'31"S, 145° 58'36"E). Gliders recorded feeding on flowering *Eucalyptus tessellaris*. Site cleared Feb 1990. Prior to that the dominant species in the upper canopy (35 m) were *E. pellita*, *E. intermedia*, *Acacia mangium*, *E. tessellaris*, *E. tereticornis* and *L. suaveolens*. Understorey (9m and 80% cover) composed of regenerating *A. flavescens*, *Planchonia careya*, *A. crassicarpa*, *Melastoma affine*. Ground layer (20% cover and grazed) of *I. cylindrica* and *Themeda triandra*, *S. australis* and *Lomandra longifolia*. Soil, grey sand, TVT 24 with remnants of 17.

(ii) North eastern bank (18°02'22-23"S, 145°58'52"E). Gliders recorded feeding and heard grunting in flowering *E. tereticornis*. Remnant vegetation along immediate edge of Barretts Lagoon. Isolated specimens (to 30m) of *A. mangium*, *E. tessellaris* , *L. suaveolens*, *M. leucadendron* and *M. dealbata*. TVT 24.

(iii) 'Rice Fields' (18°01'26"S, 145°58'46"E). Gliders feeding in *E. pellita*, *E. intermedia*, *L. suaveolens*, *X. johnsonii*. See detailed vegetation analysis 'Nest site 3', Table 4. TVT 17.

(iv) East (18°01'33"S, 145°59'34"E). Gliders feeding in *X. johnsonii* and *M. dealbata*. Dominant species in the upper canopy (20m with 50% cover), *E. pellita* (C), *E. intermedia* (C), *L. suaveolens* (C), *A. crassicarpa* (C), *M. dealbata* (O), *Deplanchea tetraphylla* (U). Understorey (30% cover) composed of *A. flavescens* (C), *M. viridiflora* (C), *Banksia integrifolia* var. *aquilina* (U), *Casuarina littoralis* (C) and *Pandanus* sp. Ground layer (40% cover) of *T. triandra* (C), *L. longifolia* (C), *Lindsaea ensifolia* (A), *Leptocarpus ramosus* (A) and *X. johnsonii* (A). In wetter gullies at base of swales, dominant canopy species (18-20m with 50% cover) changed to *E. pellita* (A), *Lophostemon suaveolens* (A) and *A. mangium* with an understorey (15% cover) of *A. flavescens* (O), *A. crassicarpa* (O), *Pandanus* sp.(O) and *Dillenia alata*. Ground layer (30% cover) of *Gonocarpus ?acanthocarpus* (C), *Lindsaea ensifolia* (C), *Dicranthopteris linearis* (O), *Melastoma affine* (C), *Eriocaulon* sp., *Scleria laevis* (C), *Ishmaeum australe* (A), *Flagellaria indica* (O) with *Eria fitzalanii* and *Dendrobium smilliae*. Soil, dark drown sandy loam, TVT 17.

20. **Hull River** (17°58'29"S, 146°02'02"E). Glider feeding in *E. intermedia*. Dominant species of the upper stratum (30m with 40% cover), *Eucalyptus intermedia* (C), *E. pellita* (A), *A. mangium* (C), *Lophostemon suaveolens* (O) and *Deplanchea tetraphylla* (O). Understorey (70% cover) composed of *Davidsonia pruriens* (C), *Polyscias australiana* (C), *A. muelleri* (C), *Dillenia alata* (O), *Wilkiea nuegeliana* (C), *Rhodomyrtus* sp., *Pandanus* sp., *Syzygium wilsonii*, *Lepidozamia hopei*, and *A. flavescens* (A). Ground layer (<10% cover) of *Calamus caryotoides*, *C. moti*, *Smilax australis*, *F. indica*, *Lygopodium* sp., with *Eria fitzalanii*, *Dendrobium smilliae*, *Cymbidium madidum* and *Platycorys hillii*. Soil, brown sand to sandy loam, TVT 17 adjacent to TVT 15a.

Spotlighting

Spotlighting surveys for *P. gracilis* were conducted at a number of sites (Table 3). The species was recorded at 16 of the 36 localities and represented a total of 1334 manhours of observation. In habitats supporting *P. gracilis*, the most commonly observed arboreal marsupial assemblage comprised *P. gracilis*, *Dactylopsila trivirgata*, *P. breviceps* and *Acrobates pygmaeus*. The presence of this group of exudivores and insectivores and the obvious absence of such foliovores as *Trichosurus vulpecula*, *Pseudocheirus peregrinus*, *Petauroides volans* and *Phascolarctos cinereus* may have been a reflection of possible nutritional deficiency in vegetation of the coastal alluvium, however this was not addressed in the study.

Trichosurus vulpecula was extremely rare in habitat considered optimal for *P. gracilis*. Only 1 specimen of the brushtail was recorded near such habitat (Dalachy Creek) and at that site *T. vulpecula* was recorded from a tree isolated in improved (fertilised) pasture. Where *T. vulpecula* occured commonly with *P. gracilis* (e.g. Wharps Holding) the habitat was considered marginal or poor for the glider.

Bioclim Prediction

A climate profile (Table 5) was generated by the BIOCLIM prediction system (see Nix & Switzer, 1991) after completion of field surveys. Using core predictions [geographic points matching all 28 climatic values (7 for radiation, 7 for

temperature, 7 for precipitation and 7 for moisture index) between the 5% and 95% values (the 90 percentile range) in the climate profile] the presence of *P. gracilis* was predicted beyond that area encompassed by the field results presented in Table 1 only on the north western tip of Hinchinbrook Is. (Fig. 15). Soils of the north western tip developed in situ largely from massive rhyolitic to dacitic volcanics and to a much lesser extent riebeckite granite near Scraggy Point. The north western lowland woodland communities there do not reflect a mirror image of the woodlands of the Coastal Floodplains and Piedmont Slopes (TVT 19) across the Hinchinbrook Channel on the mainland. Many potential sites (TVT 13e, 15b) appeared to be losing their identity under the encroachment of rainforest species, and drier forest types tended to be dominated by *Eucalyptus clohesiana* which grew from near sea level to well above the 100m contour. To date *P. gracilis* has not been recorded from *E. clohesiana*. In Sept 1992 two nights were spent surveying in woodland slopes supporting *E. intermedia*, *E. clohesiana*, *E. tessellaris*, *E. acmenoides*, *Melaleuca leucodendron*, *Pandanus* sp. and *Xanthorrhoea johnsonii* (Table 3) without success. Hinchinbrook Is. should be resurveyed for *P. gracilis*.

Using marginal predictions (all 28 climate values falling within the total range in the climate profile) *P. gracilis* was again only predicted to occur inside the core area plotted for the north west tip of Hinchinbrook Is.

Trapping

A total of 721 trapnights resulted in the capture of one *P. breviceps* from degraded habitat being cleared at Barretts Lagoon (16 Feb 1991). No *P. gracilis* were collected by this method in spite of the trapping program being conducted under the on-site advice of field researchers skilled at capturing other petaurids such as *P. breviceps*, *P. australis* and *P. norfolcensis*. The degree of difficulty in trapping *P. gracilis* by traditional methods greatly impinges on the understanding of its social organisation which is fundamental to the process of estimating its population density.

Artificial Hollows

Two sub-adult female *P.gracilis* (ear tagged T4027, T4028) were caught together in 'nestbox' No. 8 on 10 May 1991. No other *P. gracilis* were trapped by this method but other individuals were known to use the tubes e.g. radio-tagged adult male T4030 was recorded once (7Aug 1991) in 'nestbox' 12, and an unmarked adult male (possibly T4030) escaped from 'nestbox' 27 before the entrance could be reached and plugged (4 Aug 1991). Subadult female T4028 used 'nestbox' 12 and 13 on 5 days during the period 11-19 May 1991. Tubes were more frequently inhabited by Brown Tree-snakes (*Boiga irregularis*), Green Tree Ants *(Oecophylla smaragdina)* and less frequently by Sugar Gliders *(P.breviceps)* (adult male and female, 'nestbox' 14, 25 May 1992; group in 'nestbox' 7 (east), 8 Oct 1992).

Home Range Determination

Shortcomings associated with this part of the study are referred to under 'Methods'. Results of home range analysis and plots of dens appear in Figs 16-19. The 95% isopleth of the harmonic mean distance minimum gave a value of 23.01ha for adult female T4026 (110 fixes), 9.04ha for sub-adult female T4027 (36 fixes) and 13.86ha for sub-adult female T4028 (36 fixes). These results should be taken as preliminary and minimal as the plots indicate that the curves have not quite asymptoted (see Quin et al., 1992; Goldingay, 1992). Areas estimated using the miminum convex polygon (MCP) were 18.65, 16.48 and 10.96ha respectively. Overlap is shown in Fig. 19. Possible underestimation of home range size could be partly or wholly offset by patches of treeless swale included in the estimates. Subadults T4027 and T4028 may have been dispersing offspring of T4026. Insufficient fixes were taken of adult male T4030 (who dislodged his transmitter after 3 nights) or female T4031 (for which den fixes only were taken) to allow estimation of home ranges. However, male T4030 was known to have moved between the home range of adult female T4026 and one of the dens of adult female T4031 (see 'Reproduction' and Fig. 19). Serial den use (Kehl & Boorsboom, 1984) was noted between adult female T4026 and sub-adult female T4028, adult male T4030 and sub-adult female T4028 . Conjoint den use was noted between adult male T4030 and adult female T4026, adult male T4030 and adult female T4031, and between the two sub-adult females T4027 and T4028.

Reproduction

Petaurus gracilis appears to give birth in the spring, although this pattern is complicated by the record of hairless young in the pouch of a female collected in mid-February and an observed September copulation involving a female known to be carrying two hairless pouch young.

Two adult females captured 5 and 9 Aug 1991

FIG. 13. Vegetation surrounding Nest Site 3 (of Table 4), Barretts Lagoon. Den tree is arrowed.

(T4026 and T4031 respectively) each carried two hairless pouch young. Young measured approx 35mm crown to cloaca. Females resisted attempts to examine pouch young by contracting muscles surrounding the pouch opening. By 26 Nov 1991 young of T4026 [T4032 (M) and T4033 (F)] weighed 65g and 69g (respectively) (see Table 2 and Fig. 20) and the pouch of T4026 was noted to be divided longitudinal into two halves by a thin septum (see Calaby, 1966 for description in *P. australis*). The right pouch side was thinly covered with long ginger-brown hairs and the left contained two elongated nipples, each 6mm long. Adult female T4031 was not recaptured. The pouch of adult female JM7290 collected 14 Feb 1973 contained two hairless young. The pouch of female JM8549 (which died ensnared on a barbed wire fence Oct 1990) contained one newly furred young JM8550 (43g). The right posterior corner of the pouch contained well developed mammary tissue, anterior to which (close to the body) was a covering of long ginger hair. The single nipple measured 11mm.

The following copulatory behaviour was noted between female T4026 and male T4030 (both captured in *Lophostemon suaveolens* den, nest site 3 of Table 4, Sept 5 1991) at a time when female T4026 was carrying 2 hairless pouch young. Observations on 7 Sept 1991 commenced at 1900hrs with female motionless in *L. suaveolens* close to den. At 2030hrs, male T4030 appeared in tree 7 metres away from the tree in which the female was sitting. Both remained motionless until 2100hrs. The male then produced a soft but hoarse call resembling 'chew-chew-chew-chew' at which the female made immediate efforts to join him (but was interrupted by noise from observers on the ground). At 2226hrs the male glided to the female's tree. The female appeared to sniff and lick the male's rump (probably applying male scent as observed in *P. australis* by Henry & Craig, 1984; Russell, 1984) and followed him up the trunk to sit together in the canopy. The female then glided to a nearby large *E. pellita*, was followed by the male and the two remained motionless, 'curled up' around one another in the canopy until 0040hrs. The female then leapt to a nearby tree and was followed closely by the male. From 0057hrs to 0155hrs the two remained motionless in a 'ball' whereupon the male lunged at the female and the two copulated until 0217hrs. During copulation male and female adopted a vertical, head-down position on the trunk with the female's head pushed against an ant plant (*Myrmecodia beccarii*). The male thrust intermittently, grasping the female's dorsum in a position not unlike that adopted by young back-riding gliders newly emerged from the pouch. A neck bite was maintained by the male until the two separated, whereupon the male licked and groomed his penis. The female leapt to a nearby *E. pellita*, was followed by the male and the two sat closely and motionless until 0400hrs whereupon the female made bursts of 'glide-and-freeze' (thought not to be induced by the presence of observers) toward a den which was some way off and reached by 0545hrs. The male had lost interest in the female by 0400hrs and moved elsewhere. The male did not share the den occupied by female adult T4026, but shared an *E. intermedia* den occupied by another adult female, T4031 (with pouch young). This den could be reached over a minimum distance of approx 1.5km from where T4026 and T4030 separated.

The following night (8 Aug 1991) observation commenced with female T4026 at 1830hrs. At

TABLE 5. BIOCLIM climate profile for *Petaurus gracilis* in tropical north Queensland based on all Queensland Museum records and observations. 1930hrs the female began moving between trees with apparent resolve only to sit 'frozen' for extended periods then move off in the same manner. Male T4030 appeared in a nearby tree at 2318hrs. The female made soft 'chee-chee-chee-chee' calls which brought the male into her tree. The two sat closely until 0200hrs (when observations were abandoned). The pair did not share a daytime den.

The next night (9 Aug 1991) the same pair were noted consorting (only) from 2305-0100hrs. Observations continued to 15 Aug 1991 but the pair were not seen to consort again.

DENNING (see Table 4)

A total of 19 dens were recorded at Barretts Lagoon (see Figs 16-19). These varied from a dead stag of undetermined species (13m) to living examples of *E. intermedia* (8), *L. suaveolens* (2), *M. quinquenervia* (2), and *E. pellita* (6) up to 27m in height (Figs 11-14). In tall trees it was usually impossible to determine either the den entrance or the den position inside the trunk. In two cases (sites 1 and 3, Table 4), both were known. At site 1 (Figs 11 and 21) the den was made in a 7m living *E. intermedia*. The 50mm entrance hole was 5.8m above ground, the nest cavity approx. 200mm dia. and the nest of dried leaves approx 3m below the entrance. At site 3 (Figs 13 and 22) The den was made in a 10m living *L. suaveolens*. The 45mm entrance hole was 3.8m above ground, the nest

FIG. 14. Vegetation surrounding Nest Site 4 (of Table 4), Barretts Lagoon. Den tree is arrowed.

cavity approx. 250mm diameter and the nest of dried leaves approx. 50cm below the entrance.

There was no apparent shortage of hollow limbs and termite-ravaged trunks in the woodland habitat occupied by *P. gracilis* and while individual gliders showed preference for certain dens they regularly moved nests and used a variety of widely separated dens through their home range (Figs 16-19), e.g. in the period 10-20 May 1991, adult female T4026 used the 'favoured' nest (nest site 3 of Table 4) on 4 of those days and 7 different dens on the seven remaining days. This female was recorded using a total of 10 different dens.

In addition, gliders familiarised themselves with the mature trees of their home range and spent considerable time exploring hollows and holes in trees other than those known to contain dens. In one case, on consecutive nights, female T4026 descended to investigate a large, long, burnt-out log lying on the forest floor. On both nights the end of the log was entered at ground level and the glider crawled inside to finally peer out a ground-level pophole for approx 30min before returning to the trees. (On investigation, the inside of the log was found to contain crumbled charcoal, soil and remains of goanna skin, some Echidna quills and some patches of pungently smelling possum fur (? *Dactylopsila trivirgata*).

Nests in dens consisted of a thick mat of eucalypt leaves. Animals were not observed collecting or carrying these.

Vocalisation

Petaurus gracilis was quiet and difficult to locate by calls. The most commonly heard call was a deep, nasal, coarse grunt 'na-when, na-when'. It was not always possible to determine the sex of animals making this call, but those that were sexed were males. The call was sometimes made in response to the play-back defense gurgle ('urga-urga-urga', common to other Petaurids) of another individual (see Van Dyck, 1992b). It was also made in response to a human imitation of the 'na-when' call, and imitation was used to survey potential glider sites. One male was heard monotonously repeating this call. This individual was located 3m above ground, pressed head down against the trunk of a *Pandanus citraceus* and in its manner resembled a calling *P. breviceps*. This call was often shortened to a single nasal grunt 'hoy', and often appended by a low 'urga' or two. One sub-adult female once made the simple grunt 'arrgh' on detecting an adult female in a tree nearby. Animals unsure of their security (when exploring unfamiliar territory or when being handled) uttered a soft 'tock-tock'. Calls associated with consorting have been described under 'Reproduction'. Nestling young reunited with their mother after brief separation made a soft 'tzzz-tzzz' call on contact with the female.

Diet

The diet was assessed by directly observing gliders feeding or by analysis of faeces from captured individuals. The feeding observations described below are summarised in Table 6. See Van Dyck (1992b) for further discussion.

Nectar and pollen: Gliders were observed licking nectar (and presumably pollen) from the flowers of a range of trees and shrub species (Table 6). Five faecal pellets were collected during 4 months in 1991 and analysed for food items (Table 7). The pollen assemblage in February was entirely of Myrtaceae pollen, most of which was

FIG. 15. Core and marginal predictions of *P. gracilis* distribution generated by the BIOCLIM prediction system. (Dotted line shows actual profile of coast).

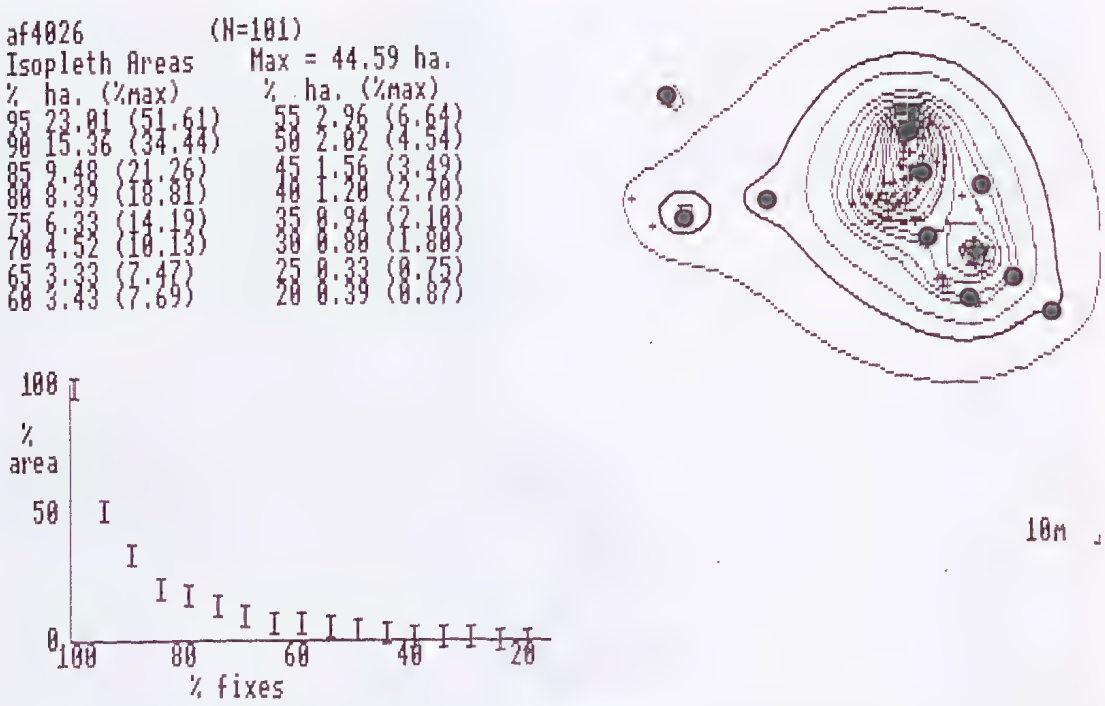

FIG. 16. Harmonic Mean Measure of home range and analysis for adult female T4026. Hard line is drawn over the 95% isopleth. Dots indicate dens used.

comparable to that of *Eucalyptus*. In May, plant material dominated the sample, but pollen was represented in low proportions; also represented were rhomboids of silica. The pollen assemblage contained approximately equal proportions of pollen of *Banksia* and *Xanthorrhoea*. *Banksia integrifolia aquilina*, the only species of banksia recorded at Barretts Lagoon occured very rarely at the study site.

One female glider was noted eating flower tassels of *Acacia crassicarpa* (each approx. 40mm long: 1 on 12 May 1991, 6-8 on 16 May 1991). Since this wattle produces no discernable nectar it was concluded that such ingestion constituted deliberate pollen feeding.

Xanthorrhoea johnsonii:Two radio-tagged female gliders (T4027, T4028) were observed over extended periods feeding on *X. johnsonii* during May 1991 when flowering was heavy (Table 6). Evidence of scape visitation ('scape' is used for the woody spear-like stalk of the *Xanthorrhoea* fruiting body) at other sites through footprinted scapes (see Fig. 23 and Van Dyck, 1992b) and scape damage, suggested that many other *P.gracilis* visited *X. johnsonii* (e.g. % green scapes footprinted at Nest Site (NS) 1 (see Table 4): 22%; NS2: 25%; NS3: 26%; NS4: 63%). The gliders' process of appraisal of the condition of scapes of *X. johnsonii* was conducted mostly at heights of less than 3m above the ground. Scapes were reached by leaps between thin saplings, small shrubs, dead sticks or other scapes. After landing on a scape, a glider would face downward, descend to within 30cm of the base, then turn and climb quickly up the spear. To reach more isolated scapes gliders crossed open ground in a series of rabbit-like hops through long grass. Fresh spikes ('spike' is used for the flowering head of the *Xanthorrhoea* fruiting body) were glided onto directly, but dried, seeded spikes were not, and although scapes of the previous season were climbed and investigated, the appraisal was abandoned usually within 30-60cm of the spike.

Young scapes with unformed spikes were chewed at the spike base and also at the scape base (Fig. 24) among the leaf insertions, and any amber-coloured mucilagenous exudate from earlier gougings licked off and eaten. *Xanthorrhoea* evaluation by *P. gracilis* occurred in frenetic bouts which ran for as long as 2.5hrs and covered linear distances of up to 800m. Suitable flowering heads were licked thoroughly for nectar (Fig. 25).

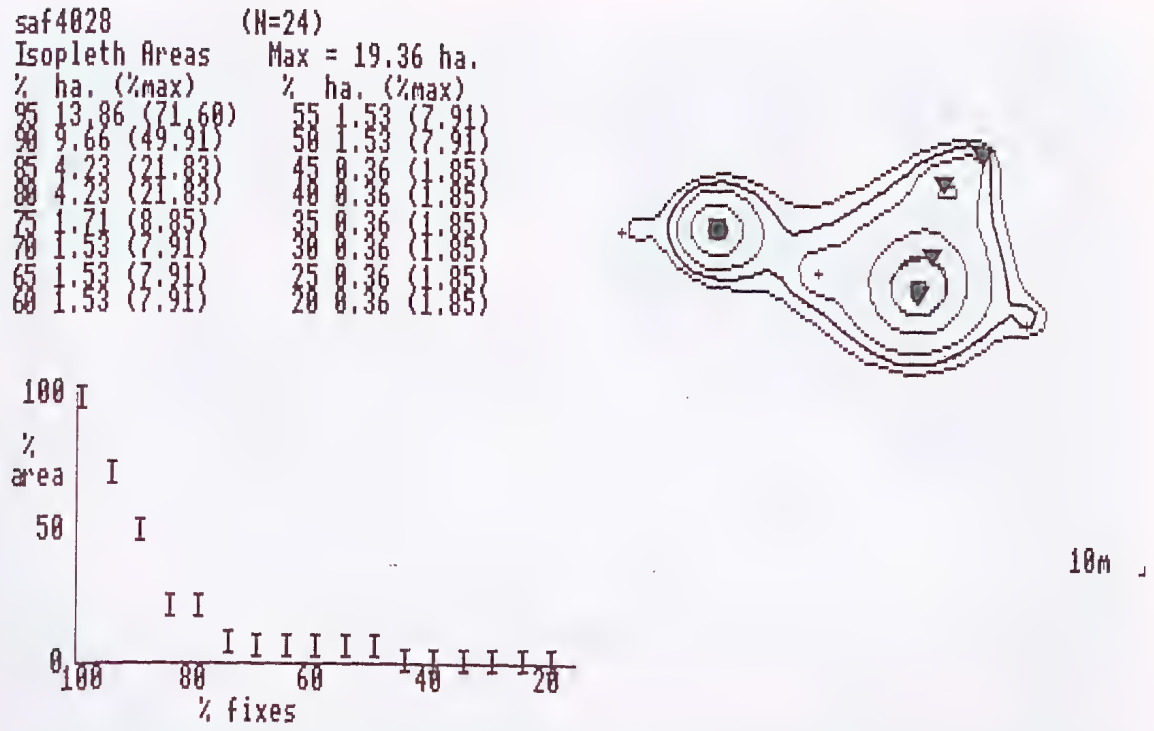

FIG. 17. Harmonic Mean Measure of home range and analysis for sub-adult female T4028. Hard line is drawn over the 95% isopleth. Dot indicates den used serially with adult female T4026. Triangles indicate other dens used.

One instance of eating unopened flowers was noted.

By August 1991 most *X. johnsonii* flowers had seeded (e.g. NS 1: 80%; NS 2: 50%; NS 3: 58%; NS 4: 62%) and experimental cuts which I made (5 Aug 1991) on immature scapes had produced no exudate up to 5 days after cutting. Although nectar-producing flowers occurred in the study area and pollen was abundant in one of two faecal samples taken (6, 9 Aug) (Table 7), none of the three gliders tracked during this period were recorded feeding on them. Hall (1956) demonstrated significant changes in spike component analysis from preflowering through to flowering. These included drops in protein (11.1% to 6.8%), carbohydrate (63.7% to 45.9%), fat (2.2% to 1.2%), phosphate (0.47% to 0.31%) and an increase in fibre (19.0% to 42.7%) as the spike matured.

Preliminary analysis results of dried gum exudate scraped from *X. johnsonii* scapes in Aug 1991 were as follows: moisture= 25.6%, protein (N×6.25)=2.5%. Infra-red spectroscopy showed that the substance was a complex mixture consisting of polymerised and/or unpolymerised higher alcohols and acids. Some carbohydrates in free or bound form were probably also present, but no simple sugars were detected (N. Douglas, pers. comm.). No analysis was made of May *Xanthorrhoea* exudate.

Eucalyptus intermedia and E. pellita sap and/or kino: Gliders were often observed feeding at wound sites on *E. intermedia* (Table 6). Here they would pick crusts of dried exudate and lick the surface from which the crust had been taken. The wound was often accompanied by fresh red dribblings of kino which may have been ingested also.

One female glider (T4026) was observed licking and stripping fresh and old longitudinal incisions in the canopy branchlets of *E. intermedia* and *E. pellita* (Table 6). From the *E. intermedia* canopy the process was difficult to observe clearly, but large lumps of hard exudate falling from the glider's mouth were collected on the ground. The process was observed between 2050hrs 11 Aug 1991 and 0327hrs 12 Aug 1991 and involved alternating bouts of licking-biting and motionless rest with mouth away from the wound and eyes often closed (10min feeding, 1hr

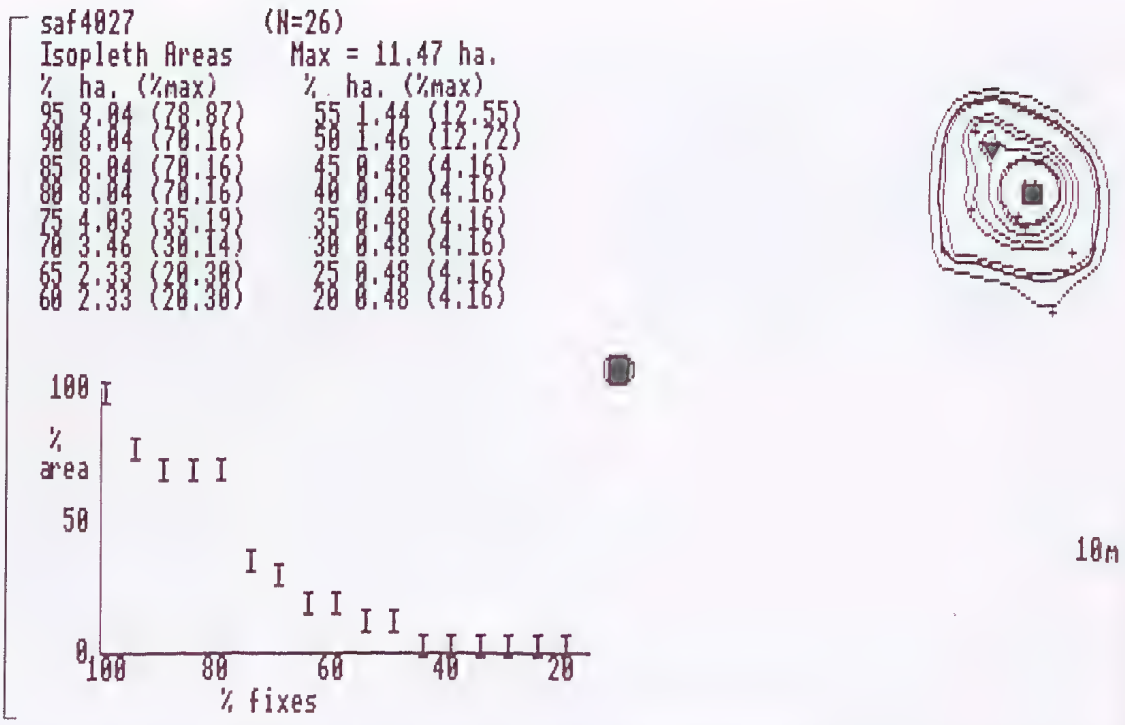

FIG. 18. Harmonic Mean Measure of home range and analysis for sub-adult female T4027. Hard line is drawn over the 95% isopleth. Triangle indicates den used conjointly with sub-adult female T4028. Squares indicate other dens used.

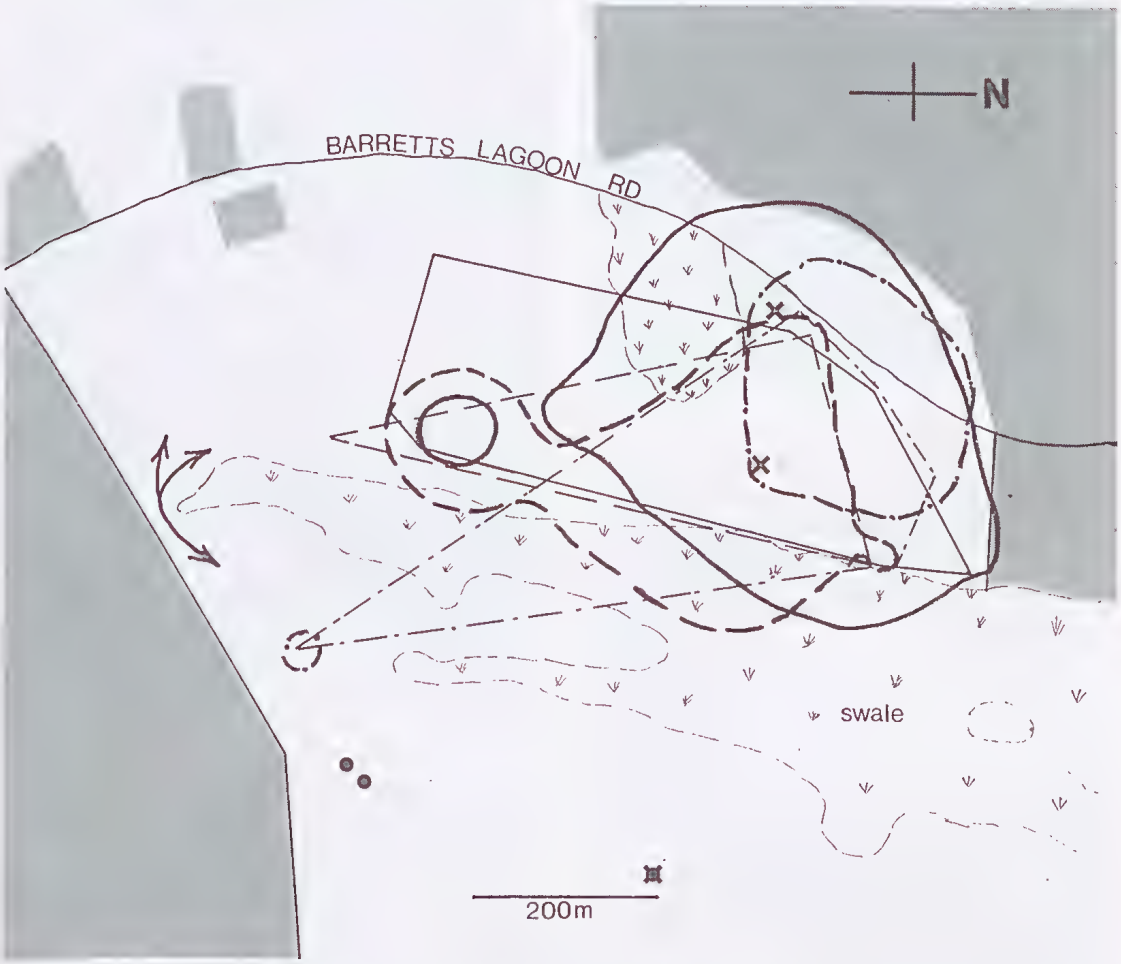
25min resting, 6min feeding, 28min resting, 7min feeding, 16min rest, 9min feeding, 5min rest. Total time feeding in *E. intermedia* 57min; total time resting 2hrs 27min. For *E. pellita* total time feeding 29min; resting 36min). Branchlets retrieved the following day from the feeding sites (approx. 17m high in the *E.intermedia* and approx. 8m in the *E. pellita*) showed many incisions of varying size and state of repair on thin branches that ranged from 4.7mm to 14mm in diameter (Fig. 26). For the *E. intermedia* sample (diameter 4.7- 12.9mm), incised cut lengths varied from 9.2-87.6mm (mean length= 46.4mm, N=16 from 9 branchlets all less than 40cm long) and cut width varied from 1.3-3.9mm (mean width: 3.2mm). For the *E. pellita* sample (diameter 10.1-14.00mm) incised cut lengths varied from 59.6-133.00mm (mean length= 91.5, N= 6 from 4 branchlets all less than 40cm long) and cut width varied from 2.0-7.6mm (mean width 3.3mm). Cuts from both species of eucalypt had healed and calloused leaving a raised 'lip'-like ridge around a ribbon of exposed sapwood. Cicadas had oviposited in the sapwood of most of these cuts (exposed sapwood of all long incisions (i.e. 9 >50mm) in the *E. intermedia* sample and of 4 in the *E. pellita* sample). The fresh *E. intermedia* incision sites carried red kino stain on and under the calloused edges of the incision, but this was not as apparent in the *E. pellita* incisions.

A sample of bloodwood kino was taken from the branches showing fresh incisions. Preliminary analysis results were as follows: moisture 39.6%, protein (N×6.25) 1.3%. Infra-red spectroscopy showed the substance was a complex mixture consisting of polymerised and/or unpolymerised higher alcohols, probably containing carbohydrate material either in bound or free form. It was not possible to characterise these components more precisely, or to determine the proportion of apparent carbohydrate in the exudate. However no simple sugars were present in free form (N. Douglas, pers. comm.).

Although not visible from the ground, wounds similar to those described above are very common in the small branches of the canopy in *E. intermedia, E. pellita* and *E. clarksoniana* throughout the range of *P. gracilis*. As yet there are no criteria for distinguishing cuts made by *P. gracilis* from those of *P. breviceps*, which occurs sympatrically with *P. gracilis* but is not tolerated socially by it.

FIG. 19. Overlap in home ranges of adult female T4026 (_____), sub-adult female T4027 (_ . _ . _) and sub-adult female T4028 (_ _ _ _). The MCP boundaries are represented by thin lines corresponding in pattern with the respective 95% isopleth indicated by the thick, curved lines. Crosses indicate the location of the 3 dens used by adult male T4030 over 3 consecutive nights (7-9 Sept 1991). Dots indicate the only 3 dens used by adult female T4031 during the period 9-15 Sept 1991. Arrows indicate the only natural corridor connecting land north and south of the central swale. Shaded areas indicate cleared land.



Acacia arils and gum: One female (T4026) was observed on 27 Nov 1991 from 1742 hrs to 0330 hrs (28 Nov 91) (Table 6). During that time the glider, which had fully furred young in the nest, fed almost exclusively on arils of *A. crassicarpa* (Fig. 27) which it collected from gaping pods. The only other food eaten during the night was a grasshopper/katydid caught by the glider while in the process of aril feeding. Gum exudates of *A. crassicarpa* were licked and new sites on a trunk were roughly gouged and torn open.

Lichens: A female (T4026) was observed 16 Aug 1991 from 0200hrs-0230hrs feeding on lichen growing on the bark of *Lophostemon suaveolens*. The glider chipped off flakes of bark, licked the lichens off then let the bark chip fall. A sample of lichen taken from the feeding site contained only clonal reproducing bodies (soredia) and was unidentifiable (R. Rogers, pers. comm.).

Psyllids and honey dew: A female (T4026) was observed on 13 Aug 1992 from 2000-2130hrs feeding on the psyllid *Eriococcus* sp. (Fig. 28) which had infested the underside of leaves in the canopy (at 10m) of an *E. pellita* (Table 6). The glider appeared to scrape and lick psyllids off the leaves' mid-vein. Results of preliminary analysis of scale insects are as follows: moisture= 55%, lipids= 13.2%, protein (N×6.25)= 20%. Of the

FIG. 20. Nestling young of female T4026 (T4032 and T4033) photographed 26 Nov 1991.

13.2% lipids in the sample, 6.3% could be regarded as higher molecular weight glyceride waxes and the remaining 6.9% as fatty oils. The protein figure was obtained by applying the conversion factor normally used for converting nitrogen content to protein, however nitrogen would be present not only in the protein but also in the chitin. The analysis was not able to differentiate between nitrogen derived from protein and that contained in chitin (N. Douglas, pers. comm.).

A male was observed on 2 Oct 1992 licking along the underside of *E. intermedia* leaves. It appeared to consume both the psyllid *Eucalyptolyma distincta* and its lerp (Fig. 29).

A female (T4026) was observed 13 Aug 1991 licking honey dew off the upper and lower surfaces of leaves of *E.pellita*.

Other arthropods and arachnids: Large insects were usually manipulated and consumed while the glider hung upside-down by the hind legs against a tree trunk, leaving the forelimbs free to manipulate prey. In the case of a large grasshopper, the gut was dismembered and extracted by biting and holding one end of the insect in the mouth, holding the other end in the forefeet, extending the forelimbs fully, tossing the head back and thereby stretching out the gut in a long string. A female (T4026) was once observed catching a flying moth by grabbing it with the forefeet alone.

On 13 Aug 1991, a female glider (T4026) was observed tearing into an occupied arboreal nest of Green Tree Ants and for 5 minutes after, eating something taken from the nest. The act of breaching the nest was undertaken at some apparent discomfort to the glider which shook its legs and flicked ants off its body for the following 20 minutes.

The stomach of an adult male glider collected on 9 Dec 1989 while feeding in flowering *E. tessellaris* contained the remains of numerous scarabaeid beetles which, presumably, had also been feeding at the flowers.

Water: After rain, gliders were observed licking water off petioles and leaves of *L. suaveolens* and *E. intermedia*. During rain, one glider was observed to move under the protective cover of a thick semi-horizontal branch. It remained still with head down until the rain passed. This animal dried its wet tail by thrashing it from side to side.

DISCUSSION

TAXONOMY

Alexander (1981) commented that, of the recognised subspecies of *P. norfolcensis* and *P. breviceps*, *P. n. gracilis* and *P. b. longicaudatus* needed further detailed revision before they could be accepted as valid races. He noted that *P. n. gracilis* was based on one specimen from north of Cardwell, differing from the nominate subspecies in its markings, shorter ears, and a more slender tail; all features he demonstrated to be highly variable in specimens of *P. norfolcensis* from Queensland to Victoria. Had de Vis drawn attention to only those features, it could have been said that he described *P. gracilis* for all the wrong reasons. But de Vis also made a note that 'In size [*P. gracilis* was] intermediate between *B. australis* and *B. sciureus* [*P. norfolcensis*]' (de Vis, 1883: 620), a significant statement that has not received the attention due to it in the literature. The set of measurements which accompany the de Vis description lie well outside those given by Thomas (1888) for specimens of *P. norfolcensis*. The lowland Tully-Ingham gliders I have attributed to *P. gracilis* are, in size, consistent with the large dimensions outlined in the de Vis description and, by the veracity they impart to the original measurements, reinforce the suspicion that neither Thomas nor subsequent authors who also dealt with *P. gracilis* as a synonym of *P. norfolcensis* had ever made a personal examination of either the specimen de Vis described in 1883, or of any other similar glider from nearby.

In body and tail length *P. gracilis* is similar to the large New Guinean glider *P. abidi* (Fig. 5).

FIG. 21. *Eucalyptus intermedia* nest tree (Nest Site 1 of Table 4) showing entrance hole (top arrow) 3m above nest (bottom arrow).

However, dental and biochemical systematic studies (Van Dyck, 1990; Colgan & Flannery, 1992) put *P. gracilis* closest to *P. norfolcensis*. The dental morphology of *P. abidi*, in particular the unreduced nature of P^2, the unreduced protocone of M^2, and the broad ectoloph of M^2 and M^3 suggest a more pleisomorphic species from which the Australian species *P. gracilis*, *P. norfolcensis* and *P. breviceps* could have been derived.

The large size of *P. gracilis* is worth noting in the context of its close affinities with *P. norfolcensis*. Alexander (1981) concluded that Victorian populations of *P. norfolcensis* were significantly larger than those of southeast Queensland, and that the size increase from north to south was gradual and continuous, thereby representing a latitudinal clinal variation in body size which could be attributed to Bergmann's rule. All adult specimens of *P. gracilis* examined (from latitudes 18°02'-18°27') were larger in skull length (maxskull length: mean= 51.14, N= 7, SD= 0.95) than Victorian *P. norfolcensis* (mean= 47.52, N= 5, SD= 0.64) from latitudes 36°23'-38°26', and significantly larger ($P<0.001$) in body length than Victorian *P.norfolcensis* (for *P. gracilis* mean= 247.45, N= 11, SD= 15.86; for *P. norfolcensis* mean= 212.40, N= 5, SD= 16.69). This reversal in the clinal trend in *P. gracilis* is offset by normal trends attributable to Bergmann's rule seen in other possums and gliders such as *P. breviceps* (Smith, 1973), *P. australis* (Russell, 1984), *Petauroides volans* and *Trichosurus vulpecula* (Yom-Tov & Nix, 1986).

Food Selection

It is as difficult to account for the selective pressures resulting in large body size in *P. gracilis*, as it is to interpret the 'impetus for body size development' (Smith & Lee, 1984) in the entire Petauridae given the minor dietary differences between the species. Among exudivores *P. gracilis* is more of a dietary opportunist, feeding on nectar, pollen, arthropods, arachnids, wattle exudates, honeydew and eucalypt saps when these food items become seasonally available. Although similar diets have been thoroughly documented for other petaurids such as *P. breviceps* (Fleay, 1947; Smith, 1980, 1982; Suckling, 1980; Suckling & McFarlane, 1983) and *P. australis* (Smith & Russell, 1982; Henry & Craig, 1984; Craig, 1985; Goldingay, 1986, 1987; Kavanagh, 1987a, 1987b) the occurrence of other significant dietary items such as *Acacia* arils, *Xanthorrhoea* exudates, *E.intermedia* sap and/or kino, lichens and green tree ants (or the contents of their nests) has not been reported for the group.

Australian *Acacia* species have been divided into three dispersal groups (O'Dowd & Gill, 1986): 1, arillate *Acacia* that are bird dispersed (17% of 92 species sampled); 2, arillate *Acacia* that are ant dispersed (74%); and 3, the remaining non-arillate *Acacia* species (9%) that do not correlate with dispersal by ants or birds. O'Dowd & Gill showed that in bird-syndrome species diaspores (dispersal units) were as follows: predominately bicoloured, displayed in dehisced pods retained in the canopy, high in aril mass and lipid content and significantly longer and more contorted than in ant dispersed *Acacia* . Diaspores of ant-syndrome species were presented inconspicuously on the ground and investment was low.

In the broad sense, bird and ant dispersed seeds are thought to escape from interspecific competition, fire, parental competition and seed predators, and/or benefit from transportation to

FIG. 22. *Lophostemon suaveolens* nest tree (Nest Site 3 of Table 4) showing relative size of entrance hole.

microsites with superior nutrients (Holldobler & Wilson, 1990). O'Dowd & Gill (1986) considered two of these most relevant to the *Acacia* group: escape from the detrimental effects associated with the parent plant, and an increased chance of being directed to specific microhabitats by the dispersal agent. They note that in some *Acacia* species, lipids might account for 70% of the aril dry mass, a value comparable to the highest lipid contents observed in seeds and fruits. They argue that lipids provide a greater energy reward per unit mass of aril, since lipids yield roughly twice the energy upon catabolism as carbohydrates, and they conclude that since most of the known dispersal agents of *Acacia* are generalist feeders and incorporate insects into their diet, the higher proportion of saturated fatty acids may 'mimic' the saturated fatty acid composition typically found in animal prey.

Petaurus gracilis stands to gain much from the summer aril harvest provided by *A. crassicarpa*, a bird-syndrome *Acacia* whose arils, though not brightly coloured, are long (convoluted around 14mm) and prominently displayed (Fig. 27) in the canopy over many weeks. Female gliders in late lactation (December) with nestling young in dens surrounded by seeding *A. crassicarpa* might be expected to significantly reduce energy costs by foraging on arils close to the nursery den. As the gliders did not eat the *Acacia* seeds, but discarded them below the tree, it is doubtful that the tree derives anything advantageous from the relationship.

The August 1991 observation of a glider breaching an occupied arboreal nest of Green Tree Ants and for 5 minutes thereafter eating something taken from the nest, deserves comment here. Larvae were initially considered the objects of the glider's attention. However, nests breached by M. Hopkins (pers. comm.) in an

FIG. 23. New scapes of *Xanthorrhoea johnsonii* carry a 'bloom' of waxy spicules. Gliders visiting scapes leave long-lasting footprints in the wax. Surveys of *P. gracilis* habitat are facilitated by an inspection of *Xanthorrhoea* inflorescenses.

FIG. 24. *Xanthorrhoea johnsonii* scape showing tapping gouges attributed to *P. gracilis.*

unrelated study, were found to contain abundant harvested *Acacia* arils. Three *Acacia* species occur commonly in *P. gracilis* habitat: *A. crassicarpa*, *A. flavescens* and *A. mangium*. However the three species flower concurrently through May making it unlikely that mature arils would be available for harvest and storage as early as mid-August. Given the longevity of arils it is possible that the items extracted from the nest were arils harvested by the ants the previous summer.

The grasstree *Xanthorrhoea johnsonii* has a wide geographic and environmental range on the east coast, tablelands and western slopes from Cape York Peninsula south to Singleton, New South Wales (Bedford et al., 1986). Unlike most other glider sites within the surveyed area, *X. johnsonii* was common at Barretts Lagoon with densities exceeding 1000 plants per 1000m^2. There, soils were waterlogged for extended periods during the wet season, and flowering in both 1991 (a non-fire year) and 1992 (severe fire in early January) occurred from May to August. During this time both *P. gracilis* and *P. breviceps* were observed feeding (separately) on spike nectar, but only *P.gracilis* was observed tapping young scapes for exudate (Van Dyck, 1992b). As scapes and spikes matured it became difficult to distinguish between scape damage due to gliders and that caused by insects. Large crickets were noted grazing broad (5mm) shallow channels in immature upper scapes which later oozed exudate and calloused to leave scars similar to those left by gliders. As scapes further matured, a glider's bite at the base of a scape could have been interpreted as either a gum tap or an attempt to get at worm-like beetle larvae that sometimes excavated burrow networks in the lower part of the scape.

Pollen analysis showed *Xanthorrhoea* pollen intake between May and August and rhomboidal crystals of silica in the May 10 sample. The presence of the silica crystals demonstrates that

FIG. 25. *Xanthorrhoea johnsonii* spike being licked by sub-adult female *P. gracilis* T4027.

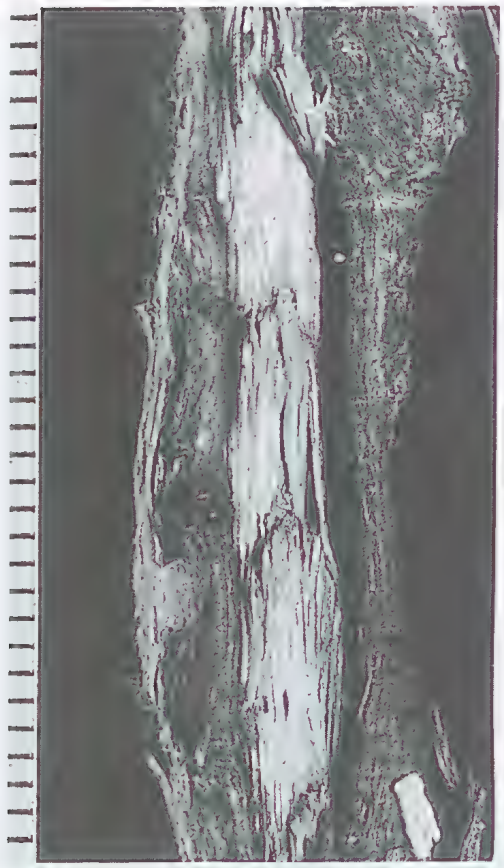


FIG. 26. Branch of *Eucalyptus intermedia* stripped for sap and/or kino by *P. gracilis*. Note cicada ovipositions.

the glider may have foraged scape tissue of *Xanthorrhoea*, as rhomboidal silica surrounds the secondary bundles of this taxon (Staff & Waterhouse, 1982). In May, a high proportion of scapes were tender and, presumably most productive when tapped. The results also suggest a high percentage (up to 70%) of *Xanthorrhoea* pollen is available for digestion through release of the contents via the aperture. *Xanthorrhoea* pollen may provide a convenient and rich source of protein by virtue of the high ratio of pollen aperture to surface area making the contents more readily available than pollen from other sources e.g. *Eucalyptus* (M. Dettmann, pers. comm.). Pollen has a high protein content (6-34%, Smith, 1982). Given the carbohydrate and protein rewards offered by *X. johnsonii* over a long period, the intake of scape exudate is noteworthy in respect of its possible digestibility-reducing or toxic secondary plant compounds. Investigations of the complex mixture of aromatic compounds found in *Xanthorrhoea* have concentrated on resins present in the trunk (Birch & Hextall, 1955; Duewell 1955, 1965, 1968; Duewell & Haig 1968) but not in the scape. Phenols and flavinoids are known components of young scapes (D. Bedford, pers. comm.) and their injestion by cattle has been attributed to poisonings during autumn and early winter in north Queensland (the sometimes fatal condition known as 'wamps' or 'crampy disease'). The toxic principle involved in such poisonings has not been investigated (Everist, 1974). Hall (1956, 1965) noted that young *Xanthorrhoea* spikes (probably *X. fulva*, D. Bedford, pers. comm.) appeared to be more toxic than old ones, and there was evidence to suggest that the scape was more poisonous than the spike.

Australian folivorous marsupials have been shown to exhibit a number of physiological and morphological adaptations to cope with xenobiotic compounds such as tannins and other polyphenols in their diets (Hume et al., 1984; Foley, 1987; Foley & Hume, 1987; Foley et al., 1987). The development of the hindgut, in particular the caecum, into a fermenting chamber, is

FIG. 27. Prominently displayed seeds and arils of the 'bird-syndrome' *Acacia crassicarpa*. This *Acacia* is an important understorey component of *P. gracilis* habitat.

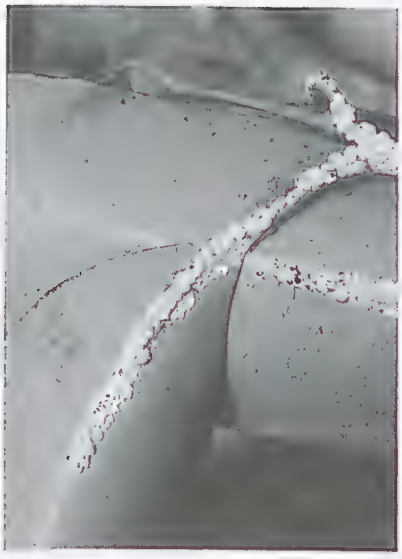

FIG. 28. *Eriococcus* sp. on *Eucalyptus pellita* foliage. Both scale and psyllid are eaten by *P. gracilis*.

one of these adaptations and its role in the bacterial fermentation of carbohydrate polymers (some plant gums) eaten by petaurids is discussed by Smith (1982a, 1982b). In external proportions, the alimentary tract of *P. gracilis* (Fig. 30) resembles that of *P. breviceps*. In one specimen of *P. gracilis* (JM7400), the small intestine (44cm) tapered gradually from 1.3cm diameter below the duodenum to 2.9cm diameter at the point of juncture with the hindgut and caecum. The caecum was 7.8cm long and broadest at 1.5cm. The colon was long (25cm). The length of the caecum in *P. gracilis* was roughly twice that (or 11.3% of total gut length) of the caecum in the striped possum *Dactylopsila trivirgata* (6.9% of total gut length, see Smith, 1982b). The colon in *P. gracilis* occupied approximately 36% of total gut length and compared to 17.2% in *D. trivirgata*. The striped possum has a similar body weight to, and occurs sympatrically with, *P. gracilis* through most of the latter's range. If this difference in the capacity of the hindgut reflects a physiological advantage in *P gracilis* to deal more successfully with the toxic polyphenols and complex carbohydrates of *Xanthorrhoea* gums and exudates, it may provide further ecological segregation between the two species.

This segregation may further be reinforced by the ability of *P. gracilis* to deal with lichens whose secondary chemicals (toxic polyphenols) may be a defense response to predation or an aggressive allelopathic response (Lawrey, 1986; Rogers, 1990) and Pink Bloodwood (*E. intermedia*) sap and/or kino (although precisely which one of these or what proportions the glider takes from branchlet slashings and small trunk wounds is not known). Old, red-stained, calloused slashings were often found to be fed by kino ducts, and did not display crusted kino on the wound, suggesting that either this type of wound may not crust over naturally, or gliders may have cleared away or eaten the crystalline form and then fed on kino liquor as it leaked into the wound. Kino, the 'blood' from which the group of 'bloodwood' eucalypts are renowned and named, is astringent to taste and contains large quantities of toxic polyphenols (Smith, 1982). The results of chemical analysis of Pink Bloodwood kino from Barretts Lagoon suggested broad superficial similarities to *Xanthorrhoea* exudate. Gliders of any species have not previously been reported to feed on kino.

Phloem sap feeding is well documented for *P.*

FIG. 29. *Eucalyptolyma distincta* on *Eucalyptus intermedia* foliage. Both lerp and psyllid are eaten by *P. gracilis*.

FIG. 30. Dissected gut of *P. gracilis* (JM7400).

breviceps and *P. australis* (see previous references). Smith (1982) noted that when gliders fed on sap they were generally seen to chew the sides of the wound and Craig (1985) described bark stripping in *P. australis* where bark and adhering conducting tissues of both *E. cypellocarpa* and *E. obliqua* were stripped to a depth of 1-2mm and torn free in long slivers, which were immediately discarded and the damaged surface licked intensively. It is possible that similar gouging behaviour observed in *P. gracilis* in the canopies of both *E. intermedia* and *E. pellita* was directed at phloem sap and not at kino. In that no actively worked sap-site trunks such as those characteristic of *P. australis* were detected over the course of the survey, it may be that for *E. intermedia* at least, thin canopy branches provide the most convenient access to phloem sap where trunk gouging might be too quickly counteracted by a kino injury response. Given the critical importance of the northern bloodwood complex (*E. intermedia*, *E. clarksoniana*, *E. dolichocarpa*) to the distribution of *P. gracilis* (see below), the shortcomings associated with knowledge of this glider's relationship with these species need to be addressed. Given its relatively large size, *P. gracilis* may be dependent on this group for incising and thereby the geographic range of the glider is, in part, determined by the presence of these trees.

Distribution and Habitat

Sites supporting *P. gracilis* are characterised by very high (seasonal) precipitation and a woodland vegetation blend that is shaped and maintained by fire. The glider's narrow range coincides with the wettest zone in Australia (Tully's mean yearly total rainfall is 4188mm). Coastal areas at the southern limit of the *P. gracilis* range may appear suitable in habitat (e.g. Clemant State Forest 34, near Rollingstone) yet fail to support petaurids other than *P. breviceps*. Large, mature woodland trees of the coastal ridges and plains (e.g. *E. intermedia*, *E. pellita*, *L. suaveolens*) are shallow-rooted, and although trees in such low-lying areas are subject to protracted periods of seasonal inundation, their sandy soils also drain quickly and thoroughly during the extended winter-spring dry season. It is most likely that the ultimate climatic parameter determining the distribution of *P. gracilis* is a dry season moisture threshold (probably close to 100mm dry quarter precipitation) below which its moisture demands cannot be easily satisfied.

Ironically, the high rainfall requirement which partly determines the glider's presence in an area also potentially undermines its long-term survival prospects. Many dryland communities suitable to *P. gracilis* are actively evolving from sclerophyll to vine forest because of changing fire regimes (P. Stanton pers. comm.). Traditional burning practices no longer operate in the area and the threat of economic loss through damage to sugarcane and pine plantations acts as a discouragement to burning-off in adjoining woodland areas. This is linked to a public perception that fires are a 'bad' thing and rainforests are 'best'. Rapidly evolving rainforest communities

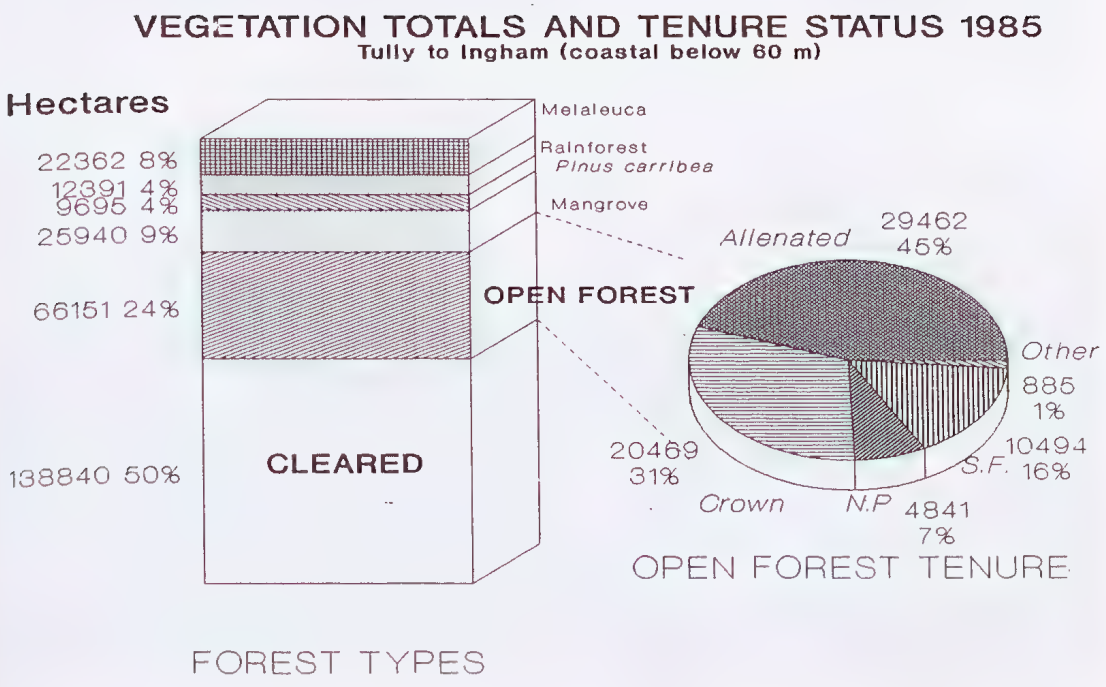

FIG. 31.The status of vegetation types (in general) and open forest (in particular) throughout the range of *P. gracilis*. For coverage see Fig. 1 (Smiths Gap south to Bambaru). Figures supplied by Queensland Forest Service.

were noted in woodlands at the Hull River site, Edmund Kennedy National Park, Murray Upper, Hinchinbrook Is. and parts of Barretts Lagoon.

Petaurus gracilis is dependent on mature stands of mixed-species remnant woodland. The presence of at least one of the 'bloodwood' group (*E. intermedia*, *E. clarksoniana*, *E. dolichocarpa*) and an accompanying species of bird-syndrome *Acacia* (usually *A. crassicarpa*, less often *A. flavescens* or *A. mangium*) is suggested as a minimal basis for suitable habitat. In a few cases, the place of a bloodwood might be taken by *E. pellita*. This species flowers heavily in February and March, coinciding with bloodwood flowering. Hypanthums of *E. pellita* blossoms range from 6-10mm, and gliders have been observed to spend entire nights feeding in individual trees (see Goldingay, 1987, 1989 for similar behaviour in *P. australis* at single sap-sites). The presence of *E. pellita* was considered to indicate areas of high quality glider habitat. Where mature *E. pellita* combined with *Xanthorrhoea johnsonii*, the resultant habitat blend could often be regarded as optimal (e.g. areas of Barretts Lagoon). Habitat considered sub-optimal was characterised by a trend toward species-poor assemblages and dominance by a single eucalypt species e.g. *E. platyphylla* (Wharps Holding), *E. clohesiana* (Hinchinbrook Is.), *E. intermedia* (Graham Range National Park). A curious human bias toward leaving mature *E. tereticornis* in cultivated paddocks and narrow belts along roadsides (e.g. Kennedy Valley, Ashton and Lannercost Creeks) has meant that gliders can often occupy heavily degraded and fragmented habitat where vestiges of suitable riparian (gully) habitat provide summer requirements. *Eucalyptus tereticornis*, a mid-winter flowering species is known as a major source of winter pollen and a useful source of nectar (Penfold & Willis, 1961; Chippendale, 1988). Also the presence of many large mature specimens of *Deplanchea tetraphylla* distributed sparsely but evenly throughout the glider's range is considered important in that they provided an abundant source of nectar (and perhaps pollen) at a time (August, September) when little else is in flower.

Social Organisation and Home Range

The small sample size upon which these comments are based should not be ignored. Barretts

FIG. 32. Lowland woodland clearing for *Pinus carribea* plantations has accounted for a loss of at least 9,695ha of *P. gracilis* habitat. In late 1992 Queensland Forest Service suspended clearing of native forests near Cardwell following the recording of *P. gracilis* in foothill remnants at Porters Creek (shown here overlooking Hinchinbrook Is.).

Lagoon, where a total of five gliders were radio-tagged, included patches of habitat considered optimal for *P. gracilis*. The woodland community was structurally complex with abundant species of *Eucalyptus* (4), *Melaleuca* (4), *Acacia* (4) and with a dense understorey of *Xanthorrhoea*. The availability of diverse sources of carbohydrate and protein throughout the year (see Table 6), combined with an abundance of nest sites, could be expected to be reflected in a polygynous mating system (Emlen & Oring, 1977; Lee & Cockburn, 1985; Henry, 1984; Goldingay, 1992) as polygyny in the Petauridae is thought to evolve when resources are abundant enough for male gliders to defend a territory which can support more than one female consort. However, *P. gracilis* appears unconventional in its pattern of social organisation. The two adult females in this study had home ranges that appeared to be relatively exclusive of one another (Fig. 19). Two dispersing sub-adult females were largely solitary although their home ranges overlapped consistently with one another and with one of the adult females (presumed to be their mother). The adult male denned either alone or with either solitary adult female and regularly spent time with at least one of them for part of the night. This system is a departure from the nature of polygynous mating systems generally attributed to either *P. breviceps* (polygynous: Smith, 1980; Suckling, 1980) or *P. australis* (monogamous: Craig, 1985; Goldingay & Kavanagh, 1990; polygynous or monogamous: Russell, 1984; Goldingay, 1992). The apparent system in *P. gracilis* more closely approximates that seen in *Petauroides volans* (Henry, 1984; Kehl & Boorsboom, 1984), although the home range is much larger in *P. gracilis* (23ha for an adult female compared to 1.25-2.5ha in a *P. volans* female), and the investment in female and/or resource defense by male *P. gracilis* could be anticipated to greatly exceed that by male *P. volans*.

It is tempting to draw similarities between the social behaviour of *P. gracilis* and that of the tropical African exudivorous prosimian *Galago senegalensis moholi* as reviewed by Bearder

TABLE 6. Food items recorded for *P. gracilis* by direct observation.

Food item	Source	Month recorded	Locality (from Table 1)

(1987). In *G. senegalensis moholi*, female territories are large enough to support feeding throughout the year and in homogeneous habitat, home ranges of females are approximately equal in size. Females signal territory ownership to conspecifics by scent marking and vocalisation; only adult females are repulsed. At first an adult daughter may share her mother's terrritory, but later there is less overlap although related females may share critical resources (up to 4 adult *P. gracilis* were once recorded feeding simultaneously in a single flowering *E. tessellaris* at Barretts Lagoon). Territories of male *G. senegalensis moholi* (i.e. 'A-males', which are older, heavier and territorial and have preferential contacts with females) overlap those of one or more females. A-male territories are signalled by scent and vocalisation and other adult males are repulsed. There is no relationship between male territory size and dietary requirements. A special bond of familiarity links a territorial male to his females. This bond is serviced by regular visits that involve direct contact with the females. The direct contact may be prolonged (several hours). Additionally, calling and indirect contact using scent marking may be employed. Male stability and territoriality depends on the presence of females. Male-male and female-female territories (between matriachies) have zones of overlap where territorial signals are exchanged.

Bearder (1987) notes that such a strategy in *G. senegalensis moholi* ensures the even spacing of single females or matriarchies throughout areas of suitable habitat and ensures that the nature of male territoriality ensures mating access to females without wasting energy on subordinates. Smith & Lee (1984) comment that theoretically, female possums might be expected to obtain more nutrients for survival and reproduction when solitary (and defending solitary territories) except when specific advantages of clumping outweigh the disadvantages of sharing resources. Given the combination of its moderately large size, and the benign tropical climate associated with its habitat, *P. gracilis* could be expected to have a low relative cost of thermoregulation and as a result it may avoid group huddling.

The threat from Rufous Owls (*Ninox rufa*) and Lesser Sooty Owls (*Tyto multipunctata*) which occur commonly throughout the range of *P. gracilis* may also make lone foraging a response to crypsis for defense (Henry, 1984, for this behaviour in *P. volans*). Of 5 regurgitated pellets retrieved from a Rufous Owl's nest site at Lannercost, 1 pellet contained maxillary fragments of an adult specimen of *P. gracilis*.

The Barretts Lagoon situation may reflect an artificial situation in that the adult female home ranges were separated by an extensive treeless swale with one narrow natural corridor connection at the southern end (Fig. 19). The western side of one of those home ranges was bordered by a road. Investments in female resource defense by the male may have thereby been greatly reduced, and elsewhere, in areas of more contiguous habitat, *P. gracilis* way prove to exhibit a mating system compatible with that described for other petaurids.

If the mating system at Barretts Lagoon was

typical, the quasi-polygynous system may offer abundant resources of food and time to reproductive males, yet just sufficient resources for reproductive females to feed themselves, and tolerate two, large, weaned young (and perhaps a second litter) dispersing slowly from the female's home range. The use by females of multiple dens scattered throughout the home range may represent a cost effective method of territory defense. Home range size and mating strategy have been shown to vary in *P. australis* with the productivity of the site (see Goldingay, 1992 for review). It is likely that in marginal to poor habitats (e.g. Wharps Holding), the sociecology of *P. gracilis* will vary from that of Barretts Lagoon.

Conservation Status

Most records of *P. gracilis* (Table 1) have come from altitudes below the 60m contour (mean altitude= 17m; SD= 19.8; SE= 0.35; N= 57). The total area encompassing site records to date of *P. gracilis* is shown in Fig. 31. Of this total area which amounts to 438,454ha, approx. 63% (275,379ha) occurs below the 60m contour. Of this lowland vegetation approx. 50.4% (138,840 ha) has been totally cleared of forest through primary production (mainly establishment of sugar-cane, cattle, bananas, pineapples, fruit trees, aquaculture), logging, and the cultivation of *Pinus carribea* in plantations (9,695 ha) since 1967. The balance of open forest which totals approx. 66,151ha and represents a surviving approx. 20% of the original component of lowland open forest (P. Stanton, I. Robb, pers. comms), is highly fragmented, the subject of ad hoc fire regimes and mostly unprotected. Approximately 76% of this remnant is potentially available for future development (45% alienated (i.e. freehold/leased), 31% Crown). *Petaurus gracilis* is poorly represented in the 7% (4841ha) open forest protected by National Park tenure (see preceding), and the remaining significant slice of 16% (State Forest, 10,494ha) is highly fragmented. In late 1992, Queensland Forest Service (QFS) suspended clearing of native forest near Cardwell following the recording of *P. gracilis* in State Forest at Porters Creek. Seven specific areas of the coastal lowlands had been selected by QFS for clearing prior to the establishment of exotic pine plantations (total area 3710 ha). Each area was investigated by the QFS Fauna Conservation and Ecology Section in October 1992 to determine the presence of *P. gracilis* and to allow an evaluation of the conservation significance of each proposed area as *P. gracilis* habitat. Gliders were detected in 4 of the 7 sites investigated (total area 3050ha) and in locating gliders at Wharps Holding, QFS ecologists extended the known southerly distribution of the species (J. Kehl, pers. comm.).

Core areas predicted by the BIOCLIM system have been mostly cleared from the north and south and replaced along the Ingham-Tully coast by plantation pine (Fig. 32). Records from predicted marginal areas indicate the present day distribution is concentrated near foothills and relictual riparian corridors. The extensive area east and south of Barretts Lagoon represents a significant remnant core area.

The endangered status of *P. gracilis* (Van Dyck, 1991) in tropical Queensland should not be regarded in isolation, but seen as symptomatic of a pattern of decline of abundance and extinction repeated across Australia. The threats faced by this glider are not unique to it but shared by the entire tropical coastal lowland woodland ecosystem of which it is one component. In 1982, Tracey commented that his Vegetation Types 18 (Swampy Coastal Plains) and 19 (Coastal Floodplains and Piedmont Swamps) had been either cleared and drained for sugar-cane, or where they had once been common along the Tully River and Murray River were now practically extinct. Braby (1992) reviewed the status and biology of eleven species of butterfly dependent on the Cardwell Basin lowland woodlands and concluded that their habitat ranked among the most threatened habitats in north Queensland. Recher & Lim (1990) presented data suggesting that the decline of vertebrates first observed in southern Australia has extended to the northern parts of the continent and that fauna of the wetter coastal regions may also be affected. They predicted that if such observations are correct, the outcome will be the rapid extinction of species throughout Australia in the next few decades. They recommend that in the conservation of terrestrial fauna, the emphasis needs to shift from species preservation to the management of ecosystems.

'The scale of change is not of individuals or populations, but of functional units of interacting organisms. Once destroyed it is no more likely that an ecosystem can be restored to its original state than an extinct species can be resurrected from its bones recovered from a museum drawer' (Recher & Lim, 1990: 295).

ACKNOWLEDGEMENTS

I am particularly indebted to Paul Stumkat (Queensland Museum) and Scott Burnett (James

Cook University) who were prepared to work, to be paid, and to smell like slaves during the field component of this survey. Their monumental effort is warmly acknowledged.

I gratefully acknowledge the field assistance and photographic input of Bruce and Carolyn Cowell (Queensland Museum), the enthusiastic help of Queensland Department of Environment and Heritage staff (Townsville, Ingham and Cardwell) in particular Sally Townley, Rob Buck, Claud Azzapardi, Keith McDonald, Warren Price, Mark Hermann, Felicity Savage, Mark Bernham, Peter Venables, Gethen Morgan, Sev Mostachetti, Keith Smith and John Hicks. Other invaluable help came from Sue Churchill, Judy Conrad, Darren Quin, David Pollock, John Young (who collected the Rufous Owl pellets), Steve Look (who made the nest boxes), Mrs Margaret Thorsborne and Joan and Ben Bentrupperbaumer.

I acknowledge the professional help of Chick Robb and John Kehl (Queensland Forest Service) whose jobs were greatly compounded by my job. QFS staff, in particular John Doyle and Marty Schultz in the north and Brisbane based Chris Corben, Paul Flower, Luke Hogan and Teresa Eyre are thanked for their field assistance and for making their survey data available to me.

Peter Bostock and staff of the Queensland Herbarium generously identified plant specimens for me, Niel Douglas (Government Chemical Laboratory, Brisbane) undertook the analysis of exudates and psyllids, and Mary Dettmann (University of Queensland) analysed pollen samples. Tim Flannery and Linda Gibson (Australian Museum, Sydney), Joan Dixon (Victoria Museum, Melbourne), Paula Jenkins (British Museum, Natural History, London) and Guy Mussser (American Museum of Natural History, New York) allowed me access to specimens in their care. Advice, specialist identifications and essential literature was freely offered by Rod Rogers and David Lamb (University of Queensland), David Bedford (Royal Botanic Gardens, Sydney), David Titley (Titley Electronics, Ballina), Mike Hopkins and Keith Taylor (CSIRO, Atherton and Canberra), Peter Stanton and Alister Melzer (Queensland Department of Environment and Heritage, Cairns and Rockhampton), Anne-Marie Watt, Hans Duewell and Ross Goldingay. Dean Howell, Department of Environment and Heritage is thanked for producing the distribution map of which the G.I.S. vegetation data was supplied by Queensland Forest Service. Bill Lavarack and Russell Cummings (Queensland Department of Environment and Heritage, Townsville) generously supplied me with vegetation proformas of glider sites we visited together. I thank the Australian Army for access to restricted areas, and am particularly grateful to Henry Nix and John Stein (Australian National University, Canberra) for supplying me with the BIOCLIM analysis and prediction and to Don Colgan (Australian Museum, Sydney) for early results of his biochemical analysis.

With much affection I acknowledge the help of the local residents who allowed us to work on their private land, to sleep in their banana packing sheds and under their tractors, and generally disrupt life on their properties. In particular I thank Max, Dorothy, Milton, Margaret and Jonothan Jones, Tony Cain, Jenny and Niel Wadsworth, David and Jenny McDonald, Horst and Chris Klotz, 'Buck' Roger, Tony, Nancy, John, David

and Dennis Marsilio, Angus and Lil Mackee. Marilyn and Daryl Tagget provided luxury ad lib through accomodation and electricity at their Barretts Lagoon 'lodge'.

Critical comments from Ross Goldingay (University of Wollongong) and Darren Quin (New England University) greatly improved earlier drafts of this work.

This study was funded through 1991 and 1992 by an Australian Research Council grant.

THE PRODUCTION AND DISPOSAL OF PIGS BY KUBO PEOPLE OF PAPUA NEW GUINEA

PETER D. DWYER

Dwyer, P.D. 1993 06 30: The production and disposal of pigs by Kubo people of Papua New Guinea. *Memoirs of the Queensland Museum* 33(1): 123-142. Brisbane. ISSN 0079-8835.

In 1986-87, a small community of Kubo people, of the interior lowlands of Papua New Guinea, kept from 0.27 to 0.54 domestic pigs per person. The animals were fathered by wild boars and born to both wild and domestic sows. Male pigs were castrated. For about 18 months each pig was in the care of a particular woman; thereafter, it was released to forage in the backswamps but was regularly monitored by its carer and, like village-based pigs, provided with much fodder, particularly the pith from sago palms. An exceptionally close bond was established between each domestic pig and its carer. Men contributed little to the management of domestic pigs, and carers participated actively when pork from pigs that had been in their charge was distributed. Domestic pigs were not important as a protein source. Their significance was primarily social. On several counts, patterns of production and disposal of pigs by Kubo did not conform to expectations based in earlier comparative and theoretical analyses of New Guinean procedures. Kubo patterns are located within a comparative frame that concerns ratios of pigs to people, work entailed in maintaining pigs, nutritional matters and gender roles. □ *Socio-ecology, animal husbandry, domestic pigs, nutrition, protein, gender roles, Kubo, Western Province, Papua New Guinea.*

Peter D. Dwyer, Department of Zoology, University of Queensland, Brisbane, Queensland 4072, Australia; *1 August, 1992.*

Domestic pigs are important to most New Guineans. They are often focal in the social exchanges that connect different groups of people and, through the time and labour entailed in management, significant in the ecological exchanges that connect people with environment (e.g. Morren, 1977; Rubel & Rosman, 1978). These linked dimensions of the role of pigs were made clear in Rappaport's (1968) classic study among Tsembaga Maring. Indeed, in recent literature that addresses questions of social and agricultural evolution within New Guinea, the place of pigs is central (e.g. Feil, 1987; Kelly, 1988; Bayliss-Smith & Golson, 1992).

Despite the importance of pigs to both New Guineans and anthropological theorists there are few studies that include substantive detail of the husbandry practices of specific groups of people (cf. Boyd, 1984). Notable exceptions are Rappaport (1968), Hide (1981), Boyd (1984, 1985) and Kelly (1988) but these do not capture the full diversity of New Guinean pig-keeping practices (cf. Baldwin, 1990; Yen, 1991). Without an appreciation of that diversity the value of comparative analysis and evolutionary speculation will remain limited (Hide, 1981: 563).

This paper describes the production and disposal of pigs by a small group of people living in the interior lowlands of the Western Province of Papua New Guinea. These people are horticulturalists who, on the basis of extrapolating from earlier theoretical literature (e.g. Morren, 1977; Watson, 1977; Modjeska, 1982; Feil, 1987; Kelly 1988; Baldwin, 1990) might have been expected to keep few pigs or none at all, rear only wild-born piglets, raise them on forage rather than fodder, devote very little time or effort to their maintenance and use them to meet nutritional rather than social needs. Kubo people did not conform to these expectations.

KUBO PEOPLE

About 450 speakers of the Kubo language live north and northwest of the Government station at Nomad, Western Province, immediately south of the Muller and Blucher Ranges (Fig. 1; Dwyer, Minnegal & Woodyard, 1993). Between August 1986 and November 1987, with Monica Minnegal, I lived with 25 people at the village of Gwaimasi (5°54'S, 142°6'E; 80m ASL) on the west bank of the Strickland River. Our research embraced all aspects of the socio- ecology of the people and earlier reports provide details of environment, subsistence, social life and the historical context within which we worked (e.g. Dwyer & Minnegal, 1991a,b, 1992a). Details of the composition of the village population are available in Dwyer & Minnegal (1993). Here, I summarize

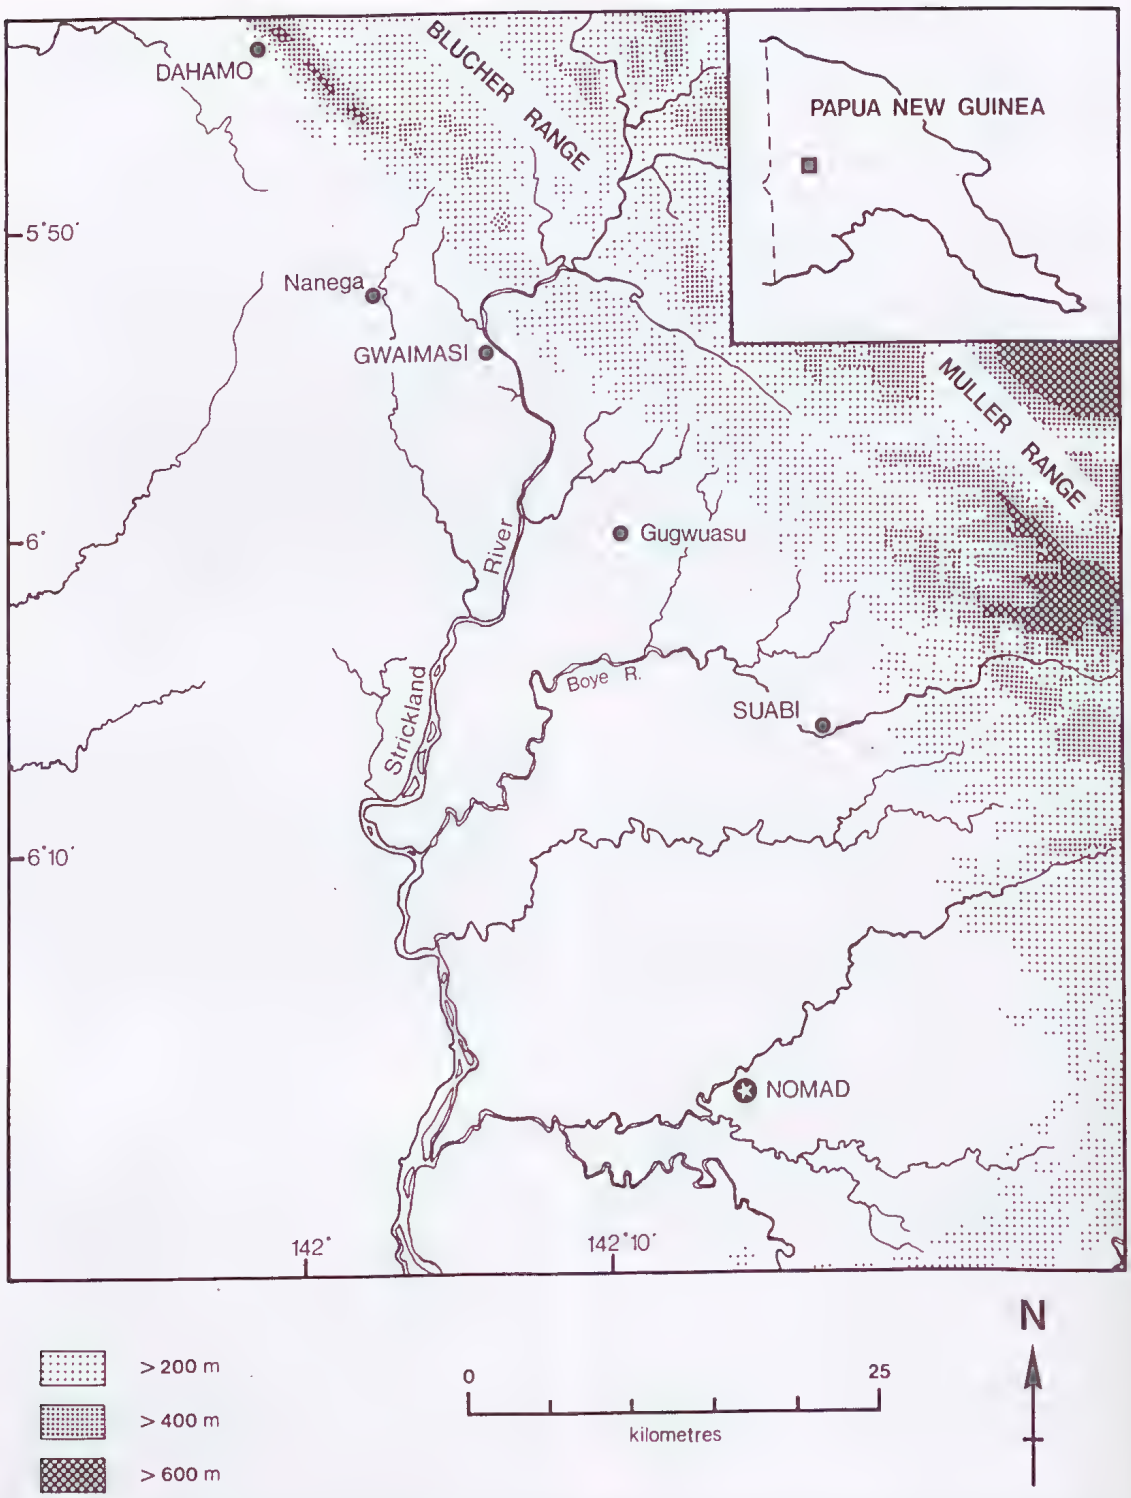

FIG. 1. Location of Gwaimasi and neighbouring communities. The large symbol shows the Government station at Nomad. Small symbols show villages mentioned in the text; names of Gwaimasi and neighbouring mission stations are capitalized.

information that is relevant to reporting matters about domestic pigs.

Gwaimasi village was centrally located within 50km^2 of foothill rainforest and swamp forest that was drained by numerous streams and the Strickland River itself. Within this area the residents of Gwaimasi produced their food. Rainfall was approximately 6m per year with recorded monthly falls never less than 300mm. The people grew bananas at small unfenced gardens made on levee banks of the river and larger streams, and extracted sago flour from both planted and wild *Metroxylon* palms that were abundant in the backswamps. These carbohydrate foods were of approximately equal importance though at different times one or the other was dominant.

Most protein was derived from animals. Wild pigs and catfish contributed most protein, in terms of weight, but many other vertebrates and invertebrates were included in the diet. Forest products, other than animals, were used as food (e.g. fern fronds, fungi, wild yams and the fruit, nuts and leaves of certain trees) and to fulfil many material needs (e.g. clothing, building and the manufacture of hunting equipment and canoes). Despite the apparent commitment, encouraged by Government and Mission contact, to establish and live in villages Kubo people remained very mobile both within and between local subsistence zones. At Gwaimasi, family groups spent long periods living at forest and garden houses away from the village and often, at these times, had little or no access to garden produce. Since about 1960 there appears to have been increased emphasis upon gardening and less emphasis upon sago extraction to satisfy calorific needs (Dwyer & Minnegal, 1992a).

Dogs and pigs were kept as domestic animals by Kubo. There were nearly as many dogs as there were people and the animals were essential to the successful pursuit-hunting of wild pigs. Domestic pigs, the subject of this paper, were less numerous. My concern here is with what Hide (1981: 406-407) called the 'ecological population': the domestic pigs cared for by a localized group of people within the area that the people themselves routinely traversed. This population need not be identical with the 'sociological population' which comprises the domestic pigs owned by a localized group of people irrespective of where those pigs are located. In New Guinea this distinction is necessary because agistment of pigs is common.

I classed domestic pigs as either 'tended' or 'free foraging'. Pigs in the former category were under almost daily supervision and spent nearly every night at or near the houses where their carers slept. Pigs in the latter category had been released to forage alone in the backswamps. At different times during its life a pig might qualify as 'tended' or as 'free foraging'. Sometimes a 'tended' pig failed to return to the village for several successive nights. Analyses presented here do not reclassify these cases as 'free foraging'; categorization as 'tended' or 'free foraging' takes the *intention* of the pig's carer to be primary. A recalcitrant 'tended' pig simply increased the work load of its carer who now had to search for it. 'Primary carers' are defined as women who had primary responsibility for particular pigs, wherever those pigs were located, and 'secondary carers' as people who were in charge of pigs for which they did not have primary responsibility. People were classed as carers of 'tended' pigs only if they had been responsible for those pigs through the day and following night. Brief periods of assistance provided during the day are not included in the analyses though they were common. Public perceptions were such that there was no ambiguity concerning the identity of primary carers of 'free foraging' pigs. My classifications of domestic pigs as 'tended' or 'free foraging' and of carers as 'primary' or 'secondary' conform closely with Kubo perceptions.

Most of the data reported below were obtained by monitoring the activities and locations of people and pigs, by direct observation of circumstances of disposal and by asking questions. Estimates of pig weight should be regarded as rough approximations. I did not have direct access to domestic pigs for measurement; the people, but not the pigs, would have tolerated this intrusion. However, where possible, wild pigs were weighed after they were killed and, before weighing, I could usually judge the weight to within 10 percent. Sixteen wild pigs with a weight range from 1.5 to 74.5kg yielded the following relationship between weight (W = intact weight in kilograms) and mandible length (M = length of horizontal ramus of mandible in millimetres): log.W = 2.91log.M - 5.07. In a few cases this formula was used to estimate the weight of domestic pigs; values obtained in this way are underestimates because domestic pigs were usually fatter than their wild counterparts. Edible weights were estimated as 0.65, 0.70 and 0.75 of intact weight for, respectively, pigs heavier than 10kg, between 5 and 10kg, and less than 5kg.

THE PIG POPULATION

Between September 1986 and November 1987 from seven to 13 domestic pigs were managed by residents of Gwaimasi (0.27 to 0.54 pigs/resident; Fig. 2). These values include piglets only from the date they were removed from sows and taken into the care of women. Piglets that were either eaten (n = 13) or exported beyond the Gwaimasi area (n = 1) on the day they were taken from a domestic sow were not counted as members of the population.

In September 1986 there were five sows and four large males; four of these animals had been born to domestic sows, the status of the others is not known. Three of the males were confirmed as castrates and the fourth was probably a castrate. One of the sows and two of the males were alive in November 1987. All recruitment during the period of study was as small piglets; five born to local domestic sows, three born to wild sows and one as an import from a neighbouring community. Males and females were included among the recruits but details are incomplete. Losses from the population were four natural deaths at estimated weights of 1.0, 1.5, 4.0 and 12.5kg and seven pigs (15-80kg) killed by people; only the latter were eaten.

Peak biomass of the pig population was in December with about 20kg live weight per resident (Fig. 2). Removals for consumption in January and March halved this value and the combination of additions, estimated growth and losses through the next 7.5 months resulted in only a minor increase in per-person biomass.

MANAGEMENT OF PIGS

At Gwaimasi, all pigs, from the time they were taken from sows, were in the care of women. The 'caring' role was unevenly distributed among available women and was strongly connected with their current reproductive status (Table 1). Caring for pigs was incompatible with caring for a nursing infant. Thus, Wafu and Gogoi did not have 'tended' pigs, Mabei's 'tended' pig was killed six months before she gave birth and the 'tended' pigs of Kose and Bowa were cared for by other women from shortly before Kose and Bowa gave birth, to several weeks after their infants died. The perceived danger to small infants arose from the possibility that pigs might consume body wastes and proximity between pigs and babies was avoided both at the village and in the forest. (Kubo people believed that an infant's health was placed at risk if its body wastes were eaten by pigs.) Carers assumed the primary responsibility for this, though, in the forest, mothers disposed of their infants' wastes and, at the village, one couple enclosed the area beneath their house so pigs could not reach wastes that might fall through the slat floor. In fact, pigs were not allowed to wander at will within the village area[1].

The married but childless woman Sisigia participated actively as a carer but it was the widow Gogo who contributed most (i.e. 41% and 64% of days associated with the care of 'tended' and 'free foraging' pigs respectively). As a widow who was probably postmenopausal Gogo's lack of direct association with nursing infants was more certain than that of any other woman. One teenaged girl ceased caring for a young pig at the time of her departure from the village to marry and another, who came in marriage, did not assume the role during the following 10 months. The caring role may have been constrained during early marriage.

The foregoing depicts differential patterns of responsibility but does not reveal the varied nature or extent of those responsibilities. I turn to these matters here, summarizing developmental events in the life of domestic pigs and the work associated with their care.

Domestic sows were impregnated by boars that lived in the backswamps. Of six successful matings, three occurred after our arrival; two of these latter were to a 'free foraging' sow and the last was to a 'tended' sow. The last case shows that insemination by wild boars did not require that sows were managed as 'free foraging' animals (cf. Kelly, 1988: 155).

When births were expected, carers or their agents monitored the sow regularly or, if it was a 'tended' pig, released it into the backswamps or remained with it away from the village. Neither pigs nor women gave birth at the village. Most piglets were captured and either killed or retained when they were from two to four weeks old. In one case a piglet was allowed intermittent access to its mother for a month after capture and, in

[1]Monica Minnegal and I visited Gwaimasi for six weeks in October and November 1991. During the first four weeks there were no children under three years and two large 'tended' pigs often wandered free near the edge of the village clearing. A child was born on November 12, 1991 and, from that time, the pigs were always tethered when mother and child were present.

another, a piglet was left with its 'free foraging' mother for six or seven weeks before it was killed and eaten. Management procedures of these kinds could inhibit return to oestrus by sows and, hence, allow some control over the timing of pregnancies (cf. Hughes & Varley, 1980: 149-151).

Capture of piglets born to domestic sows entailed an overnight stay away from the village by four to six people (female and male) together with some dogs. The presence of dogs resulted in the immediate death of some piglets and injury to others. One badly injured piglet failed to eat sat-

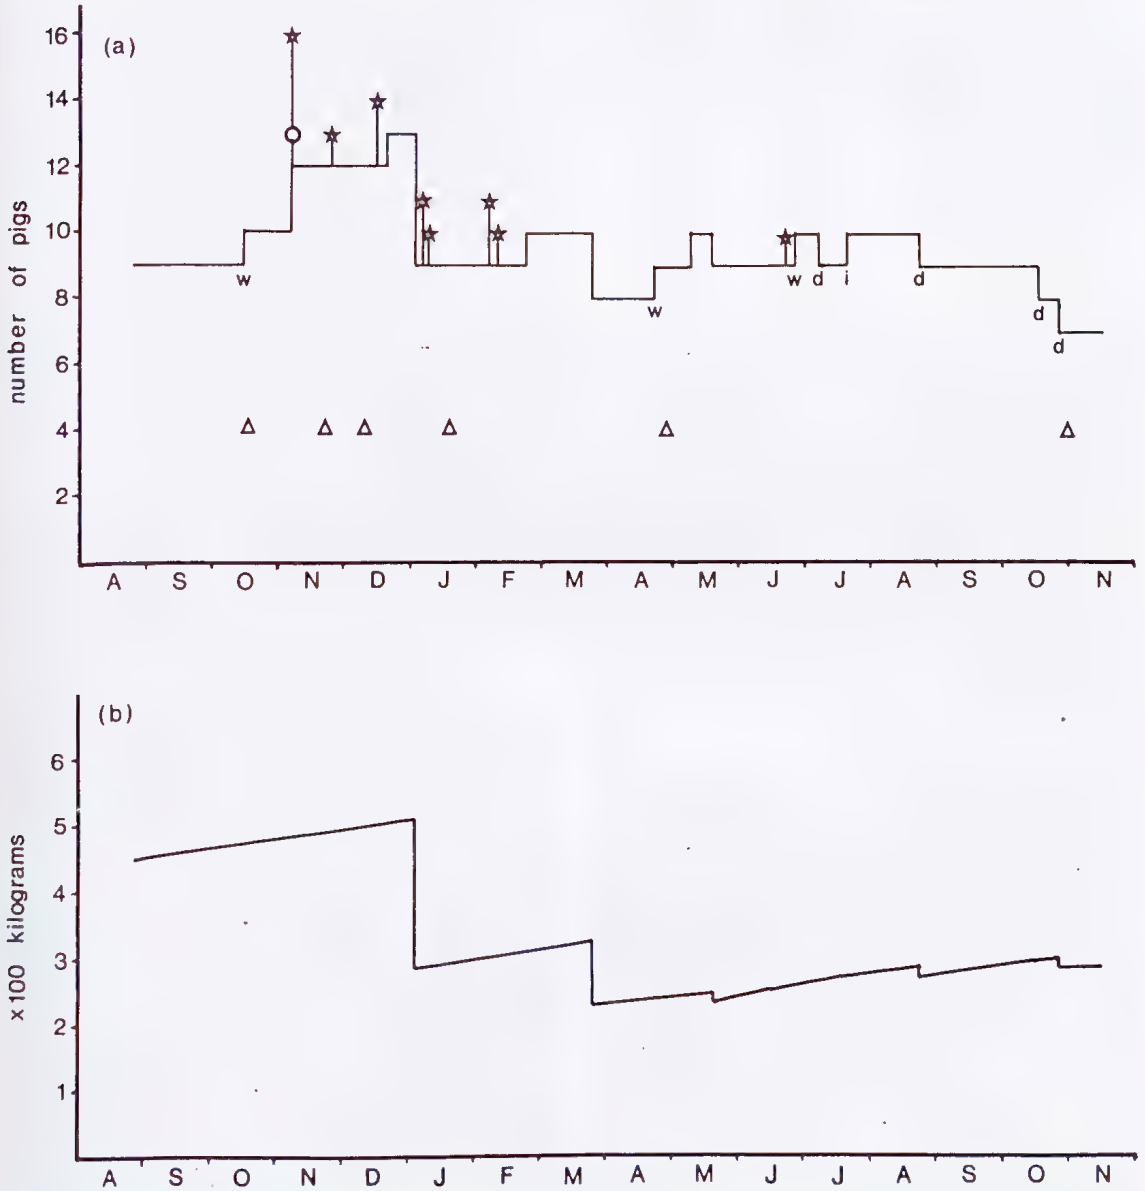

FIG. 2. (a) The size and (b) approximate biomass of the population of domestic pigs; August 1986 to November 1987. In section (a) vertical lines terminating with a star indicate piglets that were captured from domestic sows and killed and eaten on the same day; the open circle indicates one piglet that was exported on the day of capture. 'w' denotes recruitment of piglets born to wild sows, 'i' denotes an imported piglet, 'd' denotes natural deaths and open triangles record the approximate dates on which domestic sows farrowed. Capitalized letters on the horizontal axes code consecutive months.

TABLE 1. The cumulative numbers of days spent caring for pigs by female residents of Gwaimasi: August 25, 1986 to November 15, 1987[1].

		Tended pigs					Free foragers

1. Values are partitioned according to the status of pigs as 'tended' or 'free foraging', as village-based or forest-based in the case of 'tended' animals, and as associated with a primary or secondary carer. All effort associated with pigs classed as 'free foraging' is attributed to primary carers though this does not accurately represent the facts (see text for further details). Half values appear in the table because two women sometimes shared the role of secondary carer. Details are not known for 173 carer-days.
2. Kose gave birth on June 10, 1987 and the child died on July 11, 1987; Mabei gave birth on July 1, 1987 and was lactating thereafter; Gogoi was lactating throughout; Wafu gave birth on January 9, 1987 and was lactating thereafter; and Bowa gave birth on July 9, 1987 and the child died the same day. Yasobidua became a resident of Gwaimasi on January 30, 1987 and Mugwa's residency ceased on the same day. The following values record the numbers of 'tended' and 'free foraging' pigs attributed to each primary carer followed by the maximum number of pigs in care at any one time: Gogo 6,3,6; Kose 2,0,2; Sisigia 2,0,2; Mabei 1,1,2; Gogoi 0,1,1; Bowa 2,0,2; Mugwa 1,0,1. When Mugwa departed from Gwaimasi her pig was transferred to Gogo's care.
3. Ages, in years, are estimates only.
4. The caring role was attributed to a visiting woman on one day and to the husband of a primary carer on another.

isfactorily and grew exceptionally slowly during 6.5 months after capture.

For more than a year after capture, pigs were closely associated with carers. For a week or two they were carried, often but not always in string bags, and petted and kissed by their primary carer and other females. From the outset they were trained to accept a lead attached to one front leg and, within a few weeks, would be led to and from the village and allowed to run free when in the forest. But intermittent carrying often continued for three months or more, by which age young pigs had been personally named and were sometimes tethered alone or near another pig in the forest. At about four and a half months their ears and tail were cut and males were castrated, and not until about five months did they spend a day foraging in the forest near the village untethered and unaccompanied by their carer. As long as they remained 'tended' pigs they were usually taken from the village on a lead though, when older than one year, they might often return unattached in the evening.

The precise timing of the events described varied between both piglets and carers. Piglets that grew slowly were treated as though they had aged slowly and some carers were more inclined than others to reduce effort by hastening the independence of pigs. Piglets usually slept in the house of their carer for the first three or four months after capture and were then tethered at night under the house. But, in one case, this bond was not broken until nine months and then only after the carer's husband became seriously ill. Women who prolonged a close attachment to pigs were also more inclined to punish misbehaviour by shouting and smacking: children were never punished in these ways unless, as infants, they defaecated in public.

The bond between pigs and their carers was strong and the effort entailed was considerable. The strength of the bond is evidenced by the minor involvement of secondary carers (Table 1) and by the facts that secondary carers were more likely than primary carers to be resident at the village (79% vs 66%; $P<0.01$) and less likely than

primary carers to take the pig to the forest to forage (56% of 68 vs 91% of 597 recorded days; $P<0.001$). When pigs that usually free foraged were located at the village secondary caring was rare (one in 52 observed days) and even the primary carer was unlikely to take the pig into the forest (two of 51 days). Other people's large pigs were difficult to manage; only after about a week of close attention from a secondary carer did even a moderately large pig become manageable.

At the village, carers were responsible for keeping pigs away from the central village area and from small household gardens, for tethering the animals at night and for matters of hygiene (e.g. cleaning sleeping quarters and removing faeces that were dropped when pigs were taken through the village to the forest). Ropes, made from the bark of trees, were made for tethering and as leads and the animals were often groomed by their carer. The pigs also had to be fed. Fodder was usually provided both in the morning and the evening. In addition, pigs were often taken to the forest where they might be tethered, accompany the carer at her pace (on or off a lead) to a place where she intended working or released to forage alone. Pigs were also 'herded', meaning that a carer accompanied by a pig or pigs, travelling at their pace, either took more time than needed to reach a place (e.g. a garden) where she intended working or spent many hours in the forest for the sole purpose of allowing the pigs to forage.

The relative importance of these different management strategies cannot be quantified here beyond noting that pigs were taken to the forest on a minimum of 87% of the days when they, and their carers, were based at the village ($n = 665$). Pig management was often embedded in other activities undertaken by carers and different carers favoured different strategies. Two women who often worked at gardens near the village favoured forest tethering; four others who worked at more distant gardens favoured other strategies. Their preferences were probably influenced by the risk that untethered pigs might return to the village and raid household gardens.

Bananas and the pith (*woko*) from sago palms were the staple fodder provided to 'tended' pigs. (Very occasionally both 'tended' and 'free foraging' pigs were fed fish. Sanio-Hewa and Gadio Enga also sometimes fed small animals to their pigs; Townsend, 1969: 50; Dornstreich, 1973: 245) Women who were based at the village nearly always took their pig(s) to places where they processed sago palms; the pigs fed at the accumulating heaps of waste pith. Chunks of *woko* from these palms were carried to the village and fed to pigs at night; portions were sometimes given to women who had not worked but who had pigs. Other palms were felled as fodder for pigs and large quantities of *woko* were buried in muddy stream beds for retrieval as needed. Again, palms at which flour extraction was completed were visited by women who 'herded' pigs. During 14 months, at least five palms were felled to provide fodder for village-based pigs that, additionally, had access to waste and unused pith from 17 palms processed on behalf of people. Only once did I see sago flour fed to a pig. In this case a woman chewed sugar cane, spat the sweet extract into crumbled flour, and hand fed the mixture to a small, sickly piglet.

When bananas were abundant they were often fed to pigs. They were cooked green, usually by boiling, peeled and sometimes mashed before delivery on a platter to the pig. Between August and November 1986 banana production was low and few were fed to pigs. Thereafter, they were used often as fodder. A tentative estimate is that at least 200 bunches of bananas were fed to pigs from September 1986 to October 1987; this represents six percent of total banana production at Gwaimasi and nearly 500g edible weight of bananas per pig for each day it was village-based (Dwyer & Minnegal, 1993). I did not see ripe bananas fed to pigs, which contrasts with Beek's (1987: 19) observation that Bedamuni, who live to the southeast of Kubo, regarded ripe bananas as fit for pigs (and anthropologists!) but not for people.

The management of 'tended' pigs was less constrained when carers lived at forest houses away from the village. Pigs could forage freely in the forest though they were encouraged to return to the house each evening and were probably usually provided with some fodder. Bananas were seldom available as food - gardens made at a distance from the village had not yielded by the time we departed - but waste and untreated pith from sago palms were available more often than at the village. The pith from 18 palms processed to provide flour was available to 'tended' pigs when they resided with their carers away from the village; i.e. 44 vs 77.5 pig-days per palm when pigs resided at the village. It is likely that additional palms were felled to fodder these pigs.

The management of 'free foraging' pigs was largely invisible to me. Contact was maintained through visits by the primary carer or by a secondary carer who monitored the whereabouts of the pig and reported pending or recent births. Be-

tween December 1986 and November 1987 Gogo visited and remained in the area where two 'free foraging' pigs were under her care on 11 trips totalling 82 days. Similarly, from November 1986 to November 1987, Mabei visited and remained in the area where one pig lived on nine trips (26 days) and Sisigia, who often monitored this pig, visited the area on another 14 trips (39 days). These values exclude day trips to the areas. Activities other than those concerned with pigs were often undertaken during these trips though, in fact, Mabei's 'free foraging' pig was focal to eight of her nine visits.

At least five sago palms were felled as fodder for 'free foraging' pigs and the animals had access to left-overs from at least 15 sago processing ventures (approximately 79 pig-days per palm). Four of the palms were felled during a five month period on behalf of one sow (47 pig-days per palm) and it is probable that the number of palms felled for 'free foraging' pigs greatly exceeded five. At Gwaimasi the pigs classed as 'free foraging' may have been effectively foddered for much of the time though, because the fodder was sago pith, the effort entailed was not great.

By New Guinean standards Gwaimasi pigs were relatively well fed. Estimates suggest that weights in excess of 27.5kg were reached by 60 weeks; at the same age the mean weight of highland pigs from Sinasina, Simbu Province, was 21.6kg (Hide, 1981: 474). Hide remarked that Sinasina pigs grew slowly. All 'free foraging' pigs in the Gwaimasi area exceeded 40kg and two females were 42.5kg and 55kg respectively after birth of their first litters. Hide (1981: 475) reported that sows less than 25kg gave birth in the Sinasina area.

Among Kubo, 'tended' pigs were not released as 'free foragers' until they were about 18 months old and it was only near this age that females attained reproductive maturity (cf. Malynicz, 1970; Hide, 1981: 453).

In October-November 1991, 34 people were classed as residents of Gwaimasi (including one birth and one arrival in the period) and 16 pigs were located in the area. One of these pigs was a five year old barrow. The pigs to people ratio of 0.47 is reduced to 0.40 by including eight people, and one pig, who were formally aligned with Gwaimasi but spent most of their time at Dahamo (Fig. 1) where a primary school was located. Seven of the 16 pigs were 'tended' and one was 'free foraging'. The other eight, owned by members of five families, were in the care of a married couple, who had no children and lived at a fenced tuber garden on the east bank of the Strickland River. In 1986-87 and in 1991 some 'herds' of large pigs, owned by residents of the mission station at Suabi (Fig. 1), were, similarly, in the care of elderly couples without young children, who lived as much as a day's walk from Suabi. 'Swine-herding' of this sort is certainly a recent practice among Kubo. At Gwaimasi, people said they initiated the practice because pigs were spoiling gardens. This assertion sits uncomfortably with an emphasis on growing bananas, which are not attractive to pigs, with the 1986-87 observation that 'free foraging' pigs seldom spoiled gardens and with the lack of concern that wild pigs were a threat to banana gardens. In addition, the people could have fenced gardens or separated 'free foraging' pigs and gardens by the river without the need that some people lived with those pigs. Hyndman (1979: 212) reported that among Wopkaimin 'all pigs (were) kept in residentially separate pig houses ... or in hamlets used solely for pig raising'. As with Kubo in 1991, these animals were in the care of specially appointed community swine-herds (Hyndman, pers. comm.).

DISPOSAL OF PIGS

From August 25, 1986 to November 15, 1987 449.6kg of domestic pork (edible weight) were available for consumption at Gwaimasi (Table 2). This value includes all the meat from seven pigs in the care of Gwaimasi residents, four pigs in the care of non-Gwaimasi residents and 13 piglets, born to Gwaimasi sows, that were killed on the day they were taken from those sows together with portions of two pigs and one piglet that were carried as gifts to Gwaimasi. Forty-seven percent of this meat was consumed by Gwaimasi residents; an average of 25g per adult-equivalent day of residency (28g with Europeans excluded). The remaining 53% was consumed by visitors to Gwaimasi. The yield of edible meat from wild vertebrates was 255g per adult-equivalent day of residency with 56% derived from wild pigs (Europeans excluded; Dwyer & Minnegal, 1991b). Clearly the total contribution of meat from domestic pigs was minor. Nor was the killing of pigs timed to fill lulls in availability of meat from wild vertebrates; much meat from the latter was available at the time of the feast, on the day before 'nuisance' pigs were killed and on the dates of two curing rituals at which 10kg or more of domestic pork was available (see Table 2).

TABLE 2. Disposal and consumption of domestic pigs at Gwaimasi.

Description	Pigs killed (n)	Days pigs killed (n)	Total kg (edible)	Proportion consumed by residents
Payment to spirit medium	1	1	34.13	0.29
Feast	6	1	292.50	0.37
Curing ritual	3	3	36.24	0.61
Management: 'nuisance'	2	1	63.38	0.76
Management: piglets	12	7	17.40	0.86
Received as gifts[2]	3	3	5.95	1.00
Totals	27	14	449.60	0.47

1. Meat was widely and equitably shared by Kubo people. Estimates of the amounts of pork consumed by Gwaimasi residents assume, unless otherwise known (see text), that residents and visitors received shares in proportion to their numbers.
2. Portions of pigs sent as gifts to Gwaimasi; the combined weight of these portions is taken as the total weight.

Of the total edible weight of pork available at Gwaimasi 242.5kg were derived from pigs whose carers were Gwaimasi residents; removal of one pig whose male owner's residency ceased 4.5 months before the pig was killed reduces this value to 206.7kg. The estimate of 210.5kg consumed by Gwaimasi residents is a close fit to these values. However, the proportions of pork contributed and consumed by Gwaimasi residents varied according to the reasons for killing pigs. These reasons are discussed below.

Management considerations (i.e. control of herd size and elimination of 'nuisance' pigs) accounted for the disposal of 11 piglets that were only a few weeks old, one large piglet that for two months had been left with its mother and two sows that, after farrowing, often raided small village gardens. These pigs, all from the local population, contributed 30% of the domestic pork consumed by Gwaimasi residents. Eighty-six percent of the edible weight of the 12 piglets and 76% of that of the 'nuisance' pigs was eaten by residents of Gwaimasi; the latter were killed when the owner of one was visiting and he, with four companions, received a disproportionately large share of the meat.

One small piglet (1.5kg) and two pigs (17 and 40kg) were killed in connection with three curing rituals. The piglet was sacrificed over the heads of two brothers whose lives were endangered by possible contact with spirits; it was cooked and taken from Gwaimasi for consumption by a visiting male who had danced on behalf of the brothers. At both the other curing ceremonies one hind leg, together with portions of liver and entrails, were needed for ritual purposes (Dwyer & Minnegal, 1988). These portions were subsequently disposed of within the resting place of the spirits of the dead (*toi sa*, forbidden place) through a combination of consumption by bachelor males, burning and throwing to crocodile spirits. Residents contributed 38% of the edible weight of these three pigs and consumed 61%; thus, as hosts to curing ceremonies held on behalf of non-residents, they received more pork than they gave.

On the night before one of the curing ceremonies a visiting spirit medium diagnosed the causes of illness of two people; he received a 52.5kg pig in payment. The animal originated from outside Gwaimasi, was killed and cooked at Gwaimasi and portions amounting to about 10kg edible were given to residents by the spirit medium after he and his son had butchered the cooked meat.

Two medium-sized and four large pigs were killed at a feast on January 3, 1987. These six pigs represented 65% of the total edible weight of domestic pork available at Gwaimasi, and provided 52% of the edible pork consumed by Gwaimasi residents. Residents gave more than they received, contributing 51% and consuming 37% of the edible weight available. The feast was planned several months ahead and preparations were underway in late November 1986. Some people referred to the forthcoming event as *kasimes* ('Christmas', but without recognition of the etymology of that word). Visitors from Gugwuasu to the southeast arrived over several days prior to the feast and participated in arrangements. Most residents from Nanega to the west, together with some of their relatives from further afield, made a formal arrival on the evening before the feast. These people had taken several days to slowly lead (and drag!) two large pigs (100 and 120kg) that were to be killed and eaten. This embarrassed the host community which had readied two 'free foraging' pigs, each at 80kg, to feed guests. Two 35kg 'tended' pigs were selected as additions to the intended contribution.

Many of the people who resided at Gwaimasi, Gugwuasu and Nanega in 1986-87 had lived together at a different locality in late 1984. This community had split with the primary division being between what became Nanega and Gwaimasi. Nanega was established as a viable commu-

nity and village before Gwaimasi. The feast of January 3, 1987 is interpreted as an assertion by Gwaimasi residents that they now qualified as an ecologically viable and socially self-sufficient community (Dwyer & Minnegal, 1992a). Further, the feast served to reduce lingering tensions that had underlain earlier fission while, at the same time, revealing elements of intercommunity competition. This last was demonstrated as well when, on the night before the feast, two men who were perceived within their respective communities as Government-appointed 'go-betweens' (*komit*) exchanged gifts. The Gwaimasi man, who was acknowledged as 'the owner of the party', gave one tin of mackerel and a kilogram of rice and 'lost face' when, in return, he received twice the quantity of both food-stuffs.

Small quantities of domestic pork arrived at Gwaimasi as gifts from particular individuals; once, from a married man (or from his wife who had cared for the pig) to an unmarried female in acknowledgement of current restrictions on the consumption of terrestrial game and, again, as part of the distribution of a death-compensation payment to a female relative of the deceased person. Details of the third case are not known. In total these gifts comprised less than three percent of the domestic pork consumed at Gwaimasi.

With the exception of some transfers of small piglets all domestic pig transactions among Kubo were as pork and not as live animals. The primary contexts in which these transactions were made concerned statements of intracommunity solidarity, re-establishment of intercommunity relations, the needs of curing, death-compensation and, very importantly, though not witnessed by me, initiation (cf. Shaw, 1990, on neighbouring Samo). In addition, meat was eaten at feasts held to celebrate the completion of new longhouses and often this was pork. Presumably there were also a variety of situations, beyond the few seen, when small quantities of domestic pork were given by one individual to another.

WOMEN, MEN AND PIGS

Among Kubo the role of males in the day to day management of pigs was minor. Certainly, the perceptions of males were that pigs were the responsibility of women and, at the same time, the needs of pigs should not take precedence over the needs of men. It was women who should ensure that pigs did not raid gardens. On one occasion, when a woman cooked food for her pig before doing so for men who had felled trees at her new garden, a man complained that the work had made him hungry, the woman's priorities were wrong and, after all, the pig had not cut trees!

With women and dogs, men and youths participated in the capture of piglets from sows. At the village, men built secure fences around small yam plots to protect these from pigs (Dwyer & Minnegal, 1990) and it was usually men who felled sago palms used to fodder pigs. Ear clipping and castration were performed by men and they might assist when 'free foraging' pigs, which had come to the village, were returned to the backswamps. Although this last task was not frequent (n = 9 at Gwaimasi) it was arduous because these pigs were not at ease on a lead. The male kin of a carer also contributed by monitoring the whereabouts of 'free foraging' pigs, helping build sleeping platforms at forest houses and, of course, through gardening work that produced food that was fed to pigs.

It was not often, however, that males handled pigs or directly fed them. Only on one day was the role of 'carer' assigned to a male (Table 1) and only once was a man seen to collect stored sago pith to feed a pig. More often a carer's spouse might assist by taking a village-based pig to a nearby tether site and, for several months, a pig of more than 15kg was usually lifted by a man into and out of the house where it was allowed to sleep. Underlying this lack of direct engagement of males with domestic pigs was the relative exclusiveness of the bond between a carer and her pig(s); other people's pigs were difficult for anyone else to handle and at times were dangerous to approach. When a pig charged everyone ran! The most common exception to these observations was evidenced by males, especially youths, who sometimes treated small piglets as women and girls did by petting and cuddling them or, less often, taking them from the arms of a female and running off as though to steal. Youths occasionally carried a piglet in a string bag, either through the village or at departure with the piglet's carer and, once, for about 10 minutes, a 15 year-old youth walked a piglet on its lead around the village domain. His behaviour was that of public display; the transvestism was striking and was reinforced later in the day by an extended period of cross-dressing.

Details of the ownership of pigs are incomplete. Pigs were individually owned by both males and females with early teenagers eligible to be owners. Ownership and caretakership could be coincident and, usually, ownership rights went to the person who captured a piglet from a sow, wild or

domestic. One effect of this latter pattern was to disperse ownership and inhibit opportunities whereby particular owners might increase their holdings. Though, of course, both carers and owners of sows could exert some control over ownership patterns by choosing the participants in piglet capturing ventures. Pigs in the care of a woman were, if not her own, more likely to be - but were not exclusively - those of close kin. The widow Gogo cared for pigs that belonged to a clan brother, an orphaned youth with affinal links and an unrelated male. The eventual fate of some pigs in exchange was decided from the time they were piglets and, thus, long-term commitment to the caring role was itself a component of the perceived value of that exchange (Dwyer & Minnegal, 1992b).

The direct role of Kubo carers was considerable when domestic pigs were killed, butchered and distributed. For several weeks before 'free foraging' pigs were killed they were attended more closely than usual by their carer and, eventually, were brought to the village to be closely watched and regularly fed. At initiation ceremonies the need for attention was reduced by caging the pigs (cf. Shaw, 1990, on Samo). It was a woman, usually the carer, who, at the time of killing, tethered the pig to a stake, calmed it and stood within a metre or two as a man shot it using bow and arrow.

After pigs had been killed, carers moved away as men dragged the carcass to a rack where it would be butchered. Carers were sad but did not grieve openly, though once the widow Gogo sought relief by taking a year-old child from its mother and carrying the infant for 15 minutes or so. (Public grief by females was more evident when a family dog died.) But carers reappeared when men commenced butchery, standing near and sometimes sitting on the rack. They were likely to be the only women in attendance and, in the later phases of butchery when portions were selected for distribution before cooking, often gave forceful instructions to the men (Fig. 3). Carers contributed to the actual distribution of these portions and were sometimes the sole distributors; they also apportioned and distributed entrails, which women had washed, to other women. At this late phase of the precooking butchery and distribution, when most males had

FIG. 3. The woman Kose gives instructions as a pig she cared for is butchered and readied for distribution. A second woman at the butchering rack was a visitor to Gwaimasi who had been primary carer to another pig that was killed on the same occasion.

dispersed, carers might move freely about the rack as they completed a variety of tasks. Women did not contribute to laying the primary oven though some might cook ribs on an open fire for general distribution before that oven was opened. Carers reappeared and observed carefully as men took cooked pork from the oven and they sometimes participated by instruction and action in the apportionment and distribution of this meat after males had carved it.

The participation and rights of carers in the apportioning and actual distribution of pork from domestic pigs were considerable. The almost exclusive bond that existed between carer and pig presumably underlay this. Certainly, the carer was needed at the moment of killing - few other people could have tethered or calmed the pig. However, the extent of female participation varied. It was probably greatest when ownership coincided with caring. It was relatively subdued at more formal events that were attended by many guests or when they, as carers, had come as visitors with their pigs. Again, when two pigs were killed in connection with a curing ceremony that was under the close supervision of a visiting spirit medium, it was he who controlled both carving and distribution after the pork was cooked; there was no contribution from women.

DISCUSSION

This report of Kubo pig husbandry practices is based on detailed observations of a small number of pigs kept by a small number of people. These observations are sufficient, however, to show that Kubo practices were distinctive. They did not fit expectations derived from general and theoretical statements concerning the variety of strategies from New Guinea. In this sense the Kubo case enlarges understanding of the diversity of connections between people and pigs. The primary aim of the following discussion is to locate the Kubo system of pig production and disposal within a comparative frame; to highlight similarities with, and differences from, other New Guinean systems. After brief comparative comment on ratios of pigs to people I discuss (a) the work entailed in maintaining pigs, (b) the importance of domestic pigs to nutrition and (c) connections between pigs and gender roles.

Pig Populations

Ratios of domestic pigs to people vary widely throughout mainland New Guinea (e.g. Feil, 1987: 45; Kelly, 1988: 150). In broad outline these ratios are relatively high (0.60-2.0 or higher) among societies of the Central Highlands and some fringe highland groups that are either structurally and ecologically similar to, or interact often with, the former; low (0.10-0.30) among middle and low altitude societies of the rainforested interior that have little or no contact with the Highlands; and variable (0-1.0) among coastal and near coastal societies.

Geographically, ecologically and socio-culturally Kubo may be best aligned with low and mid-altitude societies such as Bedamuni, Baktaman, Wopkaimin, Miyanmin, Hewa, Sambia and Umeda where ratios of pigs to people are less than 0.30 (Gell, 1975; Hyndman, 1979; Herdt, 1981; Beek, 1987; Kelly, 1988: 150). Indeed, their territory is contiguous with that of Bedamuni to the southeast and within 60km of Baktaman to the northwest. Data from 1986-87 and 1991 reveal that Kubo kept more domestic pigs per person than did any of the other societies within this cluster. The recorded ratios of 0.27-0.54 are intermediate between those of broadly similar societies and those of Highland societies. Relative to these societies, however, Kubo are by no means intermediate according to other criteria (e.g. human population density, agricultural intensification, importance of sweet potato, existence of ceremonial cycles in which pork or live pigs are exchanged, or gender relations) that have been sometimes connected with the relative abundance of domestic pigs.

The comparative data from 1986-87 and 1991 suggest that the size of the Gwaimasi pig population in the earlier period was neither an artefact of circumstances prevailing at that time nor solely attributable to the extraordinary performance of one carer. In 1991 it was Sisigia, with her spouse, who acted as swine-herds and who had, in effect, assumed the earlier role of the widow Gogo (cf. Table 1). Gogo, in 1991, acted as primary carer to only one 'free foraging' pig. Again, in 1986-87, there was no evidence that Kubo people had increased the size of pig herds through recent decades in response to diffuse impacts of modernization. This contrasts with Kuchikura's (1990) report that Faiwol speakers, at 1000m altitude in the Upper Murray Valley, have, through the past decade, increased reliance upon sweet potato and simultaneously increased the size of pig populations.

Pig Management

Throughout the Central Highlands and in some fringe areas the absolute densities of people and

domestic pigs are relatively high. Maintenance of pigs in these areas is reliant upon provisioning the animals with food, particularly sweet potatoes, that has been grown for this specific purpose. Kelly (1988) described these systems of pig production as 'fodder-based'; they are labour intensive systems that may vary according to the relative importance of fodder and forage (cf. A.J. Strathern, 1988: 198).

Fodder-based systems of pig production permit relatively high ratios of pigs to people. But in some areas of New Guinea similarly high ratios may be achieved in a different way. Among Etoro, of the highland fringe, and Elema, of the coastal lowlands, human population densities are comparatively low but the ratios of pigs to people are like those seen in the Highlands (Kelly, 1988). The lack of significant human impact on forest habitats provides opportunities to forage domestic pigs on 'wild' foods. In these societies, therefore, after an initial period in which young pigs receive close attention and much fodder from carers they are released to forage alone. Pigs that are managed in this way become bonded to their carers and, particularly, to their usual foraging areas; this severely limits the possibility that they can be exchanged *live* between individuals or groups. Kelly (1988) described these systems of pig production as 'forage-based'; they require relatively low inputs of labour. Kelly used the Etoro case to challenge earlier theoretical argument that proposed direct causal links between the elaboration of Highland socio-economic systems and increases in the relative abundance of pigs.

In many low and mid-altitude areas of New Guinea human population density is low, forage for pigs is presumably abundant but the ratio of domestic pigs to people is low. Kelly (1988) suggested that societies located in these areas underutilize available forage. Instead, they direct minor surpluses of garden produce (or sago) to a relatively small number of mature pigs that might be either confined in cages (e.g. Keraki) or closely bonded to their carers and the normal residential sites of those carers (e.g. Marind Anim, Miyanmin, Baktaman). While agreeing that the availability of forage is not limiting in these areas I think Kelly de-emphasized the importance of forage to the pigs that *were* kept by societies of the low and mid-altitudes.

Beek (1987: 26) referred to mature Bedamuni pigs that were 'left to roam about in the forest', Barth (1975: 35) commented that 'fully trained' Baktaman pigs 'can be allowed to roam freely', Hyndman (1979: 212-213) reported that Wopkaimin allowed domestic pigs 'to spend a considerable amount of time foraging in the Mid-mountain Rainforest and secondary forest' and Baldwin (1982: 36-37) wrote that pigs kept by the coastal Gogodala 'are provided with only a minimum of food' but, rather, forage on scraps within the village area and 'venture into the nearby bush, where ... they seek out and consume such diverse wild foods as fruits, roots, worms, grubs, as well as reptiles and small mammals'. Although, in all these societies, pigs receive some rations directly from people, and, as with Etoro (Kelly, 1988: 116; Dwyer, 1990: 58), may do so through most of their lives, the impression left by most reports from low and mid-altitude societies is that, as with Etoro and as Morren (1977: 294) wrote of Miyanmin, very little human effort is expended on the production of pigs. Management of pigs by Kubo did not fit this generalization.

Management of pigs by Kubo was, at the least, time-intensive. For 12 to 18 months pigs were in the daily care of women. They were five months old before they spent the day foraging apart from their carers; among other low and mid-altitude societies, and in the Etoro case, this is about the maximum age at which the bond between pig and carer is relaxed by releasing the pig to forage alone or with other pigs. 'Tended' Kubo pigs were routinely provided with fodder, though they foraged as well, and, once released to 'free forage' in the forest, were regularly visited and often provided with pith from sago palms that had been felled on their behalf. I suggested above that 'free foraging' animals were effectively foddered for much of the time. The use of sago as a reliable source of fodder for these animals had the effect that their movements within the forest were likely to be localized and, with both 'tended' and 'free foraging' pigs, may have contributed to the moderately high growth rates inferred earlier. Hughes (1970) summarized experimental data that showed that pigs fed on sago gained more weight than others fed on sweet potato; he noted also that the fibrous pith of *Metroxylon* sago, which is favoured as pig fodder, is rich in protein. Certainly, 'free foraging' pigs were noticeably fatter than the wild pigs killed by Kubo men. Most of the latter were taken in the forested foothills; all of the former had lived in the backswamps.

On a day to day basis the management of pigs by Kubo was not labour intensive. About 6% of banana production was directed to pigs; some of this probably derived from bunches of inferior quality. This is less than Morren's (1977: 294)

estimate of 16.2% of Miyanmin garden produce fed to pigs in the form of undersized tubers and scraps and, of course, much less than the estimates of 30% or more of garden produce directed to pigs among societies of the Highlands (e.g. Rappaport, 1968; Waddell, 1972; Hide, 1981). Again, though Kubo pigs were fed much sago, the labour investment here was small. With 'tended' pigs the on-going tasks were providing (and sometimes cooking) food, attention to hygiene, making tether and lead ropes and, with larger pigs, the retrieval of animals that broke tether and wandered free within the village. Carers had much latitude as regards daytime management: they could 'herd' their pigs, which happened sometimes and had the effect that the woman concerned could do little else at the same time; they could tether the pigs in the forest which meant that the tether sites had to be changed several times in the day; or, as happened most often, they could combine the care of pigs with whatever other activity they had chosen for the day. Again, therefore, it was the investment of time and not of labour that was of primary significance in the management of pigs by Kubo. And the important outcome of this pattern of investment was that the bond established between a pig and its carer was exceptionally strong and, effectively, non-transferable. This bond was more important than bonds to specific foraging areas that might be established through long term familiarization with those areas. Domestic pigs sometimes returned from the forest, or crossed the Strickland River, to find their carers; I have no records of pigs returning to favoured foraging areas (cf. Dornstreich, 1973: 244). This argument has implications concerning patterns of management in areas where human populations are relatively mobile (cf. Hyndman, 1979: 212).

Relative to descriptions of pig management practices among other low and mid-altitude societies of the interior, Kubo practices were similar as regards low investment of labour but differed in terms of the much greater investment of time, the importance of fodder (where this includes sago) and a heightened degree of bonding. Except on one count they differed in the same ways from Etoro. Though Kelly (1988: 119) concluded that Etoro pig-keeping practices 'require minimal labor inputs' he did not refer to the fact that Etoro gardens are fenced and that this task is necessary only because both wild and domestic pigs are strongly attracted to sweet potato. Indeed, at higher altitudes of Etoro territory, wild pigs were rare and all garden fencing (8.27km in 12 months by 109 people; Dwyer, 1990) must be regarded as labour invested in the management of pigs. Thus, among Etoro, the investment of labour in the management of domestic pigs is, in fact, relatively high as, of course, it is among Highlanders who must fence gardens to protect sweet potato[2].

Among Kubo the investment of time in the care of pigs and the bond established between pigs and their carers were correlated. Both may be linked, at least in part, to the fact that Kubo kept many dogs that were life threatening to free-running piglets (Dwyer & Minnegal, 1992b) and to the necessity to isolate the numerically small domestic population of pigs from the very much larger wild population. Kubo pig management practices constructed 'psychological' fences between domestic pigs and their wild counterparts; without this barrier there might have been no 'domestic' pigs. In fact, among Kubo, the 'tended' pigs of one carer were effectively isolated from those of any other carer; this is not the usual state of affairs elsewhere in New Guinea. Taken overall, this discussion of Kubo management procedures suggests that future comparative analyses should attempt to disassociate the variables of fodder vs forage, time vs labour investment, and bonding to carer vs bonding to foraging area. In earlier studies these have been often treated simplistically. Within New Guinea, there are multiple expressions and many possible combinations of these important variables.

Pigs and Nutrition

Pigs feature prominently in proposed explanations of social and agricultural evolution in New Guinea. The central theme of most accounts within this genre is a concern with the emergence and elaboration of Central Highland's formations from precursors in which the social relations

[2]There is a problem for analysts here. When Kubo people fence tuber gardens they state that they are doing so to control pigs; it is easy to categorize the work as connected with the management of pigs. But when Highlanders, and Etoro, initiate gardens by enclosing areas within a fence their perceptions appear to be that the work is integral to gardening despite the fact that there would be no need for that work if there were no pigs. Analyses of the division of labour associated with different subsistence domains might reach different conclusions when making fences is regarded as gardening or as pig management respectively. Conclusions might vary also as the perspective of analysis shifts from 'operational' to 'cognized' in the sense of Rappaport (1968).

within and between groups were different and the production of both garden foods and pigs was less intensive (Morren, 1977; Watson, 1977; Modjeska, 1982; Feil, 1987; Kelly, 1988). These accounts differ from each other in the emphases assigned to ecological and social determinants of the context and process of change, in the connections proposed between pig production and expressions of inequality within social groups and, indeed, in situating gender inequality as relatively early or relatively late in the proposed evolutionary sequences.

One theme, however, appears to unite these interpretations: intensification of pig production within New Guinea is thought to be connected with a decrease in the availability of wild animal protein sources. This connection may be explicit or implicit. It is associated with either the earlier phases of transformation (e.g. Morren, 1977; Watson, 1977; Modjeska, 1982; Feil, 1988; see also Golson, 1982) or thought to emerge later as human and pig populations increased in parallel and the demands of the former led to forest reduction and a need to provide pigs with large amounts of garden produce in lieu of forage (Kelly, 1988). The former view, at least, implies that domestic pigs were an important source of supplementary animal protein even in areas where the ratio of pigs to people was low.

At the most, the average daily contribution of protein from domestic pigs was 3.75g per 'adult' Kubo consumer (i.e. 15% of edible meat with consumption values for children adjusted as in Dwyer & Minnegal, 1991b). This is less than 10% of the protein derived from wild vertebrates. In addition, Kubo ate many invertebrate animals, with crayfish, shrimps (*Macrobrachium*) and weevil larvae adding considerably to the intake of animal protein. Meat from domestic pigs was eaten irregularly and there was no suggestion that domestic animals were killed to fill shortfalls in the supply of meat from wild animals. By New Guinea standards, Kubo ate a lot of animals; their protein intake was probably well in excess of requirements and, hence, the minor contribution from domestic pigs cannot be interpreted as having threshold significance.

I conclude that the production of domestic pigs by Kubo was of no importance in terms of protein nutrition. It is likely that, with few caveats, this conclusion applies throughout New Guinea. It may be the case with some societies that domestic pigs are killed and consumed at times when other sources of protein are scarce or, more likely, that other sources, though available, are foregone at times when domestic pigs are eaten (cf. Morren, 1977: 289). It may be also the case among some Highland societies that protein is generally scarce and the consumption of domestic pigs tips the balance in favour of adequate requirements. But I cannot agree with the statement that for most Highlanders domestic pigs are 'the major source of high-quality protein' (Golson & Gardner, 1990: 396).

The nutritional advantage of animal foods over most plant foods is that the former provide a balanced array of amino acids and, as well, may be the only locally available source of vitamin B12. Some amino acids, often described as the 'essential' amino acids or implicated by statements such as 'complete' or 'high quality' protein, appear to be present in few plant foods. These, together with the more widespread amino acids, must be eaten regularly if human protein nutrition is to be adequate. In New Guinea, pork from domestic pigs is neither eaten in sufficient quantity nor with sufficient regularity to make a significant, on-going contribution to minimal amino acid requirements. Hide (1981: 508) estimated that Waula (Sinasina) people received only 3g protein/person/day from domestic pigs and that, on average, households consumed pork once a fortnight. Through the 12 months of Hide's study the ratio of pigs to people varied between 0.83 and 0.89. Assuming that off-take is proportional to the relative size of local pig populations it is unlikely that the protein contribution from domestic animals approaches 10g/person/day anywhere within New Guinea. Unless it is shown that this is achieved regularly and not, as the literature consistently suggests, very irregularly the conclusion remains unaltered. Norgan et al. (1974) reported high levels of protein intake derived from plant foods among Papua New Guinean Highlanders. Analyses of the amino acid content of New Guinean plant foods are needed to advance understanding of protein nutrition in areas where wild animals seem to contribute little to local diets.

Sorenson (1976: 54) wrote of the Fore that 'sometimes there were periods of several consecutive months without pork, followed by several days of glut after a ceremonial feast'. Occasions of excessive pork consumption are widely reported from Highland societies (e.g. Vayda, 1972: 906). From a nutritional perspective their significance is less likely to concern protein balance than to pose the risk of protein poisoning. Protein foods are potentially toxic unless they are eaten with sufficient quantities of

foods that supply energy (Noli & Avery, 1988; Speth, 1990, 1991). Where protein, from either plants or animals, is used as an energy source then the safe level of intake may fall well below 50% of total calories and, for pregnant females, may be as low as 25% of total calories. Further, high levels of intake of lean meat may be unsafe unless total calories from carbohydrates or fats is increased above normal levels. Noli & Avery (1988: 396), referring to earlier reviews by McGilvery and Speth, wrote that 'when protein is used as the sole source of energy by humans it can lead to nausea and diarrhoea in as little as three days .... It is also clear from the various case study examples cited by Speth that consumption of lean meat alone led to symptoms of starvation and protein poisoning within a week, diarrhoea within 7-10 days, severe debilitation within 12 days and the possibility of death within weeks'. We were reprimanded often by Kubo when we did not cook sago to accompany meals of pork; the people were not convinced that rice was a sufficient substitute for sago.

Carbohydrate foods and fats provide energy in the diet. New Guineans often reduce carbohydrate intake when pork is available in quantity but they may offset the risk of protein poisoning because they prefer, and in many societies deliberately promote, fat pigs. The thought of fat pigs was keenly anticipated by Kubo. A month before the feast one man exclaimed *'Sori! O wai safei kau'* ('Sorry! The fat of domestic pigs is abundant'). The ethnographic literature from New Guinea abounds with reports of similar statements. Baktaman rub pigs with special white, powdered earth to magically promote fat (Barth, 1975: 35), the ideal Keraki pig was one that grew so fat it could not stand (Williams, 1936: 18), Sanio Hewa castrated all domesticated male pigs 'at a few months of age "to make them lie around and get fat"' (Townsend, 1969: 49) and, for the same reason, Marind Anim kept only barrows (van Baal, 1966: 406). In the Highlands people may prevent sows from breeding or increase the supply of food to pigs as deliberate attempts to fatten animals in readiness for killing (e.g. Hide, 1981). Comparable statements or procedures that extol the value of the *meat* of domestic pigs are very rare.

Throughout New Guinea, whether the ratio of domestic pigs to people is high or low, the significance of the animals is located in the social and not the nutritional sphere. If there are, as well, nutritional benefits then these concern fat more than they concern protein. In the first place, fat pigs reduce the risk of protein poisoning, especially on occasions when much pork is eaten and the normal intake of carbohydrate foods is reduced. Here, the nutritional role of fat is indirect - it is a source of energy that reduces risks associated with eating large amounts of meat. In addition, however, early nutritional surveys within New Guinea consistently reported that fat (including lipids) was poorly represented in local diets (e.g. Oomen, 1971). On this count, therefore, the nutritional significance of the fat from domestic pigs may be also, at some times and in some places, direct.

Pigs and Gender

Conventional wisdom has it that among Highland societies inequalities among men and between men and women are intimately tied to patterns of pig production (e.g. Modjeska, 1982; A.J. Strathern, 1982; but contrast with Kelly, 1988). Men strive for prestige. They do so by publicly exchanging valuables, especially pigs and pork. But the labour and time required to rear those pigs has been, for the most part, invested by women. Thus, in pursuit of prestige and leadership, men compete with one another, appropriating the labour of women to their own ends in the process. The outcome is that relations of inequality emerge among males, and women are disenfranchised and disempowered. Under the standard argument these inequalities between individuals and sexes are likely to be greatest where the ratio of domestic pigs to people is highest (cf. Feil, 1987). Indeed, a poignant focus of Highland exchange systems is that, ultimately, the labour invested by women in the production of pigs becomes the means whereby men acquire other women as brides in exchange for those pigs[3].

Among Kubo, relations between men and women were characteristically relaxed and warm. There was no ethos of sexual antagonism and little concern with sexual pollution (cf. Sørum, 1984, on Bedamuni). Public expressions of affec-

[3]In contrast to the standard argument, Feil (1987: 57-58) asserted that gender inequalities were least severe among societies of the Western Highlands where ratios of pigs to people were particularly high and agricultural production was intensive. He thought that 'it is in societies where production and exchange are truncated and circumscribed ... that inequalities, especially between men and women in the production process are the most severe'. M. Strathern (1988) provides a challenging counter to Feil's understanding of gender relations in the Western Highlands.

tion between husband and wife were relatively common (e.g. holding hands, resting in the lap of one's spouse, play-fighting). Aggressive fights were very rare and, for husbands in particular, triggered self-recrimination and a lengthy period of awkward reconciliation. In the subsistence domain, gender roles were conventional and complementary rather than culturally legislated and they were often transgressed. Women sometimes hunted, men sometimes pounded the pith of sago palms and young girls could play with bows and arrows. Though men and women slept in different sections of the communal longhouse, women were not prohibited from entering the men's section. At family houses in the village, gardens or forest there was even less spatial separation between husband and wife.

Kubo women participated less than men in ritual life. They did not dress up and dance as men did (Dwyer & Minnegal, 1988) and, with the possible exception of a focal individual, they (and their pigs) were excluded from seances and the closing moments of curing ceremonies; here, however, the perceived danger was not so much to the women themselves as to infants, including the unborn, with whom women closely associated. But women performed as lead singers and as chorus on all occasions when men danced and, though young women were not initiated, both older men and older women acted as formal sponsors to male initiates. (Among neighbouring Samo, young women were also initiated; Shaw, 1990.)

By New Guinean standards the extent to which female carers of domestic pigs were necessary and active participants when the animals were killed, butchered and distributed was unusual. In ideal circumstances affinal exchanges of pork entailed the simultaneous distribution of meat from two pigs, one contributed by each of the participating groups. This paralleled the ideal of immediate sister exchange as the basis of Kubo marriages. With both the marriages and the exchanges of pork either of the focal women - a bride-to-be or a pig's carer - could veto the intended arrangements. Again, the ideal of simultaneity might not be met because one of the intended partners was judged to be too young or one pig was judged to be too small.

The control that Kubo women exercised over the disposal of domestic pigs may be linked to management practices. The ratio of pigs to people was unexpectedly high and the time devoted to rearing the pigs was considerable. Nearly all the work was done by women and the strategies of management were such that domestic pigs were so closely bonded to particular carers that the animals were non-transferable. (It seems unlikely that this statement will remain true in the new circumstance of communal swine- herding that is being developed by Kubo.) The permission and physical presence of a pig's carer was perceived as essential when the pig was killed. Though carers were not necessarily owners their engagement with a particular pig persisted through the life of that pig. Because pigs in the care of one woman were effectively alienated from association with other people, and from the pigs owned by those people, there was little opportunity for men to usurp the role of women as the time approached to kill the pigs.

Among Etoro it was the person who completed a process of production who controlled distribution of the product (Kelly, ms.); with domestic pigs it was men who retrieved the animals that were to be killed, who killed and butchered them and who distributed pork at events where other men were the public recipients of the gifts (see also Dwyer, 1990: 130-132). By contrast, among Kubo, women prepared the pigs for dispatch, stood with them as they were killed and officiated at distributions. Their participation was greater and more overt than that described for Baruya women by Godelier (1986: 15-16). From the perspective advanced by Kelly the role of Kubo women is understandable; they were needed to complete the process of production and, hence, shared in the process of distribution. But was that role necessary?

It is difficult to assign either ecological or social imperative to the patterns of pig production and disposal described here for Kubo. There were more pigs than expected and, by comparison with ecologically similar societies, it appears that they could have been managed with far less commitment from carers and with far more latitude for dispersing the caring role. Domestic pigs do not need to be dangerous to people who are not their primary carers! The importance of the animals was not to nutrition but, rather, to the satisfaction of a variety of social concerns. At these events the role and status of women may have been less pronounced if management strategies had been different. The simple conclusion is that Kubo patterns of pig production empowered women and contributed to the markedly egalitarian ethos of Kubo society. This conclusion may seem analogous to that of Feil (1987) regarding Tombema-Enga of the Central Highlands; the analogy, however, would be superficial because any similarities arise within social and ecological contexts that

are entirely different. Both Kubo and Tombema-Enga represent distinct transformations of the commonalties that underlie and unite Melanesian social life (cf. M. Strathern, 1988).

ACKNOWLEDGEMENTS

Thanks are due to the University of Queensland for awarding periods of leave, to the Biology Department, University of Papua New Guinea, and the Papua New Guinea National Museum for affiliation and to the Government of Papua New Guinea for granting research visas. Monica Minnegal shared the work with me and commented on my ideas. Yutaka Tani influenced my understanding of the importance of bonding; Ryutaro Ohtsuka and Tsukasa Inaoka discussed ideas concerning nutrition; and Chris Healey and Robin Hide made useful suggestions on the manuscript. I am very grateful to the pig carers of Gwaimasi, and their families, for their teaching and friendship and dedicate this paper to Gogo who died in February 1992.

David, B. & Dagg, L. 1993 06 30: Two caves. *Memoirs of the Queensland Museum* **33**(1): 143-162. Brisbane. ISSN 0079-8835.

This paper presents results obtained from two archaeological excavations undertaken in the Mitchell-Palmer limestone belt, north Queensland. The sites were excavated in order to investigate temporal patterning in the archaeological record, and especially to obtain information on the antiquity of rock art in the region. In line with previous models of change in Aboriginal prehistory, the results indicate major changes during the mid to late Holocene. They also indicate that the rock paintings from the region may largely date to the last 3500 years, whereas the peckings may be older. □ *Australian prehistory, rock art, north Queensland, intensification, cave paintings, rock engravings.*

Bruno David, Department of Anthropology and Sociology, University of Queensland, Queensland 4072, Australia; Liam Dagg, Department of Archaeology and Palaeoanthropology, University of New England, Armidale, New South Wales 2350, Australia; *14 August, 1992.*

In 1983, Lourandos argued that, in many parts of Australia, major social and cultural changes took place during the mid to late Holocene. Amongst other things, archaeological evidence for these changes include significant increases in deposition rates of cultural materials within individual sites, increases in the number of occupied sites in the landscape, a broadening of resource exploitation strategies (including diet breadth), and major changes in stone artefact technologies. Together, it has often been suggested that these points implied major increases in intensities of site and regional land use (e.g. Hughes & Lampert, 1982). What has been lacking, however, is data to determine the relationship of the separate regional sequences, so as to enable an investigation of the dynamics of structural phenomena, such as inter-regional relations, alliance systems and exchange networks. It is these issues, it is argued, that would enable us to better understand the social contexts of the archaeological changes documented so far.

This paper emanates from these concerns. It presents the results of two archaeological excavations undertaken in the Mitchell-Palmer limestone belt, north Queensland, forming part of a broader research program focusing on the dynamics of socio-cultural (inter-regional) relations during prehistory. In order to investigate socio-cultural structure in prehistory, rock art has been the object of enquiry. Rock art is treated as governed by socio-cultural conventions, so that by investigating continuities and discontinuities in the distribution of rock art through space and time, socio-cultural patterning is itself being investigated. To shed light on such patterns, a number of sub-regions within north Queensland have been systematically surveyed for rock art sites, thereby enabling an investigation of spatio-temporal trends in rock art conventions.

This paper is a contribution towards these investigations. In order to determine the antiquity of the art, a number of rock art sites were excavated. These excavations enabled the recovery of in situ pieces of pigment (the by-products of artistic endeavours), as well as information on other temporal trends (e.g. stone artefact deposition rates). Together, these data have contributed significantly to our understanding of change and stability in the region.

The aims of this paper are thus to report on excavations undertaken at Hearth Cave and Mordor Cave. In presenting the data obtained from these excavations, broad trends will be revealed, trends that are consistent with those obtained from other sites in north Queensland (David, in prep.).

THE MITCHELL-PALMER LIMESTONE BELT

The Mitchell-Palmer limestone belt consists of a 60km long and 5km wide belt of karst towers (Fig. 1). Caves are abundant throughout the limestone (Fig. 2), two of which were excavated by the author in 1989 (Mitchell River Cave and Hearth Cave). Mordor Cave, located in the Mordor North Tower, was excavated by one of us (BD) in 1991. In all cases, excavation followed the Johnson (1979) method of bucket-spits. All

cultural materials 2cm maximum size were plotted in three dimensions, and all other materials were sieved in 3mm-mesh sieves. As the results from Mitchell River Cave have already been presented elsewhere (David, 1991a), this paper only documents the Mordor Cave and Hearth Cave data.

MORDOR CAVE

Mordor Cave is a large limestone cave with an uneven, rocky floor located 12 km north of the Mitchell River. It was first rediscovered by L. Pearson on the 17 June 1979, when the Chillagoe Caving Club undertook speleological explorations in the Mitchell-Palmer limestone belt. Mordor Cave was described by the Chillagoe Caving Club Inc. (1988: 43) as having

> 'three large entrances interconnected with twilight and dark zones linking them horizontally. A peripheral system with some excellent decoration. Aboriginal paintings are executed on walls in mono- and bichrome silhouettes. There are over 140 individual paintings of human figures, dingoes, emus, bats and crocodiles. A pool of water would have served for ochre preparation. Some hand stencils and some inverted figures.'

The main entrance to the cave involves a moderate climb up boulder-strewn pediments, followed by a descent onto a flat floor located near the back wall. It is here that the only occurrence of soft, ashy deposits is located (Fig. 5). On the cave wall are 300 paintings and 11 stencils, most of which are monochrome infilled and red in colour (Table 1, Figs 3, 4). A number of roof collapses give entry to deep caverns along both ends of the cave. Two edge-ground axes and a stone flake were found amongst collapsed material which can be reached by a short walk through pitch-black corridors in these caverns. It is possible, however, that the artefacts were thrown into the collapsed chambers from the skylit chamber above (that is, the main chamber containing the soft ashy deposits).

Mordor Cave was excavated mainly because of

FIG. 2. Limestone karst tower, Mitchell-Palmer limestone belt.

FIG. 3. Mordor Cave, painting of a pig.

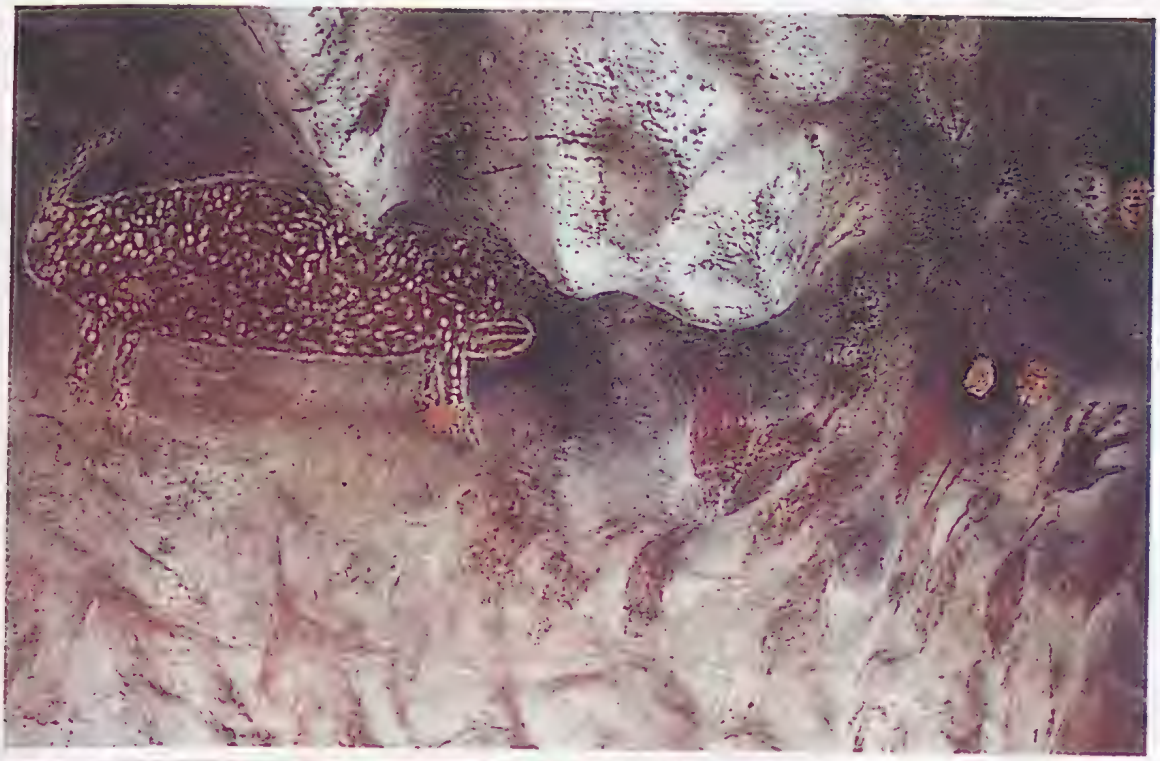

FIG. 4. Mordor Cave, main painted panel.

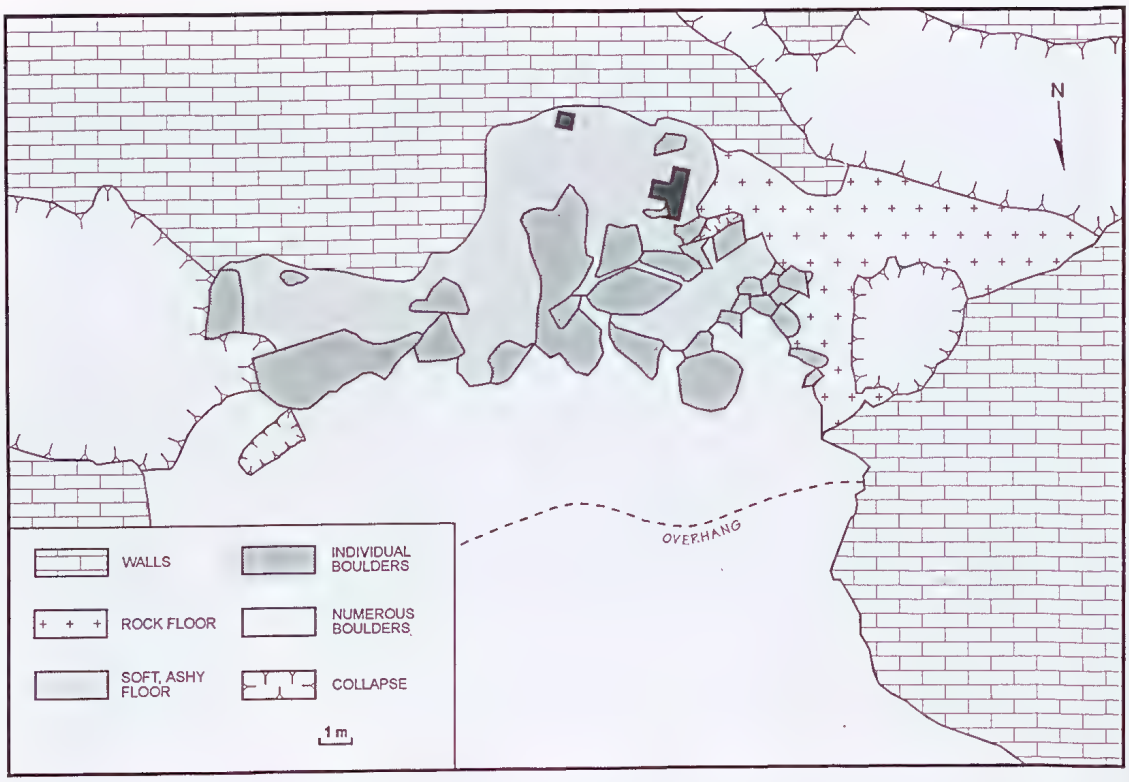

FIG. 5. Mordor Cave, site plan. The arrow points to magnetic north. The excavation squares are represented in infill; Square E18 is the isolated square, and H10 is the centre square of the T-shape excavation.

the large numbers of paintings and stencils on the cave wall, immediately adjacent to soft archaeological deposits. The great numbers of paintings located within a spatially constricted area near soft deposits were deemed to offer great potential for the recovery of in situ ochres, offering the possibility for dating the art by association with dated, in situ ochres. Two test excavations were undertaken in the soft ashy deposits. Square E18 consists of a single 50cm× 50cm pit located near the centre of the soft deposits, where sediments appear to be at their deepest in this part of the site. The main excavation was undertaken 3.5m from square E18, and consists of squares G10, H10, H11 and I10. Square H10 was initially chosen for excavation because it was located in what appeared to be the deepest part of the site. Squares E18, G10 and H10 were excavated to bedrock, while squares H11 and I10 were only partly excavated in order to enable access into adjacent squares G10 and H10. In total, 1.25m^2, or 2.0% of the 66m^2 of soft ashy floor, were excavated. All excavated sediments were very dry at the time of excavation. At some distance from the ashy deposits, closer to the dripline, large lag deposits indicate the existence of drip points and seasonal pools of water.

The excavated materials from squares E18 and H10 have been sorted and analysed and are presented here.

TABLE 2. Stratigraphic Units (SUs) from Mordor Cave, square E18.

SU	pH	Dry	Munsell	Description
1	8.5	10YR	6/2	Surface sediments, grey in colour and ashy in composition. It is loose and appears to be very disturbed. No vegetation appears on the surface.
2	8.5	10YR	6/2	Ashy sediments whose texture is similar to SU1, but with a moderate compaction. Sediments show no evidence of disturbance. No internal stratification is evident.
3a	8.5	2.5YR	3/2	Very dark, black, charcoal-rich sediments with patches of white ash
3b	7.5	10YR	5/4	Brown silty deposits with a high charcoal content. Very rich in vegetation. Vegetation appears horizontally bedded immediately above the bedrock.

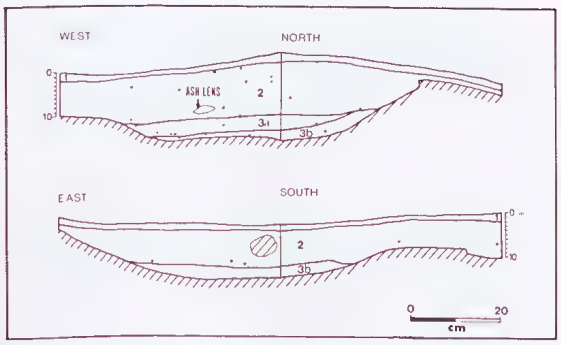

FIG. 6. Mordor Cave, Square E18 stratigraphy. The dots represent pieces of charcoal.

Square E18

Square E18 is well stratified, containing three Stratigraphic Units (SUs), SU3 being further subdivided into two sub-layers (Table 2 & Fig. 6). All stratigraphic units are well defined. Excavation proceeded in seven Excavation Units (XUs), the average thickness of which was 2.6cm.

Square E18 is 20.0cm deep. A single radiocarbon date was submitted from XU7, immediately above bedrock. A radiocarbon date of 1640±70 BP (Beta-46090) was obtained, with a $\partial^{13}C$ value of -28.4‰. The $\partial^{13}C$-adjusted age of 1580±70BP is taken to date the beginnings of occupation in this part of the site.

Table 3 presents a complete list of materials recovered from E18. The fauna is listed in Table 4. In Table 5, the raw data have been converted to deposition rates per m^2 per centimetre of deposit, to enable comparisons of deposited materials by XU. Because only a single date was obtained from square E18, the time frames covered by each spit could not be calculated. Therefore, deposition 'rates' were obtained by calculating the amounts of material recovered per m^2 per centimetre of deposit. These deposition 'rates' are graphed in Fig. 7.

SU1, represented by XU1, contains relatively low amounts of charcoal, bone, land snails, stone artefacts, eggshell, mussel shell and ochre. The proportion of burnt eggshell is also low. Compared with underlying SU2, the sediments contain large amounts of organic material (especially twigs and bark), and compaction is relatively low (as measured by weight per volume). These findings are not surprising given that, firstly, the site is not believed to have been occupied during the last 100 years, and secondly, that the surface sediments were very loose during excavation.

SU2, represented by XUs 2-5, contains large numbers of stone artefacts, land snails, eggshell, mussel shell, ochre, charcoal and burnt earth. Quantities of all cultural materials are relatively low towards the lower boundary of SU2. This may indicate that a hiatus is represented at the SU3-SU2 boundary, or that XU5, the lowermost XU from SU2, should be treated as an interface between SU3 and SU2. This interface should be treated as comprising of intermixed SU3 and SU2 materials.

SU2 contains relatively compact sediments and relatively low amounts of organic materials (mainly vegetation), except for XU5. Here, the organic content is similar to that from underlying SU3a. This further re-enforces the likelihood that XU5 contains materials from the underlying stratum.

SU3a is represented by XU6. It is rich in stone artefacts and bone, but relatively poor in all other cultural materials. Sediments are very compact

TABLE 3. List of materials excavated from Mordor Cave, Square E18.

and contain very high amounts of vegetation. The percentage of burnt eggshell is very high.

SU3b (XU7) contains low amounts of all cultural materials except for stone flakes. Sediments are not as compact as overlying SU3a, and their organic content is low. The percentage of burnt eggshell is very high.

The part of Mordor Cave represented by Square 18 is interpreted as having been first occupied approximately 1500 years ago. At that time, occupational intensities were low. During SU3a times, large amounts of organic material, including bark and twigs, were laid horizontally on the cave floor. This layer is well defined, and associated with a low deposition 'rate' of all cultural materials, except for stone artefacts and bone. Stone artefacts are very small, averaging 0.7g. These factors indicate that the sediments recovered from SU3a may have been a sleeping mat, and that during this time the area was used as a sleeping area. It is therefore possible that contemporaneous materials from other parts of the cave would reveal complementary, specialised activity areas, such as hearths and stone artefact manufacturing areas.

During SU2 times, Square E18 witnessed relatively intensive deposition of cultural materials. It is during this time that most of the paintings on the walls were probably undertaken, as indicated by peak ochre deposition rates during this time. Fires lit during SU2 times may have caused the high proportions of burnt eggshell in XU6 and XU7 underneath. As eggs cannot be roasted directly on a fire (or they would shatter or explode; L. Hughes, pers. comm., 1992), burnt fragments of eggshell are likely to represent subsequent burning by overlying hearths.

The well preserved sediments also contain one large bracket fungus (Fig. 8). It is a single sporocarp of a member of the order Aphyllopharoles, family Polyporaceae. It is probably from the genus *Polyporus*, and possibly *P. udus* (P. Bostock & C Young, pers. comm., 1992). The dryness of the cave, and the compaction of the sediments, indicate that it could not have grown in the deposits, but must have been introduced into the cave. Such fungi are known to have been eaten by Aborigines in north Queensland during ethnographic times.

SU1 times include the post-contact period, including the recent period when the site was abandoned. Consequently, the low densities of cultural materials during this time are not surprising.

Square H10

Square H10 is 114.5cm deep, containing four distinct Stratigraphic Units, some of which are further sub-divided into a number of sub-units (Fig. 9). The SUs are described in Table 6.

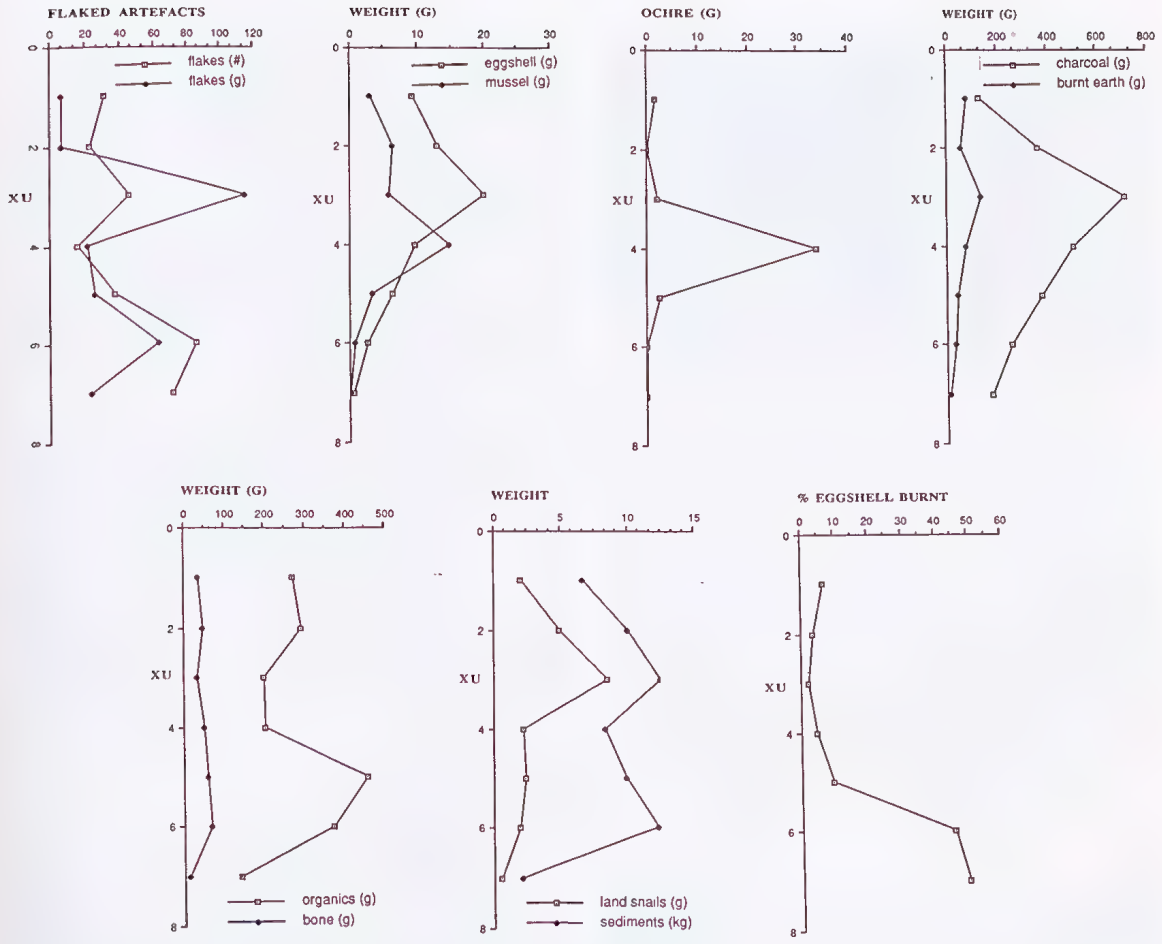

FIG. 7. Mordor Cave, Square E18, deposition rates (per m^2/cm of deposit) and proportions of burnt eggshell.

Two radiocarbon dates were obtained from Square H10 : 980±60BP (Beta-46317), located 84.7cm below the ground surface, in XU25 (SU4). The $\partial^{13}C$ value equals -27.6‰, and the ^{13}C-adjusted age is 940±60BP; and 850±50BP (Beta-46318), located 114.0cm below the ground surface in XU28 (SU4). The $\partial^{13}C$ value equals -28.2‰, and the ^{13}C-adjusted age is 800±50BP.

The two radiocarbon dates are similar and overlap at two standard deviations. They are taken to confirm the impression gained during excavation, that SU4 is an archaeologically instantaneous event.

Square H10 was excavated in 28 spits, XU10 of which was excavated in three sections (XUs 10a, b & c). Table 7 documents the amounts of materials excavated from square H10. Table 8 presents the deposition 'rates' as calculated per m^2 per centimetre of deposit (Fig. 10), while Table 9 lists the fauna identified from square H10.

SU1: this unit consists of XU1 and XU2. It contains relatively large amounts of charcoal, burnt earth, stone artefacts, mussel shell, eggshell, seeds and other vegetation. In short, SU1 represents a peak in deposition rates of a number of cultural materials.

SU3: this unit consists of XUs 3-6. It contains varying but relatively low amounts of cultural materials. XU7 is an interface between SU3 and SU4.

SU4: this unit consists of XUs 8-28. The lowermost seven XUs (23-28) are from SU4h, which appears to be a localised variant of SU4, containing leaves and seeds amongst a rich vegetation (especially bark and twig) matrix. Leaves do not occur above XU22. Whilst SU4 contains similar amounts of cultural materials to SU3, SU4h contains significantly higher amounts of bone and a greater proportion of burnt eggshells, with ochre and pandanus nuts occurring exclusively in this

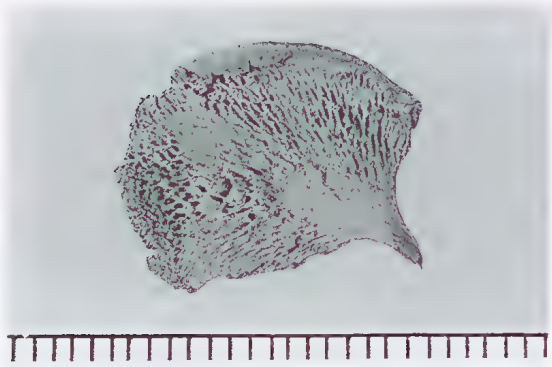

FIG. 8. Bracket fungus found in XU2, Square E18, Mordor Cave (scale in 2mm units).

unit. Amounts of charcoal are more variable between XUs of SU4h than is the case in SU4 proper above it. SU4h sediments contain a relatively high proportion of sediments over 3mm in minimum size, although stone artefacts are very rare. Interestingly, XUs 20-21, located near the boundary of SU4 and SU4h, contain 98.2% of the burnt stone recovered from Square H10. Given that relatively high percentages of burnt eggshell, as well as consistently high amounts of charcoal and burnt earth also appear in this part of the excavation, SU4 and SU4h may be related to a hearth. This is also supported by the fact that some of the vegetation making up the organics from SU4 is partly burnt. SU4 and SU4h may therefore represent materials dumped when a cooking hearth was emptied to retrieve the cooked food. However, while this explanation would explain the 'instantaneous' appearance of the deposits and the burnt material, it does not account for many of the cultural remains within SU4/4h (see below).

A number of wooden objects, including a digging stick (from XU22) and a large sheet of cut bark containing a number of pandanus nuts around and on top of it (XU25), were also located within SU4 (Fig. 11). A grinding stone with two ground surfaces was also recovered from XU 26. All of the ochre (3 white pieces, totalling 1.4g), none of which contained use-striations, came from XU25 and XU27. A fig (*Ficus virens* var *sublanceolata*, *F. obliqua*, *F. platypoda*, *F.*

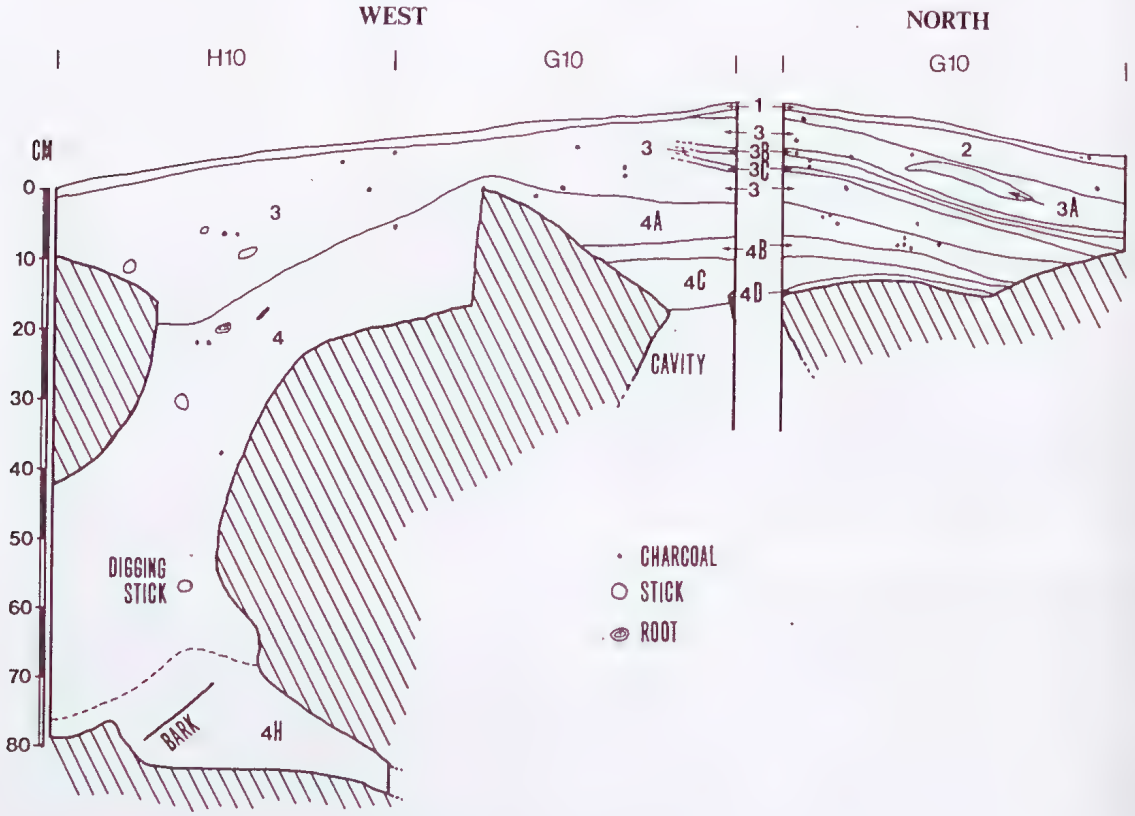

FIG. 9. Mordor Cave, Square H10 stratigraphy.

TABLE 6. Stratigraphic Units (SUs) from Mordor Cave, square E18.

SU	Dry	Munsell	Description
1	10YR	6/2	Loose, disturbed, grey, asy.
2	10YR	6/2	Some vegetation present especially in some parts of Square G10. Brownish-grey in colour. Ashy and moderately compact.
3	10YR	6/2	Ashy, grey
3a	10YR	6/2	Localised lens of vegetation.
3b	10YR	6/3	Well-defined, fairly compact.
3c	10YR	6/3	Well-defined, fairly compact.
4	10YR	5/3	Very rich in vegetation. This unit contains very little sediment apart for the matted vegetation.
4a	10YR	6/3	Dark grey vegetation sub-layers.
4b	10YR	5/3	A grey vegetation sub-layer.
4c	10YR	6/3	Dark grey vegetation sub-layers.
4d	10YR	3/1	A grey vegetation sub-layer.
4e	10YR	6/3	Dark grey vegetation sub-layers.
4f	10YR	6/2	A grey ashy unit.
4g	10YR	7/2	A grey vegetation sub-layer.
4h	10YR	5/4	A brown vegetation unit.

racemosa, *F. opposita* or *F. coronulata*; P. Bostock, pers. comm., 1992) was also retrieved from XU23. The fruit contains the dried, soft tissue, and shows no evidence of fully developed seeds (Fig. 12). All of these items come from SU4h or the SU4-SU4h interface zone, indicating that SU4h may have been a different depositional unit to SU4. Coupled with the fact that all of the pandanus nuts and leaves also come from this unit, SU4h is interpreted as having been laid immediately before SU4 was deposited. This took place sometime around 900 years BP. The most parsimonious explanation for SU4/4h may thus be that the vegetation-rich SU4h was laid together as a single unit. This involved wedging vegetation between boulders devoid of underlying sediments, thereby creating a localised 'false floor'. The digging stick, sheet of cut bark, and the pandanus nuts were then placed on top of this matted vegetation layer, and the whole lot was then covered with more vegetation (containing some hearth remains). The reasons for this are unknown, but ethnographic parallels are known from the Mitchell River delta (pers. obs., 1992). Here, Aboriginal people are known to bury people's 'rubbish' (including cherished material items) after their death. It is possible that the Mordor Cave SU4/4h layer relates to a similar practice, although this is, at this stage, mere speculation.

Discussion of Mordor Cave

An interesting parallel between both Squares E18 and H10 is the large amount of vegetation recovered from the excavations. Especially important is the presence of a bracket fungus from XU2 of Square E18, and a fig from XU23 of Square H10 (dated to approximately 900BP). The very large numbers of Brush Turkey *(Alectura lathami)* eggshell recovered from both squares and from all SUs may also indicate that the site was used on a seasonal basis, and that it was repeatedly re-occupied during the same time of the year (August-December). 2515 fragments of eggshell were excavated from square E18, and 2340 pieces from square H10, distributed throughout the excavated sequences. A single Brush Turkey feather was also recovered from H10 XU3 (Fig. 13).

It is difficult to relate the E18 stratigraphy to that of H10 given the insufficient number of radiocarbon dates obtained. Nevertheless, the peak occurrence of ochre half-way through the deposit in Square E18, whose base was dated to 1500BP, equates well with peak ochre deposition rates around 900BP in Square H10, and may indicate that most of the paintings at the site were undertaken around that time. There is no evidence for any rock art activity at the site having been undertaken before approximately 1500BP. Nevertheless, the presence of a painted pig indicates that cave painting continued into contact times.

Hearth Cave

Hearth Cave is located towards the northern end of the Mitchell-Palmer limestone belt, 9km south of the Palmer River. It was recently rediscovered during speleological explorations by the Chillagoe Caving Club, who report (1988:62):

> Located on 01/04/83 by M. Andersen on north eastern end of tower .... A phreatic slot leading back into tower, 3m wide at entrance. Floor is moss and fern covered. Slot develops to the rear far enough to provide shelter from rainfall. In the small narrow section at the back is a significant ash pile, 2m by 2m and 200mm to 300mm higher than the rest of the floor. Eroded sections of this floor shows evidence of broken bones, a possible kitchen midden.
>
> The walls have a number of Aboriginal paintings, some superimposed on each other on the left hand wall. Observed were a boomerang in white and other paintings vertical scrapings with small numbers at lesser angles. They have been apparently made by someone standing, as they are in easy reach at waist level to hand outstretched in height. Exposure is 2m long by 1m high. Right hand side has scrapings, 12 or so scratches but nothing of real significance. Cave is an archaeological site.

Subsequent recording of the site revealed a greater number of paintings and engravings than initially outlined by the Chillagoe Caving Club,

TABLE 7. List of materials excavated from Mordor Cave, Square H10.

with thirteen figurative paintings, one track painting, two non-figurative peckings and 812 abraded grooves (including twelve tridents) being determined (Figs 14,15). In addition, numerous weathered peckings are evident subimposed under a series of paintings, but their quantification and precise identification could not be determined due to their advanced stage of deterioration.

Hearth Cave was chosen for excavation because of the presence of patinated peckings at the site. Non-figurative peckings similar to those found at Hearth Cave are relatively rare in the Mitchell-Palmer region, and were believed to have considerable antiquity at the Early Man site near Laura (Rosenfeld et al., 1981). Consequently, a deep sequence was anticipated from Hearth Cave. Furthermore given that paintings occur in superimposition over the peckings, the recovery of localised in situ ochre should reveal both the antiquity of the paintings and a minimum date for the peckings at the site.

Excavation, Stratigraphy and Dating

Four juxtaposed 50cm × 50cm test pits were excavated, two of which were located against the cave wall in order to determine whether or not rock art continued below the shelter floor (Fig. 16). Only one square (Test Pit 3), however, has been fully sorted and analysed, and consequently this report does not deal with data excavated from the other three squares. It is notable that preliminary analysis of the excavated material from the

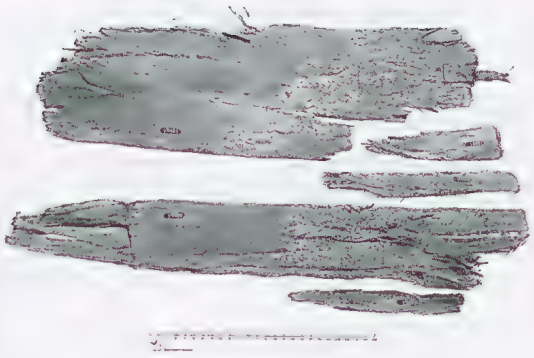

FIG. 11. Mordor Cave, large piece of cut bark excavated from XU25, Square H10.

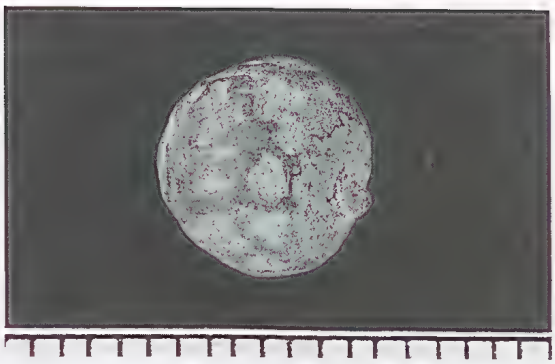

FIG. 12. Mordor Cave, fig excavated from XU23, Square H10 (scale in 2mm units).

other three squares is consistent with temporal trends observed from Test Pit 3.

Test Pit 3 revealed five stratigraphic units, the first four of which were identified during the course of the excavation (Fig. 17). SU5, the basal layer, is indistinct and was only identified whilst section-drawings were being undertaken, after the excavation was completed. The layers are described in Table 10.

Radiocarbon Dates

Four radiocarbon dates were obtained, two of which come from Test Pit 3, the other two from Test Pit 2: 2360±70BP (Wk-1716), on charcoal collected from the sieves from an excavation unit located 18.9 to 22.0cm below the ground surface. $\partial^{13}C$=-26.5‰. This date comes from near the top of SU3 in Test Pit 2; 3494±84BP (R 14023 NZA 1383). This is an AMS date obtained on charcoal from the sieves, located 36.4 to 40.0cm below the ground surface. It was obtained from slightly below the surface of SU4b in Test Pit 2. $\partial^{13}C$=-25.9‰; 4100±120 (Beta-54024), obtained on charcoal collected from the sieves. It dates excavation unit 14a (SU4b), located in Test Pit 3, 40.6 to 45.7cm below the ground surface; 21,500±250 (Wk-1719), a radiocarbon date obtained from land snails (Xanthomelon sp.) located 51.4 to 57.1cm below the ground surface (XU16a). It dates the SU4b-SU5 interface (Test Pit 3). $\partial^{13}C$=-7.2‰.

Cultural Materials

Unfortunately it is not possible to determine deposition rates for the earliest times represented by the Hearth Cave excavations, as radiocarbon dates are not available for the basal units. By assuming a *minimum* of 21,500 years of occupation, however, *maximum* deposition rates can be calculated for the earliest occupational deposits, and temporal patterns can then be explored. It is stressed, however, that the calculation of such rates are for heuristic purposes only. They are employed to determine temporal trends rather than absolute, synchronic values.

Given the uneven nature of the stratigraphic

units near the southern end of the square, especially where SU2 dips down to form a depression, the calculation of deposition rates was only attempted for those parts of the pit where strata are laid approximately horizontally. Table 11 presents the raw data excavated from Test Pit 3, whilst Table 12 transforms this data to deposition rates for each spit (excavation unit). In Table 13, a similar procedure is attempted for each stratigraphic unit.

Although occupation at Hearth Cave began sometime before 21,500±250BP, sedimentation rates peaked between approximately 3500BP and 2500BP, after which they again decreased. Deposition rates of all cultural materials show a similar pattern, being low until approximately 3500BP, and subsequently increasing until 2500-2000BP, after which they decreased slightly and remained relatively stable from then on (Tables 11,12, Fig. 18).

The Hearth Cave bone has not yet been identified to species, but it is notable that very large

TABLE 10. Stratigraphic Units (SUs) from Hearth Cave, Test Pit 3.

SU Description

1 The surface layer, consisting of loose, ashy sediments containing leaves, twigs and cultural materials.

2 Similar to SU1, but sediments are more compact. Charcoal and mussel shell are very abundant, especially immediately above SU3. Sediments are ashy silts. Unlike SU1, there are virtually no leaves or twigs in SU2. The boundary with SU1 above is marked. Towards the southern parts of the excavation, SU2 dips down, forming a depression where charcoal, burnt earth and mussel shell are particularly abundant. It is possible, but not certain, that this depression represents a hearth.

3 Extremely gravelly layer, whose boundary with SU2 above is distinct. Given the coarseness of sediments in SU3, it is thus possible that this layer represents a lag or deflated deposit. This is supported by the considerably larger mean weight of stone artefacts excavated from SU3 than from the other SUs, implying that fine sediments (including very small stone artefacts) have been washed away. Given that deposition rates of cultural materials peak during SU3 times, this may indicate that their original densities should in reality be even greater. Rootlets are common at the interface between SU2 and SU3. Cultural materials were identified in situ throughout SU3.

4a Silty clay containing very large numbers of land snails (especially *Xanthomelon* sp.). Some gravel is present, but in significantly smaller numbers than in SU3 above. SU4a is localised within Test Pit 2 only, and does not appear in Test Pit 3.

4b SU4b consists of silty clays containing cultural materials. Some very fine gravel occurs, but as was the case with SU4a, they are not as numerous as in SU3.

5 Humid clay containing numerous small calcium carbonate concretions. Although SU5 continues beyond the base of the pit, excavation was stopped because no cultural materials were noted in situ within this layer. Subsequent analysis of materials in the laboratory, however, proved that SU5 is not culturally sterile, and investigations will therefore be resumed at a later date to determine the nature of early deposits at Hearth Cave. The fact that basal occupation was not reached does not, however, affect the thrust of this paper, nor the conclusions reached here.

TABLE 11. Hearth Cave: list of materials excavated and information on sediments.

numbers of Brush Turkey egg shell occur in all cultural layers. Brush Turkeys lay their eggs from the end of the dry to the beginnings of the wet season (August-December), offering a reliable seasonal marker for when the site was used (W. Longmore, pers. comm., 1992). Although this question needs further attention, it is possible that the repeated high numbers of egg shell at Hearth Cave implies great continuity of a seasonal settlement system whereby rockshelters from the region were repeatedly occupied during the wet season. This does not deny the possibility, however, that the site was also used during other times of the year. Further research into this issue will have to await systematic investigation of the faunal material from Hearth Cave and elsewhere, as well as investigations in other sites from the region (including both rockshelter and open sites).

The stone artefacts are largely 'amorphous', although technologically they may possess highly diagnostic characteristics (this remains to be investigated). Only two formal stone tool 'types' were identified from the excavation: a fragment of 'edge-ground axe' from XU5 (1100-1450BP), and a 'burren adze slug' from XU4 (700-1100BP). Given their low numbers, however, it is difficult to make any generalisation about typological change in the stone tool assemblage from the site. It may nevertheless be significant to note that the 'burren adze' found at Hearth Cave was dated to around the same time as their appearance in other sites excavated from south-east Cape York Peninsula (David, in prep.).

The temporal distribution of in situ ochre is similar to the distribution of other types of cultural items. Numbers of ochre fragments peak during the last 3500 years, and high levels are maintained until ethnohistoric times. The very low ochre deposition rates before approximately 3500BP are likely to signify that the cave paintings currently visible at the site post-date this time, although the excavations have furnished no

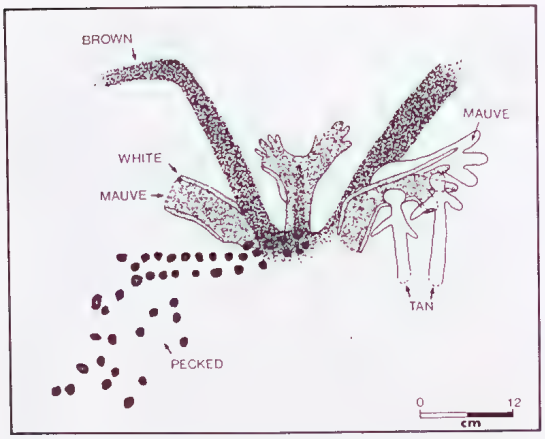

FIG. 15. Hearth Cave, freehand recording of part of the main painted and pecked panel. Not to scale.

direct indication of the age(s) of the underlying – and therefore older – peckings.

The increases in deposition rates documented from Hearth Cave after 3500BP include the following: 1, Increased sedimentation rates, which Hughes (1977) and Hughes & Lampert (1982) have argued may be related to increases in occupational intensities; 2, Increases in the deposition rates of bone, charcoal and burnt earth, which together may imply increased rates of hearth establishment and firing activity, and increases in the amounts of food consumed and discarded at the site; and 3, Increases in ochre, which implies an increase in painting activity.

It is, nevertheless, difficult to determine further the exact characteristics of the temporal frameworks involved. This is due to an absence of fine stratigraphy at the site, making it difficult to obtain discrete temporal units which can then be used to construct a chronological framework.

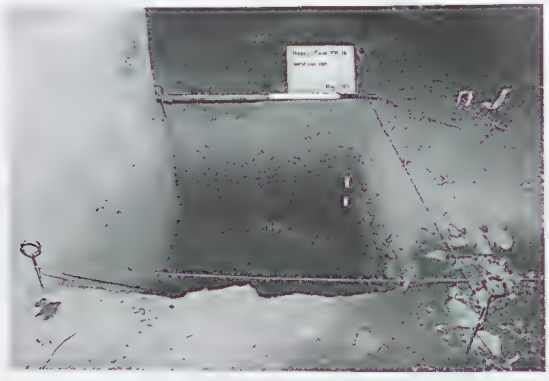

FIG. 16. Hearth Cave, the excavation pit, showing the west section (scale in 5cm units).

Consequently, we have resorted to the use of a depth-age curve to calculate temporal trends. Furthermore, the availability of three dates from 2360±70 to 4100±120BP has enabled a fairly good assessment of changes around this time.

DISCUSSION

The distribution of in situ ochres at Mordor Cave and Hearth Cave is comparable to their distributions in other excavated sites from southeast Cape York Peninsula. In all sites, peak ochre deposition rates occur late in the sequence and continue to increase until very recent times. This is the case for the following:

1, the Early Man rockshelter, where in situ ochres increase significantly after either 5000BP or during the last two millennia or so (the precise dating is debatable because of chrono-stratigraphic uncertainties) (Rosenfeld et al., 1981; David, 1991b);

2, Green Ant Rockshelter (Koolburra Plateau), where they increase dramatically after 2500BP (Flood & Horsfall, 1986; Flood pers. comm., 1991);

3, Mitchell River Cave (Mitchell River), where the only fragment of ochre was obtained from deposits dating to the last 1000 years (David, 1991a);

4, Echidna's Rest (Chillagoe), where ochre deposition rates double after 3000 years ago, and continue to increase during the last 700 years (David, 1990).

The implications of this are that cave paintings in southeast Cape York Peninsula pertain particularly to the mid to late Holocene. Painting conventions vary greatly across space throughout southeast Cape York Peninsula, indicating a highly regionalised social landscape during this

time (e.g. Rosenfeld, 1982, 1984; David & David, 1988). Considerable support for these findings have been obtained for very recent times from the ethnographic record. More problematic is an apparent, more homogeneous engraving tradition characterised by non-figurative and animal track peckings throughout the region (see Maynard, 1977, 1979). Their probable greater antiquity and relative homogeneity may imply that inter-regional networks were structured differently during earlier times (before the mid Holocene?), although this issue needs to be further investigated by obtaining more secure dates on the engravings themselves. Nevertheless, the repeated occurrence of engravings *underneath* paintings at Laura, the Koolburra Plateau, Chillagoe and elsewhere, indicates that this temporal pattern has so far withstood the test of time (cf. Flood, 1987; Rosenfeld et al., 1981; Woolston & Trezise, 1969). The conclusion that the last few thousand years of prehistory in southeast Cape York Peninsula witnessed a fundamental restructuring of artistic, and therefore probably also socio-cultural, networks appears to be strengthened with every excavation adding further support for a largely late Holocene antiquity of cave paintings. The highly regionalised nature of these paintings contrasts markedly with the relatively homogeneous nature of the preceding engravings.

Related to this question, it is noted that a significant proportion of the excavated faunal remains from Mordor Cave consist of food debris dominated by macropods — *Petrogale* sp., *Macropus agilis* and *Macropus robustus* — and other marsupials (e.g. *Trichosurus vulpecula*). The total absence of macropods from the paintings, and the general non-conformity between the range and relative representation of fauna recovered from the excavations and those represented in the paintings may be of great interest. The implications are that the animals painted on cave walls during the mid to late Holocene are not simply a reflection of dietary breadth, nor simply an indication of the symbolic importance of the hunted and foraged fauna. On the contrary, the two sources of faunal representation — the painted animals and the animals represented in the food debris — represent two distinct information domains, each of which relates to a different set of socio-cultural principals (set within a socio-cultural system or systems). In other words, data obtained from the excavated food remains relates specifically to subsistence behaviour, whereas the painted forms are an archaeological window into a totally different aspect of prehistoric life within a site and region. By investigating the latter we are investigating a system of visual forms structured by socio-cultural convention, a system of symbols whose investigation can reveal something about the nature of symbolic vocabularies but not about their related original meaning contents (cf. Frost et al., 1992). Although rock art has largely been ignored in Australian archaeology until recent times, it is important to note that once different bodies of rock art from a single region (and across space) are dated, continuities and discontinuities in visual conventions can be investigated. This does not require the art having had 'meaning' to its creator in the sense that it was created for a particular reason beyond 'art for art's

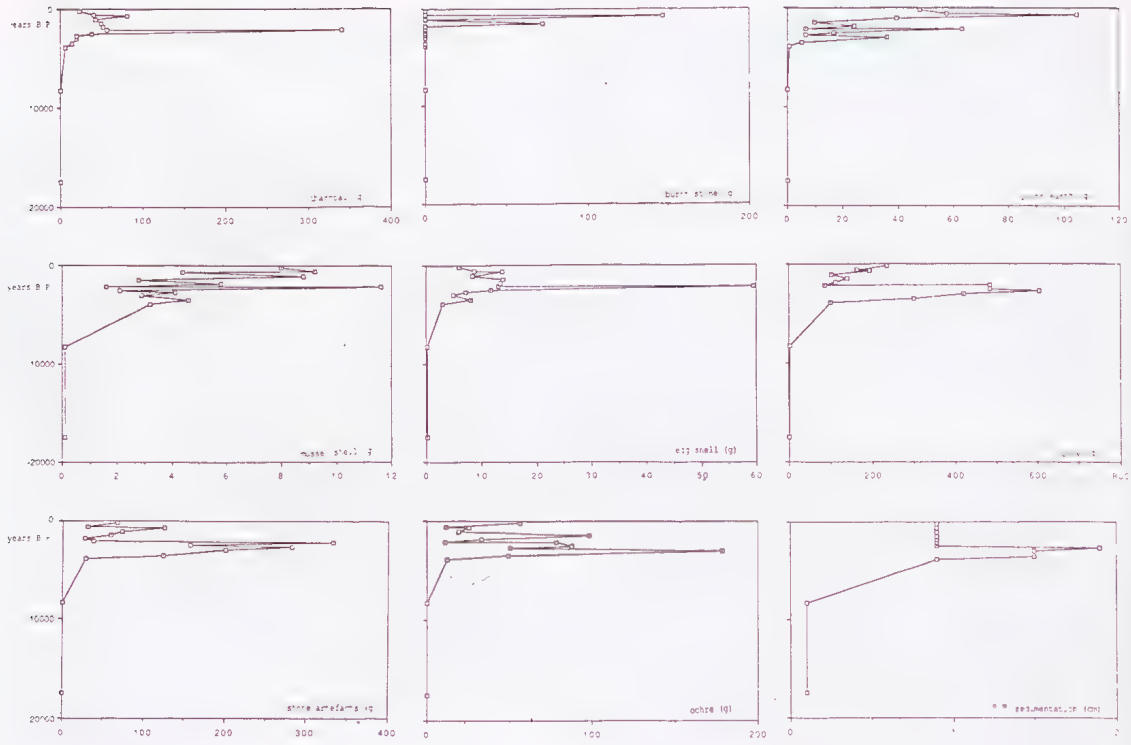

FIG. 18. Hearth Cave, deposition rates by XU (per m²/100 years). Rates for SU5 are maximum rates only, based on the assumption that cultural deposits began 21,500BP. In reality, this is only a minimum date for occupation. Therefore, the temporal trends evident in the curves would be accentuated with longer occupation at the site.

sake', for what is at stake concerns the structuring of socio-cultural imagery, of the ordering of symbols as formal representations and of the portrayal of rock art forms in specific proportions. For example, why are there no recorded macropods in the Mitchell-Palmer rock paintings, especially given their importance in the rock art of Laura to the immediate north? Why does the nature of painted representations change less than 50km to the south of the Mitchell-Palmer region, from a predominantly figurative painting region to a non-figurative one? The implications are that during relatively recent times at least, spatial discontinuities existed in the distribution of socio-cultural conventions relating to rock art through space (David, in prep.). Given that rock art does not necessarily relate to any specific aspect of social life such as subsistence, however, it does not necessarily follow that the documented discontinuities in rock art also represent differences in other social practices. But the regionalised nature of rock art traditions during the late

TABLE 13. Hearth Cave: deposition rates by SU (per m² per 100 years). Note that some XUs are interface spits, and therefore their relative contributions to the various SUs to which they belong have been taken into account in the calculations presented.

Holocene implies regionalised symbolic behaviour throughout southeast Cape York Peninsula during that time. The precise nature of this regionalisation — whether it involved broader discontinuities or not — remains unknown. It is therefore to explore such issues that we present this paper, for it is by generating systematic research on past socio-cultural systems in southeast Cape York Peninsula — that is, on the relationship between resource structures, symbolic representations, technological conventions etc., and their continuities and discontinuities across space and through time — that significant new inroads will be made in Aboriginal prehistory.

ACKNOWLEDGEMENTS

We would like to thank Brigid Cassidy, Dave Currie, Annette Davis, Gina Boutelier, Bryce Barker, Lara Lamb, Les Hall and Lana Little for their assistance and company in the field, W. Longmore and L. Hughes for assistance in identifying the eggshell, P. Bostock and C. Young for plant identifications and Harry Lourandos for stimulating discussions. We also thank Leon Satterthwait for producing the final version of Fig. 5. Special thanks also to Mr and Mrs Wilson for permission to undertake research on Palmerville Station, and Howard Kingsley on Mt Mulgrave Station. The Australian Institute of Aboriginal and Torres Strait Islanders Studies financed three of the radiocarbon dates from Hearth Cave. The Mordor Cave radiocarbon dates, and one date from Hearth Cave, were funded by the Cultural Heritage Division, Department of Environment and Heritage (Queensland). To these organisations we are extremely grateful. We also thank Bryce Barker and Ian McNiven for commenting on an earlier draft of this paper.

A NEW SPECIES OF *LYGISAURUS* DE VIS (REPTILIA: SCINCIDAE) FROM MIDEASTERN QUEENSLAND

PATRICK J. COUPER

Couper, P.J. 1993 06 30: A new species of *Lygisaurus* de Vis (Reptilia: Scincidae) from mideastern Queensland. *Memoirs of the Queensland Museum* 33(1): 163-166. Brisbane. ISSN 0079-8835.

Lygisaurus zuma sp.nov. is from open forests and riparian habitats of the Mackay district, mideastern Queensland. It is distinguished from its congeners by the following combination of characters: midbody scale count 23-24, supraciliaries usually 6, ear lobules flat and low, and palpebral disc large. Faecal analysis shows that this species feeds on small arthropods. In captivity, male *L. zuma* display territorial behaviour and both sexes give a brief, head-bobbing display when establishing themselves in a sunning position. Male *L. zuma* develop a red breeding flush on their throats and tails, which reaches full intensity by late October. A captive female produced two soft-shelled, oval shaped eggs, in mid-November.
☐ *Lygisaurus zuma, Scincidae, new species, open forest, Queensland.*

Patrick J. Couper, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; 5 January, 1993.

Ingram and Covacevich (1988) resurrected the genus *Lygisaurus* from the synonymy of *Carlia* to accommodate the small, brown litter-dwelling skinks, which had formed a discrete unit within *Carlia*. They transferred four species (*L. foliorum*, *L. aeratus*, *L. laevis* and *L. macfarlani*) to *Lygisaurus* and described three new species (*L. rococo*, *L. sesbrauna* and *L.tanneri*) from northeastern Queensland. In addition, *Menetia timlowi* (Ingram, 1977) was reallocated to the genus *Lygisaurus*. Subsequently, Greer (1991) changed the generic diagnoses of *Lygisaurus* and *Menetia* and concluded that *L. timlowi* was more closely related to *Menetia* than to *Lygisaurus*. He reassigned it accordingly.

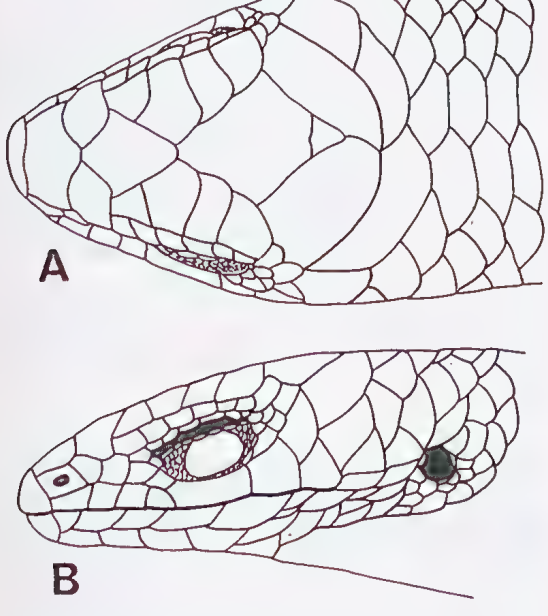

FIG. 1. *Lygisaurus zuma* (J55760). A. Dorsal view of head. B. Lateral view of head.

During recent field surveys north of Mackay, mideastern Queensland, a new *Lygisaurus* closely resembling *L. tanneri* was collected. The new species conforms to the generic diagnoses of Ingram and Covacevich (1988) and Greer (1991). On external features alone, it is readily referable to the genus *Lygisaurus* by the presence of ear lobules, which *Menetia* lacks (Greer, 1991). Further, the number of paravertebral scales in the new species (44-48) is within the range of *Lygisaurus* (39-50), whereas *Menetia* has 52-66 (Greer, 1991). The discovery of a new species of *Lygisaurus*, following a recent revision of this genus, emphasises the importance of field surveys in areas that have been previously overlooked. With the exception of the Eungella rainforest block, the forests of the Mackay area have been largely ignored because researchers have focused their attention on forests further north.

Body measurements and morphological characters follow Ingram and Covacevich (1988). SV = snout-vent length; HW = head width; TL = tail length; HL = hindlimb length. The number of supraciliaries, supraoculars, ear lobules, supralabials and subdigital lamellae have been recorded from both sides of the body. The subdigital lamellae count includes the most distal scale. In addition, the numbers of enlarged nuchal scales and paravertebals have also been counted

(sensu Greer, 1991). All specimens examined are in the Queensland Museum.

Lygisaurus zuma sp.nov.
(Figs 1-4)

MATERIAL EXAMINED

HOLOTYPE: J55760 female, Boulder Ck, via Mt Charlton, MEQ (21°01'S, 148°43'E), collected by P.J. & K.L.D. Couper on 21-23 July 1992.

PARATYPES: J53397, J55761-7, J56874-6, J56883 Boulder Ck, via Mt Charlton, MEQ; J56278, J56280 small knoll immediately WNW of Mt Ossa township, E of where Carey Ck crosses Bruce Highway, MEQ (20°55'S, 148°48'E); J56279 small knoll just east of the Geeberga-Buthurra Rd, 6.7km from where the road meets the Bruce Highway opposite Buthurra, MEQ (21°01'S, 148°48'E); J56765 Neilson Ck, at the base of Mt Blackwood, MEQ (21°01'S, 148°58'E); J56786 proposed Teemburra Ck Dam, near Pinnacle, N of Mackay, MEQ (21°13'S, 148°39'E).

DIAGNOSIS

A medium sized (maximum SV 34mm) *Lygisaurus* (Fig. 2). *L. zuma* sp. nov. has a movable lower eyelid, a character it shares with *L. aeratus*, *L. laevis*, *L. macfarlani*, *L. rococo*, *L. sesbrauna* and *L. tanneri*. *L. zuma* sp. nov. is distinguished from *L. rococo* by midbody scale count (23-24 vs 27-30); from *L. tanneri* by the number of supraciliaries (usually 6 vs usually 7); from *L. aeratus*, *L. laevis* and *L. sesbrauna* by the nature of the ear lobules (flat and low vs sharp); from *L. macfarlani* by the size of the palpebral disc (large, occupying more than half of the lower eyelid vs small, occupying less than half of the lower eyelid), a character which further distinguishes it from *L. laevis*, *L.sesbrauna* and *L. tanneri*.

DISTRIBUTION

The Mackay district, mideastern Queensland (Fig. 3).

DESCRIPTION

SV: 23-34 (N = 18, mean 30.0). Proportions, (% SV): HW, 12-16 (N = 18, mean 14.3); TL, 130-178 (N = 6, mean 151.4); HL, 28-40 (N = 18, mean 35.7). Supraciliaries 6, rarely 5 or 7 (N = 36, mean 6.0). Palpebral disc large, occupying more than half of the lower eyelid. Lower eyelid movable. Ear aperture much smaller than palpebral disc; varying in shape from round to almost

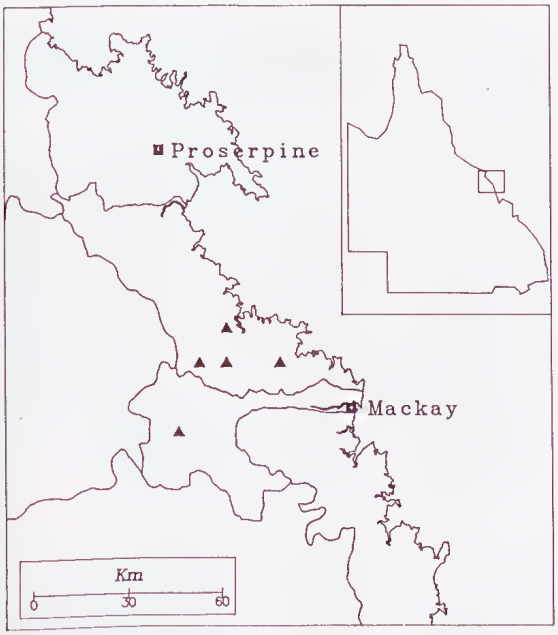

FIG. 3. Distribution of *Lygisaurus zuma*.

horizontal, with low flat lobules around the margin. Supraoculars 4, rarely 3 (N = 36, mean 3.9). Supralabials 7 (N = 36), with the fifth under the eye. Three scales between the second presubocular and the nasal scale. Enlarged nuchal scales 2-3 (N = 18, mean 2.1), with two contacting the parietal shields. Midbody scale rows 23-24 (N = 17, mean 23.7). Number of scales from chin to vent 50-58 (N = 17, mean 53.5). Number of paravertebral scales 44-48 (N = 17, mean 46.6). Number of lamellae under fourth toe 19-23 (N = 34, mean 21.3).

Dorsal colour pattern iridescent grey-brown with longitudinal rows of small black flecks that become more concentrated on the flanks, forming a darker lateral zone. Ventral surface silvery white with a dark edging to the belly scales; chin immaculate. Head coppery with scattered dark blotches. In life, eye pale green with a black pupil. Breeding males have red tails and throats.

Etymology

The name is derived from Montezuma II, the last Aztec emperor, who was a sun-worshipper. The name alludes to the lizard's basking habits. The epithet is to be treated as a noun in apposition.

Habitat

L. zuma lives in the leaf-litter of open forests and associated riparian habitats. J53397, 55760-55767, 56874-56876, 56883 were collected from a mixed, eucalypt-dominated woodland, predominantly comprised of the following species; *Eucalyptus dolichocarpa*, *E. intermedia*, *Pandanus tectorius*, *Ervatamia orientalis*, *Flindersia schottiana*, *Planchonia careya*, *Acacia flavescens*, *Randia fitzalanii*, *Mallotus philippensis*, *Glochidion sumatranum* and *Lophostemon suaveolens* (Fig. 4). J56279 was collected from a stand of *L. suaveolens* with scattered *Eucalyptus platyphylla* and young *M. philippensis*. J56280 is from an *E. intermedia* dominated forest with an understorey of *Lophostemon confertus*. J56765 was collected from a creek-bed containing riverine vegetation, immediately adjacent to a eucalypt dominated woodland. J56786 was taken from an open riparian forest dominated by *Casuarina* sp. J56278 was found in dense leaf litter in a dry gully in a patch of rainforest.

The penetration of open forest species into rainforest is discussed by Covacevich and McDonald (1991). The occurrence of *L. zuma* in rainforest may be an example of this, probably the result of severe drought. Specimen J56278 was collected during September 1992, one of the driest periods on record for the Mackay area. Field surveys conducted in October 1991 failed to find this species in rainforest, despite a total 18 man-days spent in rainforests around Mt Ossa and Mt Charlton.

Habits

Like all *Lygisaurus*, *L. zuma* is a small, ground-dwelling diurnal skink. Individuals seen at Boulder Ck during July 1992 were actively foraging through the litter layer from mid-morning to early afternoon. All observed activity was confined to patches of sunlight. Ground temperature in these sun patches ranged from 24- 28°C.

An examination of four faecal samples showed that *L. zuma* feeds on small arthropods. One of the samples contained two ground spiders of the families Lycosidae and Pisauridae and another two of the samples each contained a single planthopper (Hemiptera: Fulgoroidea). The fourth sample, while containing no prey items, consisted of numerous scales presumably ingested by the skink while sloughing. Specimens kept in captivity readily eat termites, actively avoiding the soldiers and preferring the larger, more succulent workers.

Male *L. zuma* observed at Boulder Ck during July 1992 had not yet developed their full breeding colours. While the lower labials displayed a well developed, red flush, the scales of the throat

FIG. 4. Open forest habitat of *Lygisaurus zuma*,

remained white with only a hint of orange appearing around the margins. Breeding colours develop to full intensity by late October, as was the case with J53397 and J56765, and begin to fade by early December (captive males J56874 and J56876). In captivity, territorial behaviour was evident in males well before breeding colours had fully developed. The larger of two males sharing an enclosure with two females would actively chase the other male whenever contact occurred. Both males and females gave a brief display of head-bobbing as they first established themselves in a sunning position.

Captive female J56883 (SV: 33.9mm) laid two soft-shelled, oval-shaped eggs on 18 November 1992 (± 2 days). The eggs became desiccated and required rehydrating before any measurements could be taken. Egg length ranged from 7.52-7.54mm egg width from 3.85-3.95mm.

ACKNOWLEDGEMENTS

This work was funded by a grant from the National Rainforest Conservation Programme, administered by the Department of Environment and Heritage. I am especially grateful to Duncan Limpus for his efforts in obtaining the first specimen of *L. zuma* from our Boulder Ck campsite. I also wish to thank Peta Woodgate and Lynette Dickfos for typing; Glen Ingram, Jeanette Covacevich and Steve Wilson for critically reading the manuscript; Steve Wilson for his excellent photograph; Gray Cranitch for preparing the photographic figures; David Nebauer for preparation of the map; Peter Thompson for identifying botanical specimens; Geoff Monteith and Kevin Lambkin for identifying insect fragments contained in faecal samples; Michael Cunningham, Kate Couper and Alan Beckman for their assistance in the field; Tim Low and Morgan Thomas for collecting additional material; and Lauren Keim for her assistance in the laboratory.

Davies, M., Watson, G.F., McDonald, K.R., Trenerry, M.P. & Werren, G. 1993 06 30: A new species of *Uperoleia* (Anura: Leptodactylidae: Myobatrachinae) from northeastern Australia. *Memoirs of the Queensland Museum* **33**(1): 167-174. Brisbane. ISSN 0079-8835.

Uperoleia altissima sp.nov. is from elevated sites on the Atherton and Windsor Tablelands in northeastern Queensland. The species is dentate and the call is short and pulsatile, features that distinguish it from all congeners. □ *Anura, Myobatrachinae, Leptodactylidae, Uperoleia altissima, new species, advertisement call, external morphology, osteology.*

Uperoleia is a genus of small, fossorial frogs with highly glandular skin and a conservative morphotype. The nominate species, *U. marmorata,* was described by Gray (1841) and prior to 1981 was thought to have a wide ranging distribution throughout northern and eastern Australia. Tyler et al. (1981a,b) revised the genus and raised the number of recognised species from three to 18. They restricted the known distribution of *U. marmorata* to the type locality in northern Western Australia.

Davies et al. (1985) described a further species from the Pilbara whilst Tyler et al. (1986) suppressed *U. variegata* leaving 18 recognised species. These studies were confined to the Northern Territory and northwestern Western Australia and, thus, did not deal in any detail with eastern species (*U. rugosa, U. fimbrianus* and *U. laevigata*). These they restricted to their type specimens and localities, pending revision of the *Uperoleia* in eastern Australia. When this was completed (Davies & Littlejohn, 1986; Davies et al., 1986), *U. fimbrianus* was synonymised with *U. rugosa* and an additional six species were described. Presently, 23 species are recognised within *Uperoleia.*

During the study of eastern Australian *Uperoleia* a number of specimens were located in museum collections that could not be positively identified. Amongst these were five specimens in the Queensland Museum collection taken near Atherton, NE Queensland. These frogs appeared to be dentate, so resembling *U. fusca* in Eungella National Park near Mackay, mideastern Queensland. However, they were too poorly preserved to permit positive identification.

In late January 1991, M.D., G.F.W. and K.R.McD. visited the Atherton Tableland and located a species of *Uperoleia* in the Millstream National Park. The species was dentate and conspecific with the indeterminate specimens encountered previously and with others collected at later dates from this site and the Windsor Tableland. Here we describe it as a new species.

MATERIALS AND METHODS

Material cited here is deposited in the collections of the Queensland Museum, Brisbane (QM), South Australian Museum, Adelaide (SAM), Museum of Natural History, University of Kansas (KU), and American Museum of Natural History, New York (AMNH). Measurements of specimens follow Tyler et al. (1981a). Measurements taken (in mm) were: eye diameter (E); eye to naris distance (E-N); internarial span (IN); snout to vent length (S-V); tibia length (TL).

Osteological data were obtained from cleared and stained material after the methods of Davis & Gore (1947) and Dingerkus & Uhler (1977).

The tape recording was made using a Sony TC-D5PRO cassette recorder (tape speed 4.76 cm/s) and Beyer M-88 cardioid dynamic microphone. Air wet bulb temperature (the effective temperature of a frog calling on land) was measured at the calling site using an electronic thermistor thermometer (Takara Digimulti Model

D611). The recording was analysed on a DSP 5500 digital Sona-Graph (Kay Elemetrics Corp.) using the in-built setup #10, with playback on a Nakamichi Dragon cassette recorder. Overall variations in tape speed (i.e. from recording to playback) are estimated at less than 0.5%; and the frequency responses of all audio-electronic components are close to linear within the relevant frequency range determined (based on the manufacturer's specifications). For each call, three primary attributes were determined: (i) duration as the interval from the beginning of the first pulse to the end of the last pulse (ms); (ii) number of pulses per note (direct count); and (iii) dominant frequency (Hz) as the maximum value of the spectrum of power between the cursors for the whole note. One derived attribute was determined — pulse rate [pulses/s determined from (n-1 pulses)/duration (in seconds) measured from the beginning of the first pulse to the beginning of the last pulse]. Levels of resolution were less than 1ms for temporal aspects, and less than 40Hz for dominant frequency.

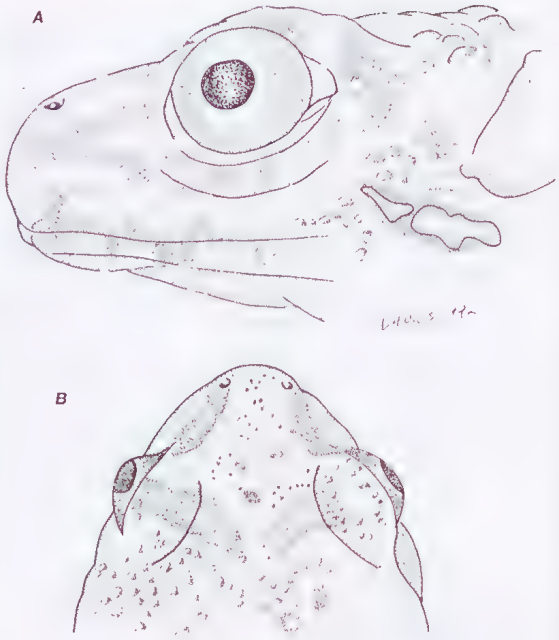

FIG. 1. A. Lateral and B. dorsal views of *Uperoleia altissima* sp.nov. (Holotype).

DEFINITION

A small species (♂♂ 19-25mm S-V) characterised by the presence of maxillary teeth; moderately developed parotoid glands; darkly pigmented ventral surface excluding the pelvic patch ventromedially on thighs; grey dorsum with strong patterning; poorly to moderately exposed frontoparietal fontanelle; no webbing between the toes; vomerine fragments present; carpus of six elements; anteromedial processes of anterior hyale of hyoid slender; ilial crest absent; advertisement call a single pulsed note of 2-3 pulses and a pulse repetition rate of 75.5 pulses/s.

DESCRIPTION OF HOLOTYPE

Maxillary teeth present. Vomerine teeth absent. Snout moderately short, slightly rounded when viewed from above, rounded in profile (Figs 1,2). Eye to naris distance greater than internarial span (E-N/IN 1.29). Canthus rostralis moderately inconspicuous and straight. Nostrils dorsolateral,

FIG. 2. *Uperoleia altissima* sp.nov. in life (Holotype).

not surrounded by prominent lip. Tympanum not visible externally.

Fingers moderately long, slender, unwebbed, slightly fringed with prominent subarticular tubercles. In order of length 3>2>4>1 (Fig. 3). Outer palmar tubercle large and prominent, inner indistinct. Hind limbs moderately short (TL/S-V 0.39). Toes long, unfringed and unwebbed. In order of length 4>3>5>2>1 (Fig. 3). Metatarsal tubercles prominent; inner elongate, lying along axis of toe 1; outer rounded, acutely angled to long axis of foot. Subarticular tubercles prominent, not conical. Parotoid glands moderately developed; inguinal glands well developed; coccygeal glands not prominent; submandibular gland prominent and discrete (Fig. 1). Cloacal flap fimbriated and prominent.

Ventral surface coarsely granular. Male with unilobular submandibular vocal sac. Cream glandular nuptial pad on thumb.

Dorsum grey in preservative with apricot tipped tubercles and overlying black patterning. Black V-shaped marking between eyes and black suprascapular plicae. Limbs banded dorsally with black. Inguinal and femoral patches cream.

Ventral surface pigmented with small cream circular patches. Femoral region unpigmented (pelvic patch). Throat darkly pigmented with tiny white stipples.

In life, dorsum grey with black patterns. Dermal glands cream; eye golden. Inguinal and femoral patches flame scarlet (Smithe, 1975).

Dimensions: S-V 21.7; TL 8.4; E-N 1.8; IN 1.4; E 2.7.

VARIATION

Uperoleia altissima is a small species ranging 18.3-25.2mm S-V. The hind limbs are short (TL/S-V, mean = 0.38 (0.35-0.43) and eye to naris distance is always greater than internarial span (E-N/IN, mean =1.40 (1.1-1.82).

SAM R40144 (recorded specimen) differs from the other topotypic paratypes in that ventral pigmentation is not as dense and the dorsal pattern is not as discrete. In addition, this paratype has an abnormal third finger on the right hand, and the dorsum is more tubercular. SAM R34318, also from the type locality, also has sparse ventral pigmentation. The paratypes from near Atherton (QM J19858, J19855-56) have reacted to preserv-

TABLE 1. Characteristics of the advertisement call of an individual of *Uperoleia altissima* sp.nov. (SAM R40144) recorded on 27 January 1991, 5.2km W of Ravenshoe, NEQ. Means (with ranges of variation in parenthesis) of 20 successive calls are shown, Effective temperature at the calling site (air wet bulb) was 24°C.

No. of pulses	Duration (ms)	Pulse repetition rate (pulses/sec)	Dominant Frequency (Hz)
2.4 (2–3)	27.51 (21.90–31.30)	75.5 (69–80)	2560 (2560)

ative and are a dense uniform chocolate brown colour, masking all dorsal and ventral pigmentation. SAM R40147 has a smaller unpigmented pelvic patch which is slightly more anterior than in the other paratypes.

Differences between topotypic and Windsor Tableland material are very slight. The tips of dorsal tubercles tend to be cream rather than apricot (probably reflecting length of time in preservative). The inner palmar tubercles of most paratypes are masked by the unpigmented glandular nuptial pad, which extends around the base of the thumb. Slight fringing of the toes and minimal basal webbing between toes 2 and 3 and 3 and 4 is present in some material. Two of the Windsor Tableland paratypes, AMNH 135814 and the largest QM J19858 show greater development of the parotoid glands.

Mating Call Structure

Twenty successive calls of the recorded individual were analysed and a summary of the call characteristics is listed in Table 1. The advertisement call of *U. altissima* is a short (mean duration 25.71ms), pulsatile call (mean pulse repetition rate 75.5 pulses/s) (Fig.4).

To the ear, the call is a sharp, loud click, repeated at a rate of about 90 calls/min. Among other species of *Uperoleia* whose calls have been described, seven (*U. aspera, U. glandulosa, U. littlejohni, U. lithomoda, U. mimula, U. minima* and *U. rugosa*) produce 'click' calls (short calls of Tyler et al., 1981a) with the call of *U. mimula* (reported ranges of variation are: duration 40-90ms; dominant frequency 2600-3300Hz; no. of pulses 3-5; pulse repetition rate 56-100 pulses/s: Davies et al., 1986) being most similar to that of *U. altissima*. The calls of these two north Queensland species are very similar except in call duration were there is no overlap in ranges of variation. Based on the calls analysed by Davies et al. (1986), the call of *U. mimula* is longer than the longer three-pulsed call of *U. altissima* (range 29.7-31.3ms). It should be noted that Davies et al. (1986) calculated pulse repetition rates using the formula 1000 (number of pulses)/ duration in ms. More accurate estimates of this derived attribute are obtained from using the formula 1000(n-1) pulses/duration in ms, or, as has been used here: 1000(n-1) pulses/duration from the beginning of the first to the beginning of the last pulses in ms. The formula used here provides the best estimate, especially in situations where the pulse duration is large compared to the interpulse interval. For comparison, recalculation of pulse repetition rate of *U. altissima*, using the formula of Davies et al. (1986), gives values of 92.8 (87-101) pulses/s.

Osteology (based on SAM R40146)

Skull well ossified. Medial ossification of dorsal sphenethmoid incomplete, overlain anteriorly by posteromedial edges of nasals; ventrally extends about 1/3 length of orbit posteriorly. Prootic not fused with exoccipital; epiotic eminences prominent. Exoccipital not fused dorso- or ventromedially. Crista parotica short, stocky; confluent laterally with long unexpanded otic ramus of squamosal. Shallow groove of carotid canal posterolaterally on frontoparietals (Fig. 5). Frontoparietal fontanelle exposed anteriorly as inverted roughly triangular area, roofed medially

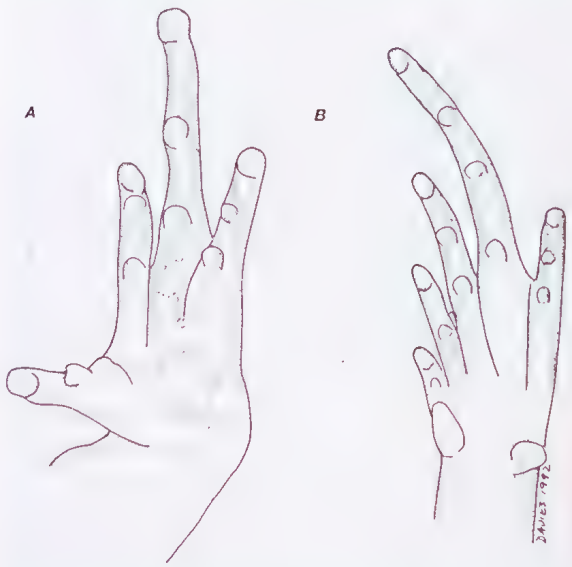

FIG. 3. A. Palmar view of hand. B. Plantar view of foot of *Uperoleia altissima* sp.nov. (Holotype).

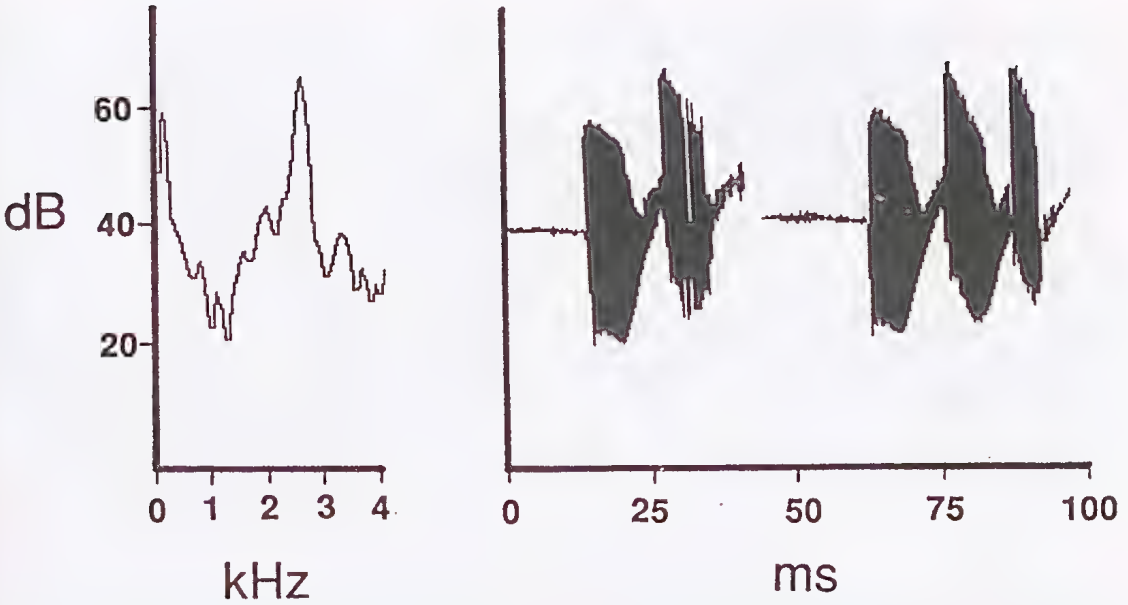

FIG. 4. Power spectrum and wave form of two advertisement calls of *Uperoleia altissima* sp.nov. (SAM R40144), recorded on 27 January 1991, 5.2km W of Ravenshoe, NEQ, at a wet bulb air temperature of 24°C. Note that the ordinate for the wave form display is not labelled because it depicts a relative linear scale in volts.

and exposed again as an approximately diamond-shaped area posteriorly. Anterior extremities of frontoparietal fontanelle about level of anterior extremities of pterygoid. Posterior extremity undefined. Frontoparietal elements well ossified reaching posterior extremities of nasals anteriorly.

Nasals well ossified, approximately triangular, closely applied medially, overlying sphenethmoid posteriorly. Maxillary process poorly developed not reaching pars facialis of maxilla. Palatines moderately broad; reduced laterally, not in contact with pars facialis of maxilla but overly sphenethmoid medially.

Parasphenoid robust. Cultriform process moderately broad, truncated terminally, not reaching level of medial extremities of palatines. Alae robust, deep, slightly angled posterolaterally reaching level of extremities of medial rami of pterygoids (Fig. 5).

Pterygoid moderately robust; slender anterior ramus in long contact with well-developed pterygoid process of maxilla. Medial ramus moderately broad, acuminate. Posterior ramus moderately broad. Small cartilaginous quadrate at articulation of base of squamosal and quadratojugal. Squamosal shaft robust; short knobbed zygomatic ramus; long unexpanded otic ramus.

Maxilla and premaxilla dentate. Teeth sparse toward pterygoid process of palatal shelf of maxilla. Teeth relatively small. Alary process of premaxilla moderately slender, not inclined posteriorly. Vomerine processes of palatal shelf of premaxilla well developed, articulating medially. Pars facialis of maxilla moderately deep posteriorly, shallower anteriorly; lacking preorbital process.

Remnant fragments of dentigerous processes of vomers medial to palatines. Bony columella extremely robust (Fig. 5).

Pectoral girdle arciferal and robust. Omosternum and xiphisternum present. Sternum cartilaginous. Left clavicle previously fractured, right slender, curved; both closely applied medially. Coracoids robust, widely separated medially. Scapula bicapitate, curved, approximately same length as clavicle. Suprascapula about one half ossified.

Eight procoelous non-imbricate presacral vertebrae. Sacral diapophyses poorly to moderately expanded. Relative widths of transverse processes: III>IV>II=V=VI>VII>VIII.

Urostyle crest about 2/3 length of urostyle. Ilium with no dorsal crest. Dorsal prominence broadly obtuse; dorsal protuberance poorly-developed dorsolaterally (Fig. 6A).

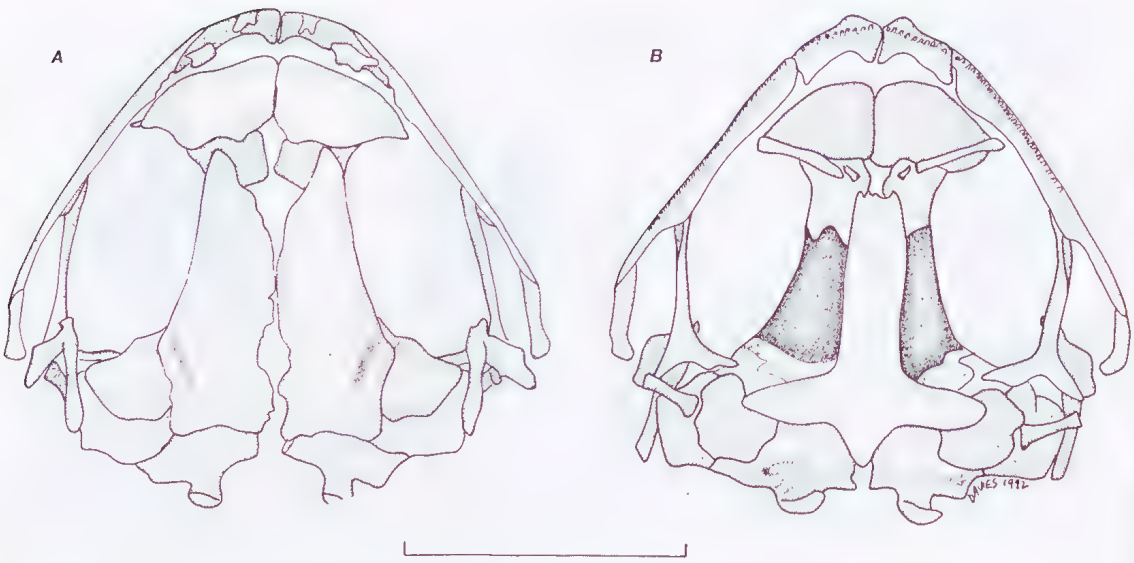

FIG. 5. A. Dorsal and B. ventral views of the skull of *Uperoleia altissima* sp.nov. (SAM R40146).

Humerus with well-developed anteroproximal crest. Phalangeal formula of hand 2,2,3,3; distal tips of terminal phalanges knobbed. Carpus of six elements, moderate torsion (Fig. 7). O. ulnare and O. radiale present. O. radiale larger of two. Both articulate with O. radioulna proximally and with each other distally. Distally both articulate with large transversely elongate O. centrale postaxiale. O. radiale articulates laterally with O. centrale preaxiale. O. centrale postaxiale articulates distally with bases of O. metacarpi III, IV and V; moderately well-developed lateral flange extends from lateroproximal corner. Palmar sesamoid anteroventrally. O. centrale preaxiale articulates laterally with O. centrale postaxiale and with unfused carpal elements of O. distale carpale 2 and 3 and laterally with basal prepollical element.

Phalangeal formula of foot 2,2,3,4,3. O. tibiale and fibulare elongated elements fused at either end. O. tibiale extends as far as distal end of O. fibulare. Three distal tarsal elements present. Lateral elements largest, lying at base of O. metatarsus III, extending laterally to articulate with medioproximal side of base of O. metatarsus IV and medially to base of O. metatarsus II. Second element lies between bases of O. metatarsi II and I. Medial element lies at the base of O. metatarsus I, articulating also with O. centrale prehallucis. Distal prepollical element subulate extending for about 2/3 length of O. metatarsus I (Fig. 7). Two sesamoids at base of prehallux.

Hyoid plate about as broad as long. Alary processes broad, not pedunculate. Anteromedial processes of anterior hyale slender and moderately long. Posterolateral processes of plate elongate. Posterior cornua long and ossified (Fig. 6B).

Variation in Osteology

Three paratypes were examined for osteological variation: QM J19581, 19587 and 51782. All are dentate but there are fewer teeth than in the described specimen. Maximum development is on the premaxilla and development decreases posteriorly. The posterior exposure of the frontoparietal fontanelle is minimal in J51782, but is the same as in the described paratype in the other two. Ossification of the nasals and of the sphenethmoid is slightly less in J51782 than that described. Development of the zygomatic ramus of the squamosal is slightly less in J19852 whilst the pars facialis of the maxilla is less crenate in J19851. Vomerine fragments are difficult to detect in this same paratype.

Etymology

The specific name is derived from the Latin *altus* meaning high, in reference to the elevations at which the species has been collected.

Comparison with other Species

Uperoleia altissima is a dentate species, a feature shared by *U. marmorata, U. mjobergi, U. micromeles, U. tyleri, U. martini, U. laevigata* and *U. fusca*.

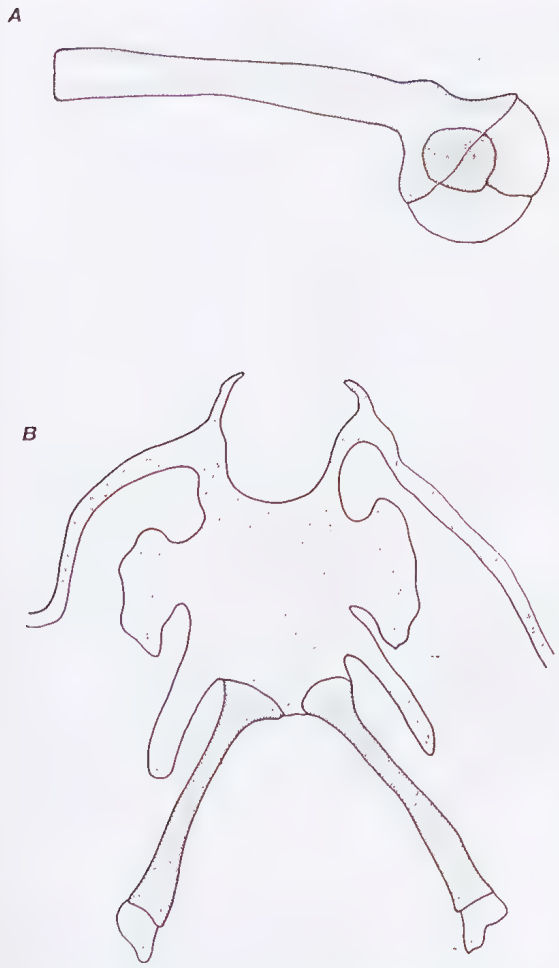

FIG. 6. A. Lateral view of the ilium (SAM R40146). B. Ventral view of the hyoid (QM J51782) of *Uperoleia altissima* sp.nov.

U. marmorata and *U. mjobergi* are confined to the Kimberley Division of Western Australia. Dentition in *U. micromeles* is sparse, similar to that found in *U. altissima*. This species is confined to desert areas in central Australia. It has very broadly spaced nasals (E-N/IN<1) and broad more elongate palatines. In addition, the shape of the nasals is unusual within *Uperoleia*. *U. tyleri* and *U. martini* are large species with hypertrophied parotoid glands and uniform ventral pigmentation. *U. altissima* is most similar morphologically to *U. laevigata* and *U. fusca*. Both these species have long calls of 32-68 or 20 pulses. In addition, both have a completely-roofed frontoparietal fontanelle and a well-developed preorbital process on the pars facialis of the maxilla.

U. altissima is most similar in call structure to *U. mimula*. This is an edentate species in which vomerine fragments are absent and which has an extremely well-developed dorsal prominence on the ilium, features not shared by *U. altissima*.

HABITAT

The type locality is medium eucalypt woodland with *Themeda triandra* and *Imperata cylindrica* (Type 16O of Tracey, 1982) and is located on Glen Gordon Volcanics. Windsor Tableland vegetation is low to medium eucalypt woodland (Type T6S) on Mareeba granites. This area was highly disturbed being near a creek system with numerous mining tracks

DISTRIBUTION

U. altissima has been located only at elevated sites on the Atherton and Windsor Tablelands, NE Queensland.

DISCUSSION

Uperoleia comprises a number of cryptic species pairs including *U. rugosa* and *U. capitulata*, *U. tyleri* and *U. martini*, *U. laevigata* and *U. fusca*, *U. inundata* and *U. arenicola*, *U. mimula* and *U. lithomoda*. The recognition of *U. altissima* adds a third example to this latter cryptic species pair.

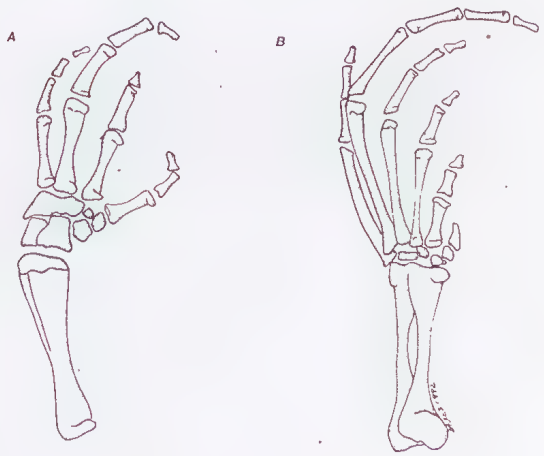

FIG. 7. A. Dorsal view of bones of hand. B. Dorsal view of bones of foot of *Uperoleia altissima* sp.nov. (SAM R40146).

Morphologically *U. mimula* and *U. lithomoda* are extremely similar (Davies et al., 1986) and close similarity in call structure between *U. mimula* and *U. altissima* exists. The presence of dentition in *U. altissima* may be the only feature that will aid field identification. Both *U. mimula* and *U. altissima* have been collected on the Windsor Tableland. The occurrence in sympatry of species with such similar call structures occurs also with *U. tyleri* and *U. martini* in southeastern Australia. To the ear on hot nights, calls of *U. mimula* and *U. lithomoda* are difficult to distinguish adding to the difficulty of field identification of this cryptic group of species.

The nature of the dentition in *U. altissima* has been shown to be a paedomorphic condition (Davies, 1989) together with a number of osteological features common to dentate species. These include the presence of vomerine fragments and the knobbed nature of the zygomatic ramus of the squamosal. Such features influenced by heterochrony provide explanations for the morphological divergences found within this enigmatic group of frogs.

ACKNOWLEDGEMENTS

Field work was supported by an Australian Research Grants Scheme award to M. Davies and M.J. Tyler. Glen Ingram and Patrick Couper are thanked for access to material in the Queensland Museum. Michael J. Tyler critically read the manuscript and is thanked for support.

THE SPINNING FIELD AND STRIDULATING APPARATUS OF PENULTIMATE MALE *MACROGRADUNGULA MOONYA* (ARANEAE: AUSTROCHILOIDEA: GRADUNGULIDAE)

VALERIE TODD DAVIES

Davies, V.T. 1993 06 30: The spinning field and stridulating apparatus of penultimate male *Macrogradungula moonya* (Araneae: Austrochiloidea: Gradungulidae). *Memoirs of the Queensland Museum* **33**(1): 175-178. Brisbane. ISSN 079-8835.

The cribellum of penultimate ♂ *Macrogradungula moonya* is essentially bipartite but has an undivided spinning field. On the ALS there is a median cluster of about 20 major ampullate gland spigots, 2 of which are larger than the rest; on the PMS there is a single large minor ampullate spigot and 2 patches of paracribellar spigots (about 60). There is a stridulating file or ridges on the distal outerface of the chelicera and a row of 'plucking' setae arising from tubercles on the prolateral surface of the palpal femur. □ *Araneae, Austrochiloidea, Gradungulidae, spinning field, stridulating apparatus.*

Valerie Todd Davies, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; 26 November, 1992.

Platnick et al.(1991) included some SEMs of the spinnerets of a juvenile *Macrogradungula moonya* in their study of haplogyne spinnerets. Apart from the possession of a cribellum and paracribellar spigots, this was shown to have greater differentiation of spigots than the ecribellate gradungulids. The penultimate ♂ (more than 20mm in body length) was expected to show this more clearly.

SPINNING FIELD

The cribellum (Figs 1,2) is narrow, six times as wide as long; the cribellar spigots are very small, close together and strobilate (Figs 3,4). The anterior spinnerets (ALS) (Figs 5,6) have a median field of about 20 major ampullate gland spigots (Map)of which 2 anterior spigots are a little larger than the rest; the ampullate spigot field is separated by a ridge from numerous piriform spigots (pi). The median spinnerets (PMS) (Figs 7,8,10) have one large minor ampullate spigot (map) with 5 aciniform spigots near its base and 11 aciniform spigots (ac) posterior to it; a large cluster of about 40 paracribellar spigots (pc) antero-medially and a further cluster of about 20 paracribellar spigots latero-distally. The posterior spinnerets (PLS) (Figs 9,11,12) have many aciniform spigots; 2 proximal spigots have wider bases than the others; tartipores (t) which are thought to be traces of spigots present in previous instars (Yu & Coddington, 1990) are present.

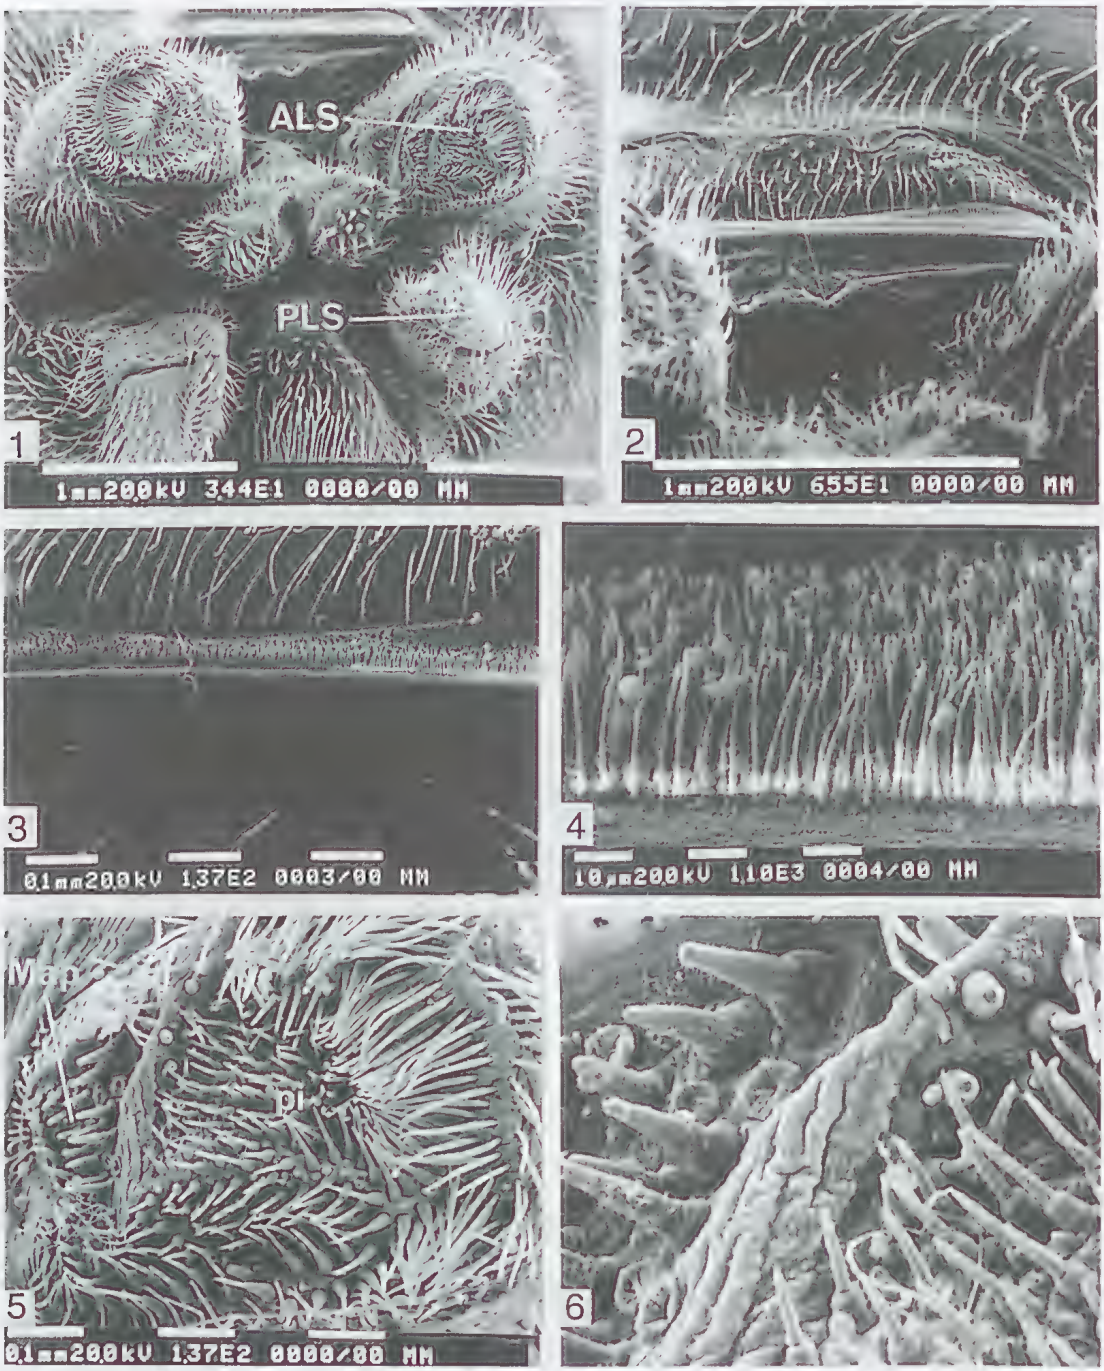
Compared with the juvenile ♀ (Platnick et al., 1991), a great increase in the number of spigots on all spinnerets is found. The bases of the paracribellar spigots are long and cylindrical, suggesting that the flat sail-like bases in the smaller spider may have been mechanically compressed to that shape.

Examination of the ♀ holotype under a light microscope revealed a similar pattern to the penultimate ♂ with an even greater number of piriform spigots on the ALS. The PMS have one large minor ampullate spigot with 2 patches of spigots (paracribellar) and a large number of aciniform spigots becoming larger proximally. The PLS have many aciniform spigots also increasing in size proximally.

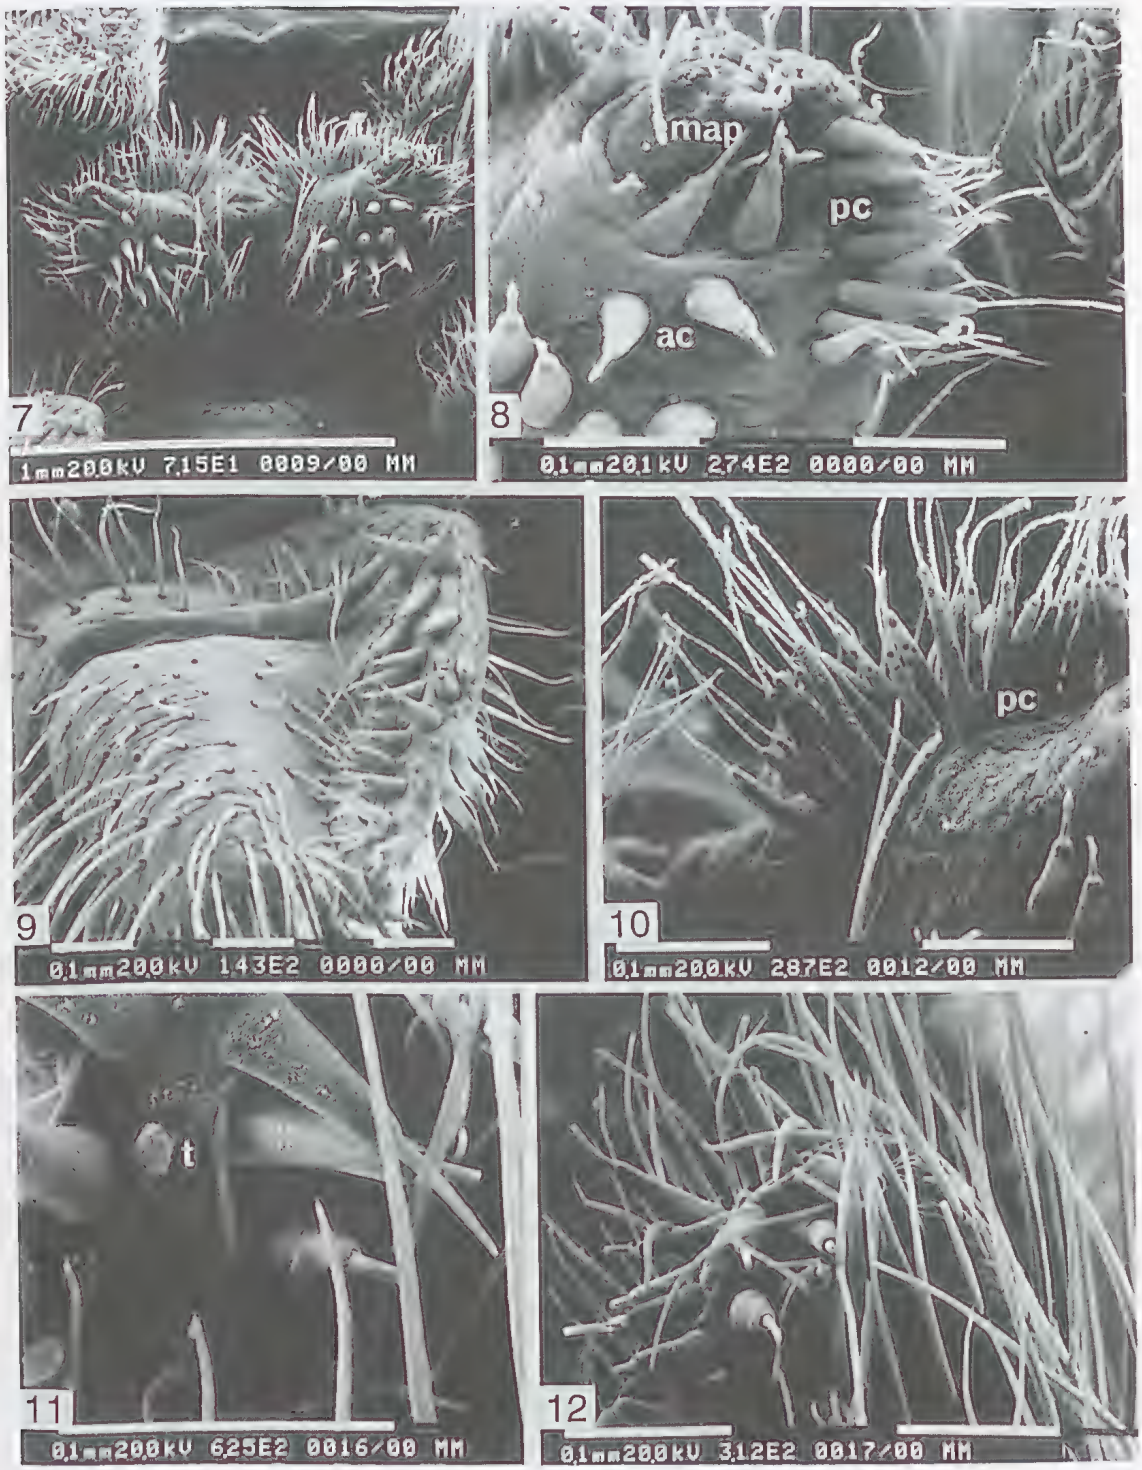
The presence of about 20 major ampullate gland spigots on the ALS is similar to that found in the hypochiloids; *Hickmania* and the South American austrochiloids have only 2 Map. Spigots on the PMS are like those in austrochiloids and have the same sculpturing pattern on the base; neither a minor ampullate spigot nor paracribellar spigots are found in the hypochiloids (Platnick et al., 1991). In the ecribellate gradungulids the minor ampullate spigot is lost along with the cribellum and paracribellar spigots.

The cribellum is homologous with the anterior median spinnerets of liphistiids and likewise the colulus when present is also homologous (Lehtinen, 1967: 398). Glatz (1972) showed that the paired muscles supplying the cribellum still persist in the colulus i.e. its bipartite history is evident. The cribellum is more than a plate of spigots; it is a movable plate supplied by muscles to each side (Glatz, loc. cit.). In the cribellum even though the cribellar field of spigots may be entire (hypochiloids and austrochiloids) the whole

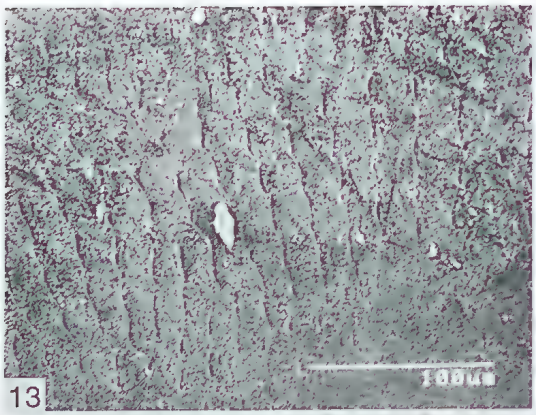
structure is essentially bipartite. This is clearly illustrated in *Macrogradungula moonya*, where the median posterior edge of the cribellum is clearly notched (Fig. 2) and the cribellar field is narrow and entire but constricted centrally (Fig. 3) suggesting that separate fields have joined.

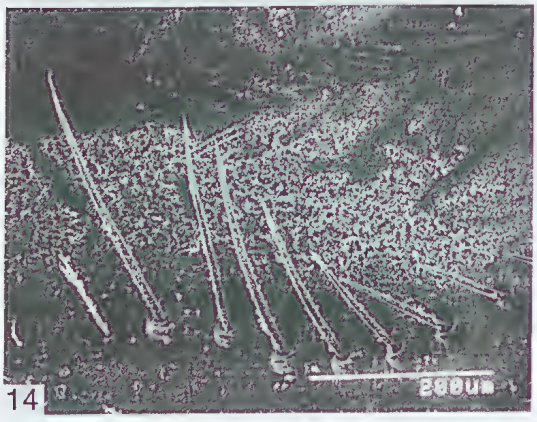


FIGS 1-6, penultimate ♂ *Macrogradungula moonya*. 1, spinning field. 2, cribellum. 3,4, cribellar spigots. 5,6, ALS, major ampullate and piriform spigots.



FIGS 7-12, penultimate ♂ *Macrogradungula moonya*. 7,8,10, PMS. 9,11,12, PLS.





FIGS 13,14, penultimate ♂ *Macrogradungula moonya* stridulatory apparatus. 13, ridged area of chelicera. 14, 'picks' on palpal femur.

Transverse serial sections of the abdomen show paired muscles from a posterior sclerite to the cribellum. Further if we consider the cribellum to be the homologue of the anterior median spinnerets and the colulus to be a functionless remnant of the cribellum then it suggests that the bipartite spinning field may be the pleisiomorphic state and the single field derived. In recent cladistic hypotheses, Platnick et al. (1991) and Coddington & Levi (1991) regard the single field as pleisiomorphic because the cribellar field of hypochiloids is entire. This single field is also found in the deinopoids, some dictynoids and some clawtufted spiders; it may have arisen more than once and is unlikely to be reversible.

STRIDULATING APPARATUS

Contrary to Gray (in Forster, Platnick & Gray, 1987: 90), a stridulatory file consisting of parallel ridges is present on a small area on the distal outerface of the chelicera, near the dorsal surface (Fig. 13). Picks in the form of enlarged setae on tubercles are found on the prolateral surface of the palpal femur (Fig. 14).

ACKNOWLEDGEMENTS

I thank Don Gowanlock of the Electron Microscopy Centre, University of Queensland for most of the scanning electron micrographs, Christine Lambkin for help with the layout of micrographs and the staff of the Queensland Museum for their help in the preparation of this paper.

FIRST SKULL OF A SPECIES OF *HIPPOSIDEROS (BRACHIPPOSIDEROS)* (MICROCHIROPTERA: HIPPOSIDERIDAE), FROM AUSTRALIAN MIOCENE SEDIMENTS

SUZANNE J. HAND

Hand, S.J. 1993 06 30: First skull of a species of *Hipposideros (Brachipposideros)* (Microchiroptera: Hipposideridae), from Australian Miocene sediments. *Memoirs of the Queensland Museum* 33(1): 179-192. Brisbane. ISSN 0079-8835.

Cranial material of a species of *Hipposideros (Brachipposideros)* is figured and described for the first time. The skull of the Australian Tertiary leaf-nosed bat *Brachipposideros nooraleebus* Sigé, Hand & Archer, 1982 is described on the basis of new material recovered from the type locality on Riversleigh Station, northwestern Queensland. As part of this study, morphological differences between three hipposiderids, *Hipposideros (Brachipposideros) nooraleebus, Rhinonicteris aurantius* and *Hipposideros (Hipposideros) speoris*, are reported. *Hipposideros (B.) nooraleebus* appears to be more similar to *R. aurantius* than to its congener *H. speoris*. □ *Tertiary, fossil, bat, skull, Hipposideridae, Riversleigh, Microsite.*

Suzanne Hand, School of Biological Science, University of New South Wales, PO Box 1, Kensington, New South Wales 2033; 21 September, 1992.

In 1982, the Tertiary leaf-nosed bat *Hipposideros (Brachipposideros) nooraleebus* was described from collections made between 1976 and 1981 from the Microsite locality on Riversleigh Station, northwestern Queensland (Sigé, Hand & Archer, 1982). The Microsite deposit, which contains the Nooraleeba Local Fauna (Sigé et al., 1982), is one of more than 150 Oligo-Miocene fossil-bearing, freshwater limestone deposits on Riversleigh Station (Archer et al., 1989, 1991).

Hipposideros (Brachipposideros) nooraleebus was the first Australian Tertiary bat to be named and the first species of the subgenus *H. (Brachipposideros)* recorded from outside of France. In France, the subgenus is known from six other species also of Oligo-Miocene age (Sigé, 1968; Legendre, 1982; Sigé et al., 1982). The Australian bat was found to most closely resemble the French Burdigalian (early middle Miocene) species *H. (B.) aguilari* (Sigé et al., 1982). The appearance of closely related taxa in Australian and European sediments is enabling intercontinental biocorrelation of Australian Tertiary mammal- bearing deposits. Sigé et al. (1982) regarded *Brachipposideros nooraleebus* to be a possible ancestor of northern Australia's living endemic Orange Horseshoe Bat *Rhinonicteris aurantius*.

In 1982, *B. nooraleebus* was described, like the French *Brachipposideros* species, mainly on the basis of its teeth. By 1982, thousands of well-preserved dentaries and partial maxillae had been collected from Microsite. Subsequently, the deposit yielded partial skulls referable to this species. In this paper, cranial material of *H. (Brachipposideros)* is described for the first time and compared with the skulls of *R. aurantius* and the type species *Hipposideros speoris speoris* of India and Sri Lanka.

Dental nomenclature follows Sigé et al. (1982). Skull terminology is modified from Sigé (1966), Barghoorn (1977) and Novacek (1986, 1991). The prefix QMF refers to the fossil collections of the Queensland Museum, Brisbane. Repositories of comparative Recent specimens are indicated by prefixes as follows: M, Australian Museum, Sydney; CM, CSIRO Division of Wildlife and Ecology, Canberra; AR, temporarily held in collections at the University of New South Wales. Stratigraphic nomenclature for the Riversleigh region follows Archer et al. (1989, 1991).

SYSTEMATICS

Hipposideros (Brachipposideros) nooraleebus
Sigé, Hand & Archer, 1982
(Figs 1-4, Table 1)

Referred Specimens

QMF19034, a rostrum preserving the palate, left M^1-M^3 and alveoli for P^4 and anterior roots for left zygomatic arch (Figs 1A,2A,3); QM F19035, a braincase preserving the skull roof and basicranium with periotic bones in situ (Figs 1B,2B,3); QMF19036, a right maxillary fragment with C^1-M^3; QMF19037, a left maxillary fragment with P^4, M^1, M^3 and anterior zygomatic arch; QMF19038, a rostrum (edentulous) with

anterior zygomatic arch; QMF19039, a rostrum with right P^4-M^3 and left M^1-M^2 ; QMF19040, a left maxillary fragment with C^1-P^4 and M^2-M^3; QMF19041, a rostrum with left M^3 and anterior zygomatic arch; QMF19042, skull fragment with left P^4-M^3 and anterior dorsal cranium; QMF19043, dorsal cranium; QMF19044, ankylosed left and right premaxillae (Fig. 4); QMF19045, a right premaxilla; QMF19046, an upper I^1; QMF19047, a lower I_1; QMF19048, a lower I_2; QMF19049, posterior skull fragment preserving basicranium, glenoid surface, postglenoid process and posterior roots of zygomatic arch; QMF19050, a left periotic; QMF19051, a right periotic.

Locality, Stratigraphic Position and Age

Microsite occurs approximately 15m south of the southern end of the exposure of Carl Creek Limestone at Tedford's (1966) Site D within the Tertiary sequence of freshwater limestone sediments on Riversleigh Station, northwestern Queensland. Sigé et al. (1982) interpreted the age of the Microsite sediments, and the contained Nooraleeba Local Fauna, to be of middle Miocene age, largely on the basis of the interpreted stage of evolution of fossil marsupials preserved with the Microsite bats. The Microsite limestone was interpreted to represent a distinct facies with an uncertain stratigraphic relationship to the Carl Creek Limestone of the nearby Site D (also interpreted then to be of middle Miocene age; Archer, 1981).

Ongoing stratigraphic and biocorrelative work on the Riversleigh Tertiary limestone sequences, including study of rich mammal- bearing deposits discovered since 1983 (Archer et al., 1989, 1991) led to a reinterpretation of the age and nature of the Microsite deposit as an early Miocene cave deposit intruded into slightly older System A sediments which themselves probably date from the late Oligocene to early Miocene (Archer et al., 1989, 1991).

Associated Fauna and Taphonomy

Hipposideros (Brachipposideros) nooraleebus is represented in the Microsite deposit by tens of hundreds of individuals. It appears to be the only hipposiderid in the Nooraleeba Local Fauna, which also contains the megadermatid bat *Macroderma godthelpi* (Hand, 1985) as well as small fish, crocodiles, turtles, passerine birds, dasyurids, potoroids, a perameloid and a petauroid (Rich et al., 1991). Postcranial and dental remains of *B. nooraleebus* are commonly very well preserved in the deposit, many being complete. However, uncrushed cranial material of *B. nooraleebus* is relatively rare. Microsite fossils are particularly fragile compared with those from Riversleigh's other Oligo-Miocene bat-bearing deposits. The fossils appear to be demineralised, possibly the result of post-depositional leaching or, alternatively, a unique palaeochemistry of the depositional environment.

Diagnosis

See Sigé, Hand & Archer (1982: 152).

Description

The comments made here are intended to supplement the accompanying photographs and drawings. The skull is known from a number of

incomplete specimens. The most complete of these are QMF19034, a rostrum preserving the nasals, palate, anterior root for the left zygomatic arch, left M^{1-3} and alveoli for P^4, and QMF19035, a braincase preserving the skull roof, basicranial and ear regions, with periotics in place. Matrix obscures part of the right ear region but has been left in place for structural support. The description is based primarily on these two specimens but other referred specimens (see list above) provide additional information. There is no evidence of crushing of cranial material but some breakage has occurred. Some details of the medial skull region are lacking.

It has not been possible to determine the precise limits of each bone in the skull. In microchiropteran bats, sutures between bones of the skull fuse completely early in development, and no juvenile specimens of *Brachipposideros nooraleebus* have yet been recovered. However, as a guide for interpreting approximate bone boundaries in the fossil hipposiderid, several juvenile rhinolophoids were examined in this study, i.e. specimens of *Hipposideros diadema* (M20478), *Rhinolophus megaphyllus* (AR17575) and *Macroderma gigas* (M11762, M27675).

General outline and proportions. The skull is small, slender and strongly constricted in the interorbital region. The rostrum is relatively broad and long. The rostral length is approximately half the length of the braincase and its greatest width, at the level of the most anterior point of the orbit

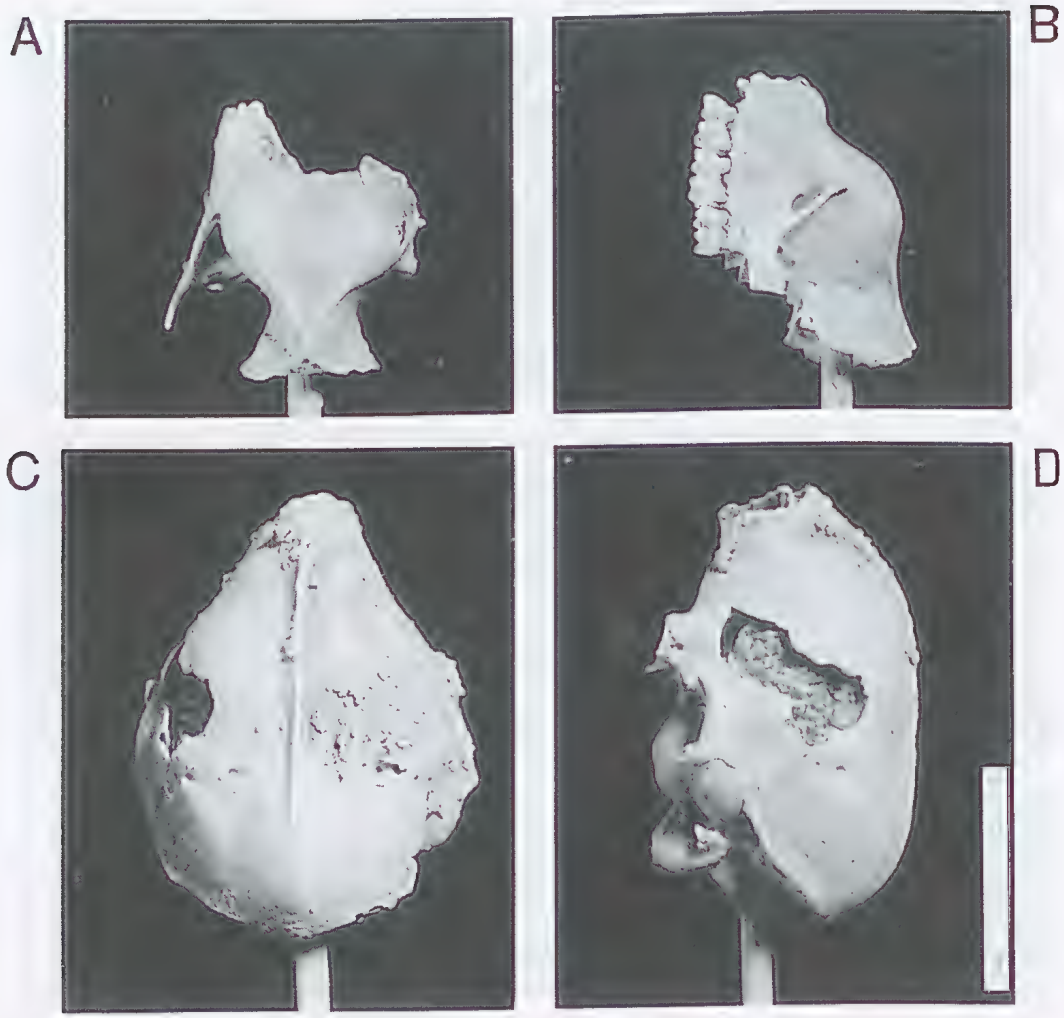

FIG. 2. *Hipposideros (Brachipposideros) nooraleebus*, Microsite, Riversleigh Station: A-B, QMF19034, dorsal and lateral views; C-D, QMF19035, dorsal and lateral views. Bar indicates 5mm.

(the lacrimal foramen), approximately two-thirds the mastoid width and more than twice the interorbital width. In height, the rostrum is lower than the braincase. The braincase is broadest across the mastoids (at the level of the post-tympanic processes). The maximum zygomatic width is not known.

Rostrum. The rostrum is square in outline, being approximately as long as wide and with subparallel lateral borders. It is deeply notched anteriorly, this indentation describing a broad arc between the maxillae. Conspicuous rostral inflations are separated by a broad, shallow trough delimited by well-developed supraorbital ridges. These are better defined posteriorly than anteriorly where they are attenuated by the nasal inflations. In the trough, at a point approximately midway between the anterior margin of the nasals and the junction of the supraorbital ridges, is a small, unpaired foramen. The rostral inflations are most conspicuous in lateral view, such that in profile the face is not gently inclined but rises almost vertically from the level of the palate to the maximum height of the rostrum.

The zygomatic arch extends onto the face as a very thin arch that joins the lateral wall of the maxilla. Under this arch (i.e. enclosed by a narrow bar of bone) opens the anteroposteriorly elongated infraorbital foramen. Hidden in lateral view by the arch, two orifices open in the lateral

wall of the face at the front of the orbital fossa. The first, the lacrimal foramen, opens under the anterior attachment point of the arch at the edge of the circumorbital rim, and is separated from the infraorbital foramen by only a thin wall of bone. Posteriorly, at the ventral part of the anterior recess of the orbital fossa, is the second orifice: a broad, deep fossa that exposes the maxillary bone covering the roots of the posterior cheekteeth. Medial to this, at the most anteroventral point of the orbit, is a post-palatal foramen which leads through into the palate. More posterodorsal and medially, in the lateral wall of the interorbital constriction, two small foramina open into a long, curved, shallow groove that leads posterodorsally from the post-palatal foramen to the optic foramen. Dorsal and medial again in the interorbital region is a deeper, shorter, anteroposteriorly directed sinus into which a number of foramina also open at the level of, or just posterior to, the cribriform plate of the ethmoid. These foramina appear to vary in number, form and position (and from one side of the skull to the other) perhaps varying epigenetically.

Palate. The palate is short. The toothrows are not convergent anteriorly. At the palate's anterior edge is a deep, V-shaped indentation, which extends posteriorly to the level of the posterior face of M^1, for the junction with the premaxillae. The palate's posterior border has two deep posterolateral indentations that extend anteriorly to at least the level of the anterior face of M^3. Each closely skirts M^3 and forms a recess beside the palatine. The posterior extension of the midline of the palate is level with the anterior face of M^3; a medial palatal spine is variably developed. The maximum width of the palate is at the level of M^2. The palate is almost flat though slightly concave longitudinally. The most constant and well developed palatal foramina are medial to the anterior face of M^1. Other foramina appear to be variable but a fossa medial to M^{2-3} is usually perforated by a number of foramina and on the midline, medial to the posterior face of M^1, an unpaired foramen occurs in some specimens.

Premaxillae. The ankylosed premaxillae comprise a small, loose element that bears a single pair of incisors. The best preserved specimens are QMF19044 (Fig. 4) and QMF19045 but the incisors have been lost from both. The premaxillae gently flare anteriorly. The incisor alveoli occur at the anterior edge in a medial position. Posteriorly, two thin premaxillary processes probably do not fully enclose large anterior palatal foramina. The premaxillae are very thick with, at their line of contact, a distinct crest on the dorsal surface. The dorsal surface is convex in both horizontal and longitudinal axes. In anterior view, the convexity is rather gentle. In lateral view, it is more acute and is accentuated by the distinct posteriorly directed crest. This reaches its maximum height about one-third the distance from the premaxillae's anterior edge. The incisors would have been directed ventrally. The ventral surface of the premaxillae is generally gently concave longitudinally but posteriorly it is domed.

Nasals. The inflated nasal cavities are bilaterally symmetric, being divided by a median septum. The dorsal border of the septum parallels the palate rather than the contour of the face. Posteriorly, the septum fuses with the anteriorly inclined cribriform plate. The posterior face of the plate is deeply concave and perforated by many foramina of varying sizes. The endocranial space is arched over the inclined cribriform plate. Posteriorly, curved lateroventral extensions of the median septum (subethmoidal shelves) partially separate each nasal cavity into a ventromedial respiratory section and more extensive dorsal and lateral olfactory sections. The latter are further subdivided, by a thin ethmoidal lattice, into anterior and posterior chambers. The ethmoturbinal mass appears to have been very simple but is not well enough preserved to be confidently described. Above the cribriform plate, the nasal cavity expands into a broad chamber roofed by the frontals.

Interorbital and pterygoid region. Immediately to the rear of the face and between the orbital fossae, the braincase narrows. The point at which the two supraorbital crests unite (i.e. where the sagittal crest originates) is clearly posterior to the point of narrowest constriction. The pterygoid wing, sloping ventrally and laterally, forms the posteromedial wall of the orbital fossa. The side wall of the skull is pinched in between the cranium and the palatine and pterygoid wings, and hence the optic foramen and sphenorbital fissure open ventrally from the braincase. The sphenorbital fissure was evidently long and wide, a very narrow bony bridge separating it from the large, almost semicircular optic foramen. Immediately lateral to the most anterolateral margin of the sphenorbital fissure is a small, round foramen. Anterior to the optic foramen is the cribriform plate of the ethmoid. Small pterygoid processes occur at a point laterally in line with the junction of the supraorbital ridges and posterior to M^3 at a distance approximately equal to the length of M^3. If hammular processes were present they are now

missing. The posterior edge of the pterygoid wing curves ventrally and posteriorly and slightly medially before forming a second, laterally-directed flange.

Zygomatic arch. The ventral margin of the zygomatic arch is slightly arched and lies dorsal to the tooth row. Anteriorly, the dorsal margin sinks in the jugal region then, posteriorly, rises at an angle of approximately 45 degrees to the ventral surface to form the very tall squamosal projection. The latter rises to at least the level of the dorsal edge of the infraorbital foramen. Its maximum height occurs dorsal to the glenoid surface. A masseteric scar occurs on the anterolateral ventral surface of the arch. In dorsal view, the junction between the zygomatic arch and its anterior extension onto the face is marked by a change in direction of the arch from posterolateral (anteriorly) to posterior, the anterior extensions diverging far more than the zygomatic arches proper. The latter appear to have been almost parallel for much of their length.

Cranial vault. The braincase is widest at the level of the post-tympanic processes, narrowest in the interorbital area and highest dorsal to the postglenoid processes. There is little development of the lambdoidal crests and no nuchal crest so that the braincase is rounded at its posterior extremity in lateral and dorsal views. The sagittal crest is variably developed (perhaps reflecting sexual dimorphism). Where it occurs, the sagittal crest is low and extends anteriorly to the supraorbital ridges and posteriorly to the interparietal at a point dorsal to the paroccipital processes. Approximately two-thirds along the length of the braincase, within the parietals, are bilaterally depressed areas that mark a conspicuous venous sinus. Its trajectory is easily traced in a lateral then anterolateral direction before it opens to the exterior in the posterior part of the postglenoid foramen. Along the sinus several small orifices open to the exterior.

Glenoid. The glenoid surface is only slightly concave and is subcircular, being almost as long as wide. It ends medial to the zygomatic process of the squamosal. The postglenoid process is weak. In height it is less than one quarter the length of the glenoid surface; its anterior face is not noticeably anteriorly recurved. The large postglenoid foramen opens vertically on the steeply sloping posterior face of the glenoid, giving the opening an elliptical shape. It opens immediately posterior to the postglenoid process. Medial to the glenoid surface, the foramen ovale opens in the alisphenoid on the side of a bony prominence or ridge. The latter separates the ventrally opening foramen ovale from a second, more posterodorsal and lateral foramen that opens posterolaterally (i.e. into the pyriform fenestra).

Temporal region. Posterior to the glenoid region and immediately anterior to the mastoid

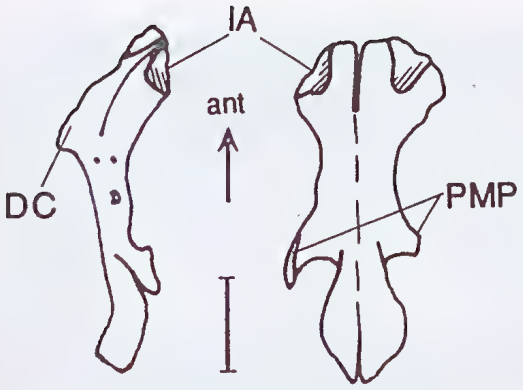

FIG. 4. *Hipposideros (Brachipposideros) nooraleebus*, Microsite, Riversleigh Station. QMF19044, left ventral view; right lateral view. Bar indicates 1mm.

region, the post-tympanic process of the squamosal is developed with a vertical process that forms a slim posteromedially directed point. In lateral view, the posteroventral part of the lateral face of the periotic is exposed and the round window visible. In the otic region, the squamosal swells slightly laterally and circumscribes an indentation which would have accommodated the tympanic ring. The squamosal laterally and anterolaterally, the alisphenoid anteriorly and the basisphenoid medially, contribute to the anterior edge of the cavity occupied by the periotic. At the anterolateral corner of the tympanic cavity, the pyriform fenestra forms a broad gap separating the posterior face of the glenoid from the anterolateral wall of the periotic. The posterolateral wall of the skull is deeply notched between the post-tympanic process of the squamosal and the paroccipital process. This notch is filled by the mastoid.

Basicranium. The medial sphenoid series (basisphenoid and presphenoid) is broadly fused with the palatine, pterygoid, alisphenoid and basioccipital. The basisphenoid appears relatively flat in its central region or perhaps only slightly concave. Faint, anteriorly convergent ridges define the basisphenoid fossa (and mark the boundary between the pterygoid and basisphenoid anteriorly and probably the alisphenoid and basisphenoid posteriorly). The periotics are not enlarged, their width being about twice the shortest distance between the two. Thus the lateral edges of the basisphenoid-basioccipital complex are relatively straight with only shallow biconcave lateral curves. The anterior margin of the basicranial area is not preserved. The periotic is bordered medially and posteriorly by the basioccipital. Anteromedially, the basisphenoid abuts the periotic; there is no lateral extension of the basisphenoid or medial extension of the petrosal.

Occipital. The most posterior region of the skull coincides with the junction of the interparietal and supraoccipitals. In lateral view, the supraoccipital is not very convex posteriorly but the exoccipitals nonetheless overhang the posteroventrally directed foramen magnum. The posterior edge of the foramen magnum is straight and not thickened. There is little development of the lambdoidal crests but a distinct ridge marks the junction of the interparietal and supraoccipitals. It parallels the posterior edge of the foramen magnum, terminating anteriorly in the region dorsal and lateral to the paroccipital process, i.e. immediately to the rear of the mastoid region. A supramastoid foramen opens on the occipital surface dorsal to the ventral condyloid fossa. There are no parietal crests and no posteriorly directed point on the skull: the nuchal line continues smoothly over the top of the skull.

In ventral view, the posterior skull contour of the supraoccipital at the level of the lambdoidal ridge is rounded. The foramen magnum is oval in shape and wider than high. Between the occipital condyle and paroccipital process is a deep condyloid fossa. The paroccipital process is well developed and forms the lateral-most part of the occipital bone. The tip is not preserved but the process appears to have articulated with the mastoid. The condyle projects most strongly ventrally at the posterior extremity, its thickened lip partially concealing the condyloid foramen in the anterolateral face.

Ear region. The ectotympanics and auditory ossicles are missing. The periotic is only weakly articulated with the surrounding basicranial elements and exhibits the condition described by Novacek (1991) as 'phanerocochlear' found in most adult microchiropterans. In this species, attachment of the periotic appears to be solely via connective tissue although the periotic closely abuts the basicranial elements medially via the basisphenoid-occipital complex and laterally via the post- tympanic process of the squamosal and the paroccipital process. The anterior part of the middle ear cavity is unossified as a pyriform fenestra which is a restricted opening between the periotic and the squamosal and most posterolateral part of the alisphenoid. There is little development of an epitympanic recess or ectotympanic groove, the bone here being no thicker than the squamosal that bounds it. Posteriorly, the large

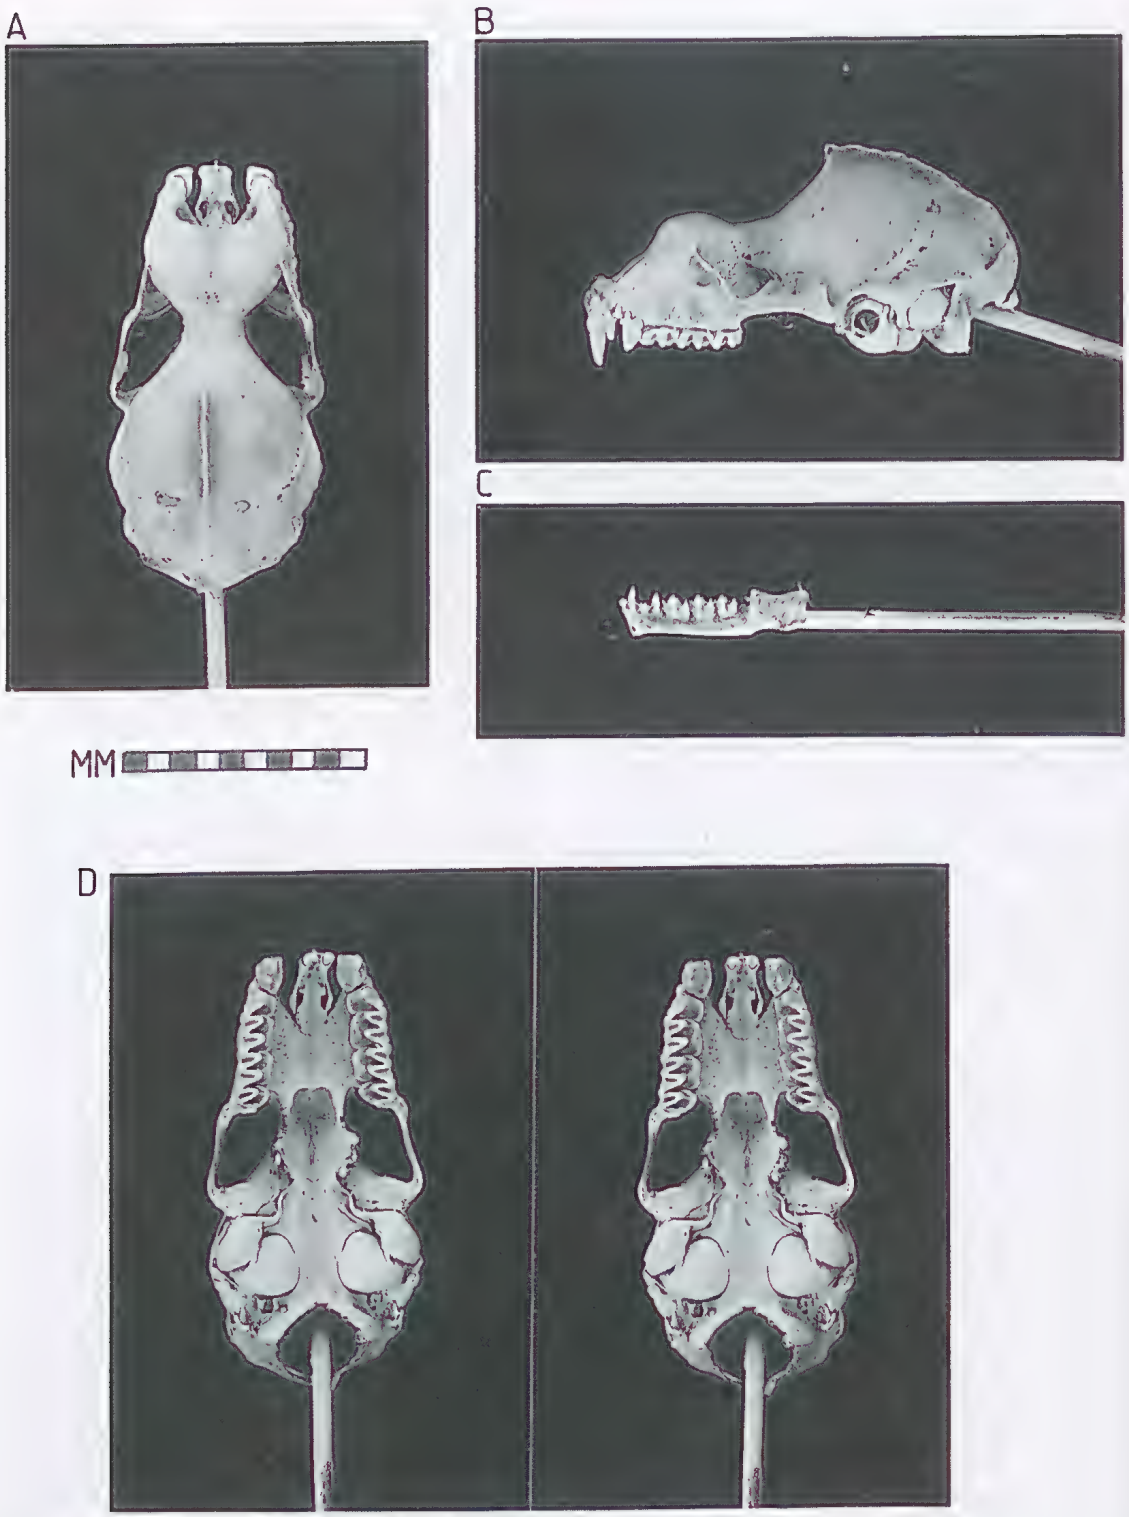

FIG. 5. *Rhinonicteris aurantius*, AR15400, Klondyke Queen Mine, Marble Bar, Western Australia. A, skull dorsal view; B, skull lateral view; C, jaw lateral view; D, skull ventral view, stereopair. Scale in mm.

jugular foramen and the more medial, very narrow basicochlear fissure are coalescent.

In ventral view, the cochlear labyrinth is visible through the thin bone of the promontorium so that the petrosal has a snail- like appearance. Three turns of the labyrinth can be detected through the bone and this is confirmed by examination of sectioned periotics.

In the lateral face of the periotic the following structures are visible. Most posteriorly, above the ventral plane of the basioccipital and facing the jugular foramen, is the aqueductus cochleae. Lateral and ventral to this, at the posterolateral corner of the periotic and distinct in ventral view, is the round window, a large, flattened oval orifice. More anteriorly and dorsally, the oval window is slightly more elongate. A very slight transverse groove, barely imprinted on the promontorium medial to the round and oval windows, marks the passage of the stapedial artery, a branch of the internal carotid. Lateral to the round and oval windows, and at the base of the promontorium, is a deep, elongate, curved depression or canal which dips from front to rear. This is the canal for the facial nerve (VII). The canal terminates posteriorly a little anterior to the round window in the region of the stapedial fossa and continues anteriorly beyond the oval window via an orifice (the apertura tympanica canalis facialis).

The lateral margin of the canal is a vertical, curved face. Anteriorly, a small process (the anterior process of the petrosal; Henson, 1970) protrudes anteromedially into the pyriform fenestra. It does not articulate with the squamosal. Near its base is a small foramen (possibly for the superior ramus of the stapedial artery). Behind this process the lateral edge of the periotic curves back and dorsal and is appressed closely to the squamosal. Immediately medial to the post-tympanic process, the lateral edge terminates in a prominent process (posterior process of the petrosal; Henson, 1970) that overhangs the stapedial fossa.

The mastoid occupies a lateral, posterior and dorsal position in the periotic. The mastoid wall only thinly covers the three semicircular canals.

Incisors. The dentition of *B. nooraleebus* has been described previously by Sigé et al. (1982), except for the incisors which are now known as follows. There is one pair of upper incisors, I^1, and two pairs of lower incisors, $I_{1\text{-}2}$. The upper incisors are bilobed with the outer lobe slightly wider but shorter than the inner lobe. The lower incisors are tricuspidate and I_1 is smaller than I_2.

COMPARISONS

RHINONICTERIS AURANTIUS

The skull of *B. nooraleebus* is smaller than that of *R. aurantius* (Gray, 1847) (AR17573, M8416, AR15400; Fig. 5) being approximately three quarters its size. Its shape is generally similar but differs as follows. The rostrum is lower in *R. aurantius* and has less prominent inflations. The trough separating the rostral inflations is deeper and narrower, poorly delimited by supraorbital ridges and is perforated by tiny foramina. The bar of bone that extends the zygomatic arch anteriorly onto the face, and encloses the infraorbital foramen, is directed dorsally (i.e. vertically) then anterodorsally so that it appears much more convex.

The postpalatal foramen is much smaller in *R. aurantius* and is surrounded by many small foramina. Dorsal and medial to this, there is one foramen (rather than two) opening into a groove. In general, unlike *B. nooraleebus*, the skull of *Rhinonicteris* is perforated by many tiny foramina, particularly in the interorbital and pterygoid regions. The palates are similar. The premaxillae are strikingly similar except that in *R. aurantius* the anterior premaxillary processes completely enclose the anterior palatal foramina. The premaxillae of both taxa exhibit a very distinctive dorsal crest as well as a dorsal convexity that results in the incisors being directed ventrally rather than anteriorly.

The sagittal crest is quite different. In *R. aurantius* it is tall and originates abruptly (with an anteriorly curved point) at the highest point of the skull (i.e. dorsal to the postglenoid process) and does not extend as far posteriorly. The vertical projection of the zygomatic arch is possibly taller and extends further anteriorly, involving the jugal and hence most of the zygomatic length. The lambdoidal crests are better developed (especially laterally) giving the posterior margin of the braincase a squared rather than rounded appearance. The postglenoid process is better developed (being more curved) and the pterygoid region less constricted. Ridges defining the basisphenoid fossa are weak and almost parallel (rather than convergent). The postglenoid foramen is elliptical and proportionately smaller. The dorsal margin of the foramen magnum is indented.

The ear region is very similar in the two taxa. The general orientation and attachment of the periotic to surrounding basicranial elements is similar and periotic morphology very similar. In the periotic the bony wing developed lateral to the

anterior and posterior processes is not as well developed.

As described by Sigé et al. (1982), C^1 of *R. aurantius* has a better developed secondary cusp and less developed cingulum, and there is more expansion of the heel on M^2. The dentaries are similar. In both taxa the horizontal ramus is short and slender with a chin process, the coronoid process is very low (the tip only exceeding the molar heights by a molar crown height or less) and the masseteric fossa has a very expanded, almost horizontal border which extends posteriorly into a wide, rounded angular process that is buccally markedly extended.

HIPPOSIDEROS (HIPPOSIDEROS) SPEORIS

The skull of *H. speoris* (Schneider, 1800) (M3468; Fig. 6) is described in so far as it differs from both *B. nooraleebus* and *R. aurantius* except where specifically stated. It is similar in size to *R. aurantius* and approximately one-third larger than *B. nooraleebus*. The rostrum is proportionately narrower, the braincase wider and the rostral inflations, and trough separating them, less conspicuous. The posterior trough is also shallower. The supraorbital ridges are much better defined laterally (being less attenuated by inflations). The facial portion of the skull slopes posterodorsally more gradually. The bar of bone anteriorly extending the zygomatic arch onto the face is directed anterodorsally and is straight (or even concave) rather than convex. The infraorbital foramen occurs above M^1 rather than M^2 and is lower on the face. The lacrimal foramen is larger (than in *R. aurantius* at least) and the ventral fossa much broader and alveolar foramina more conspicuous than in *B. nooraleebus* and *R. aurantius*. More of the lateral face is visible (i.e. the bar of bone hides less) and a third foramen, occurring dorsal and posterior to the lacrimal, is visible on the lateral wall of the rostrum.

There appear to be two foramina posterior to the palate (the more lateral one perhaps being homologous to the postpalatal foramen observed in *B. nooraleebus). Unlike B. nooraleebus* but like *R. aurantius*, the skull is perforated by many tiny foramina especially in the interorbital region, where, for example, many open into the interorbital sinus. Note that although the sinus is present in the three taxa examined it has a different form in each. The sphenoidal fissure is relatively shorter perhaps because the skull proportions differ. Compared to *R. aurantius*, the braincase of *H. speoris* is relatively longer and the interorbital region shorter.

The palate differs in that the toothrows are anteriorly convergent, the posterolateral indentations extend to the the posterior faces of M^2 and the posteromedial palate is marked by an indentation rather than a spine. There are many tiny palatal foramina but most pronounced are a pair of foramina medial to the anterior faces of M^2 and the anterior limits of the lateral indentations (i.e. medial to the posterior faces of M^2). In the premaxillae, the processes only partially enclose the anterior palatal foramina (these processes appear to diverge posteriorly), there is no dorsal crest, little lateral convexity and the incisors are directed anteriorly. The supraorbital ridges unite at the level of the narrowest constriction in the interorbital region rather than posterior to it.

The pterygoids are more constricted and there is no second flange on the pterygoid wing. The squamosal projection of the zygoma is much less well developed. In *H. speoris* it rises from approximately halfway along the zygomatic arch to quickly reach its maximum height (level with the dorsal margin of the ectotympanic ring). In *R. aurantius* it arises further anteriorly, so that its development involves almost the entire length of the zygomatic arch, to more gradually reach at least twice this height. (Note that there may be some variation in the height and shape of this projection in *R. aurantius*: cf. AR15400 and AR17573.) In both, however, the maximum height of the projection is reached at a point above the glenoid surface. In *R. aurantius* the projection leans dorsomedially towards the braincase; it is vertical in *H. speoris*.

The braincase narrows immediately anterior to the post-tympanic process rather than anterior to the postglenoid process. Like *B. nooraleebus* but unlike *R. aurantius*, there is little development of the lambdoidal crests so that the posterior margin of the skull appears rounded. The sagittal crest is similar to *B. nooraleebus* but the latter extends further posteriorly. The postglenoid process is better developed than in *B. nooraleebus* and *R. aurantius*. The articulating surface is wider; it is oval rather than subcircular. The postglenoid foramen is small and circular rather than large and oval. Dorsally and posteriorly are a number of tiny foramina which vary in number, size and position from one side of the skull to the other.

Medial to the glenoid surface are a number of foramina, the largest and most medial presumably being the foramen ovale. The sphenoid complex is concave rather than flat and the lateral margins of the basisphenoid-occipital more concave than in *B. nooraleebus* and much more so

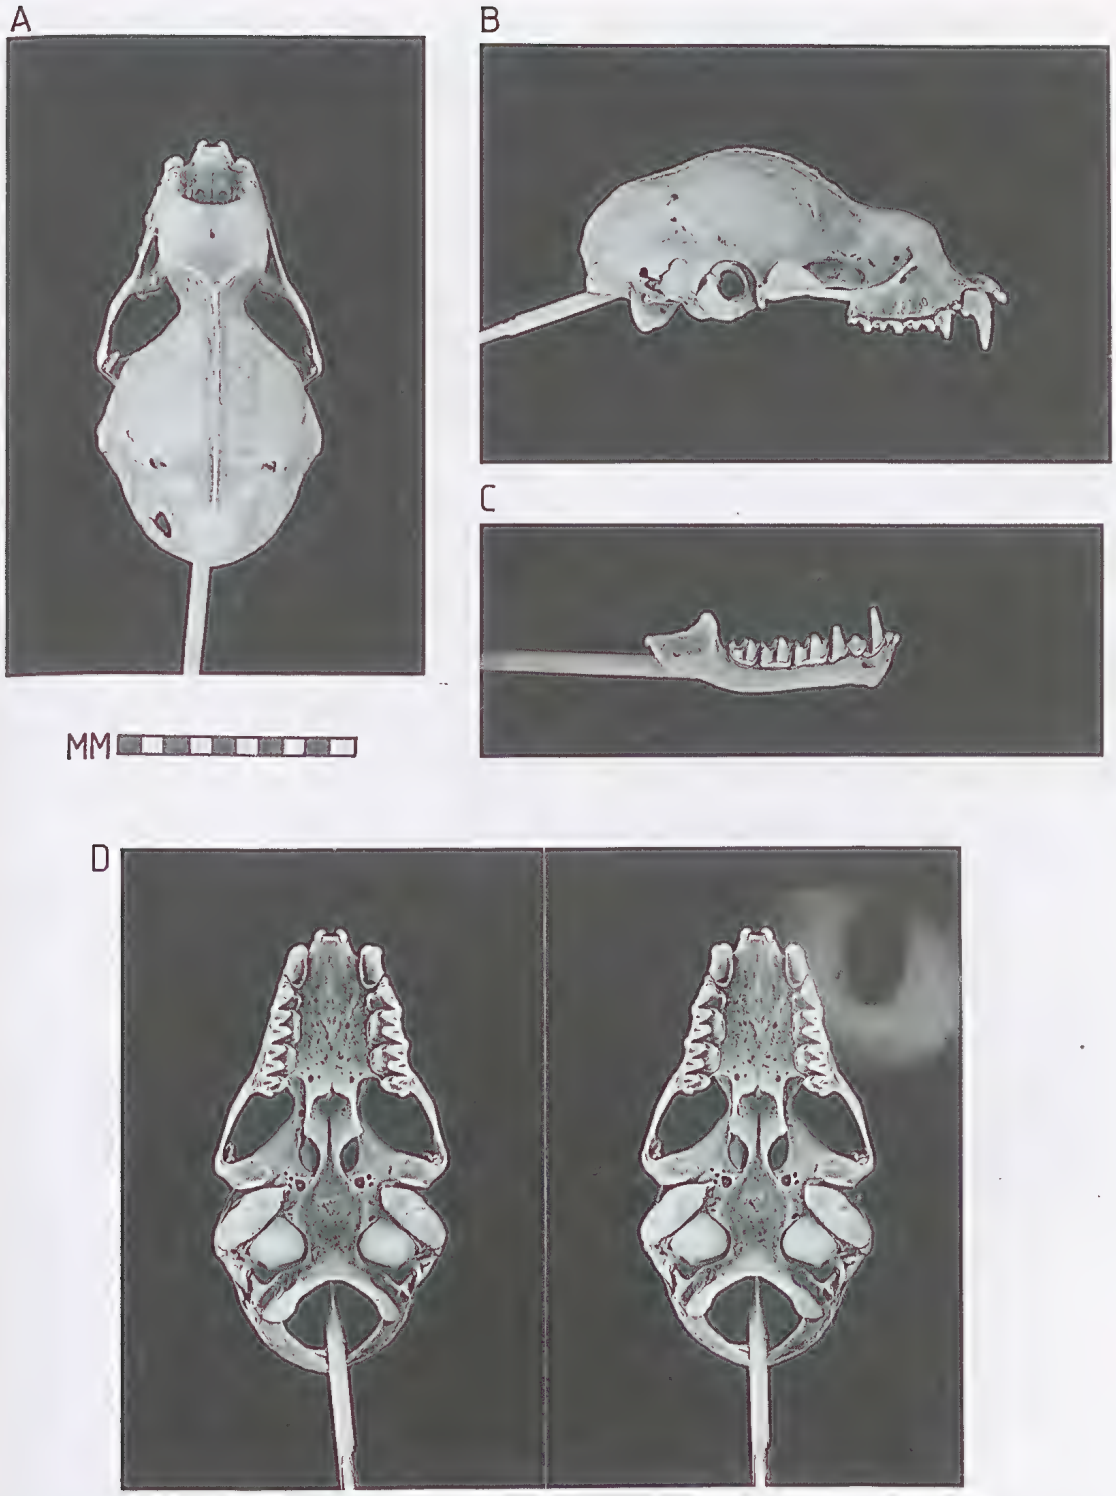

FIG. 6. *Hipposideros speoris speoris*, M3468, Kalutara, Sri Lanka. A, skull dorsal view; B, skull lateral view; C, jaw lateral view; D, skull ventral view, stereopair. Scale in mm.

than in *R. aurantius*. There is a lateral extension of the basisphenoid over the anteromedial corner of the periotic and foramina occur at the the most lateral point of the extension. As in *B. nooraleebus*, the dorsal margin of the foramen magnum is straight. The foramen magnum is oval, being conspicuously wider than long. The junction of the interparietal and supraoccipitals terminates laterally at the paroccipital process (rather than dorsolateral to it). Differentiation of the jugular foramen and basicochlear fissure is less conspicuous (i.e. their coalescence is more gradual) due to the different shape of the occipital (i.e. its lack of an extra wing). The paroccipital process articulates with the mastoid and squamosal. The notch between the paroccipital process and post-tympanic process is shallower (i.e. is filled in more posterodorsally by the squamosal and the supramastoid foramen is round rather than triangular in lateral view.

Attachment of the periotic to surrounding basicranial elements differs. The periotic abuts the basisphenoid anteromedially rather than medially and the basisphenoid extends onto the anterior promontorium. The basicochlear fissure is located medially and posteromedially and is much larger and more coalescent with the jugular foramen. The anterolateral face of the periotic is flattened. The anterior process of the periotic probably abuts the squamosal which contributes to the better- developed epitympanic recess. The pyriform fenestra appears to be narrower.

In *H. speoris*, I^1 has a reduced outer lobe, C^1 has a less developed secondary cusp and cingulum, P^2 is slightly less buccally extruded from the tooth row than in *B. nooraleebus*, M^2 heel less expanded, and M^3 more reduced such that it is narrower and shorter and the premetacrista is shorter. The coronoid process of the dentary is not as low and the angular process is narrower and extends more posterobuccally than buccally. The lower incisors protrude anteriorly, C_1 is relatively tall, P_2 small and M_3 more reduced (shorter and narrower but with a hypoconulid).

DISCUSSION

The Old World tropical to subtropical bat family Hipposideridae contains sixty-plus living species referred to the genus *Hipposideros* (approximately 50 species) and eight other genera (of one to two species each) including *Rhinonicteris*, *Coelops*, *Triaenops*, *Cloeotis*, *Asellia* and *Aselliscus* (Hill & Smith, 1984). Tertiary-aged hipposiderids, which have been recovered from mainly karstic sediments in Europe, Africa and Australia, are referred to the genera *Palaeophyllophora*, *Asellia* and the subgenera *Hipposideros (Pseudorhinolophus)* Schlosser, 1887 (late Eocene-middle Miocene taxa), *Hipposideros (Brachipposideros)* Sigé, 1968 (late Oligocene-middle Miocene taxa) and *Hipposideros (Syndesmotis)* Peters, 1871 (middle Miocene-Recent taxa). *Hipposideros (Hipposideros)* has generally been reserved (e.g. by Sigé, 1968) for Recent hipposiderid species.

Riversleigh's *Brachipposideros nooraleebus* is known from thousands of specimens and dominates the vertebrate fauna of Microsite. All other vertebrate taxa in the deposit are known from at most a few specimens each. Microsite is the only Riversleigh fossil deposit dominated by a single bat species. Because of this, it has been possible to refer incomplete hipposiderid cranial material collected from Microsite to the single taxon *Brachipposideros nooraleebus*. Most of Riversleigh's other 150-plus Oligo-Miocene fossil vertebrate deposits contain between three and ten microchiropteran taxa (see Archer et al., 1991). French fossil faunas containing *Brachipposideros* species also commonly contain more than one hipposiderid taxon and no skull material referable to a species of *Brachipposideros* has previously been described.

In the present study, the skull of *H. (B.) nooraleebus* has been compared with the skulls of a modern representative of the genus *Hipposideros*, the type species *Hipposideros speoris speoris* of India and Sri Lanka; and a probable Recent descendant of the Australian *Brachipposideros* lineage, *Rhinonicteris aurantius* (Sigé et al., 1982).

Many striking differences distinguish *H. (B.) nooraleebus* from its congener *H. (H.) speoris*. In particular, differences were observed in: overall skull proportions; rostral morphology, including the size and position of the infraorbital and lacrimal foramina and maxillary fossa; morphology of the palate, premaxilla and zygomatic arch; attachment of the periotic to the surrounding basicranial elements; squamosal articulation with the paroccipital process; and, in the dentition, the reduced M3s, I^1 with reduced outer lobe, M^2 with less expanded heel, tall C_1 and small P_2. Similarities between the two skulls include the form of the sagittal crest and general shape of the braincase.

On the other hand, the skull of *H. (B.) nooraleebus* appears to be very similar in overall form to that of *R. aurantius*. Similarities include the general proportions of the skull, the broad rostrum,

subparallel tooth rows, morphology of the palate and zygomatic arch, the crested premaxillae, general basicranial morphology, very similar periotic and otic morphology, the pronounced accessory cusp on C^1 and little reduced upper and lower M3s. Obvious differences occur in the shape of the braincase and form of the sagittal crest.

In his study of the phyletic relationships of fossil hipposiderids, Legendre (1982) recognised that *Hipposideros* probably represents a paraphyletic group (see also Sigé, 1968) and that current taxonomy does not accurately reflect understanding about the evolutionary relationships of its supraspecific groups. Species of *Brachipposideros* have been recognised to have special affinities with small Recent species of *Hipposideros* (e.g. *H. caffer), Syndesmotis* and *Rhinonicteris* (Sigé, 1968; Legendre, 1982; Sigé et al., 1982). Those of *Pseudorhinolophus* appear to have affinities with species of *Asellia* and some large Recent *Hipposideros* species (e.g. *H. armiger, H. diadema* and *H. commersoni)* (Hugueney, 1965; Sigé, 1968; Legendre, 1982).

To refine understanding about the relationships of *Brachipposideros nooraleebus* to *Rhinonicteris aurantius* and other hipposiderids, further comparisons of skull and postcranial morphology of many additional hipposiderid groups are required. Pending this much larger study, comparisons made here support Sigé et al.'s (1982) hypothesis that the Australian taxa *B. nooraleebus* and *R. aurantius* are closely related.

ACKNOWLEDGEMENTS

Work at Riversleigh has been supported by the Australian Research Council, the Department of the Arts, Sport, the Environment, Tourism and Territories, National Estate Programme Grants (Queensland), the Australian Geographic Society, ICI, the Queensland Museum and the University of New South Wales. The photos were taken by Ross Arnett of the University of New South Wales. Study of the Riversleigh bat material would not have been possible without the generosity, support and advice of Michael Archer, Henk Godthelp and all in the Vertebrate Palaeontology Unit of the University of New South Wales's School of Biological Science. Harry Parnaby, Linda Gibson and Tim Flannery of the Australian Museum and Greg Richards from CSIRO Division of Wildlife and Ecology Research, Canberra kindly provided access to comparative specimens in their institutions.

NIMBADON, A NEW GENUS AND THREE NEW SPECIES OF TERTIARY ZYGOMATURINES (MARSUPIALIA: DIPROTODONTIDAE) FROM NORTHERN AUSTRALIA, WITH A REASSESSMENT OF *NEOHELOS*

S. J. HAND, M. ARCHER, H. GODTHELP, T.H. RICH AND N.S. PLEDGE

Hand, S.J., Archer, M., Godthelp, H., Rich, T.H. & Pledge, N. S. 1993 06 30: *Nimbadon*, a new genus and three new species of Tertiary zygomaturines (Marsupialia: Diprotodontidae) from northern Australia, with a reassessment of *Neohelos*. *Memoirs of the Queensland Museum* 33(1): 193-210. Brisbane. ISSN 0079-8835.

Three new species of Oligo-Miocene zygomaturine diprotodontids are described from northern Australia. All are small, plesiomorphic and appear to comprise a distinctive clade of zygomaturines, named here *Nimbadon*. The clade is partly defined on the basis of the posteriorly inclined P^3 parastyle and blade extending from the parametacone to the lingual half of the P^3 crown and then to the anterolingual cingulum. Two of the species are known from Oligo-Miocene local faunas of Riversleigh Station, northwestern Queensland. The third is from the middle Miocene Bullock Creek Local Fauna of Camfield Station, northwestern Northern Territory. Description of additional fossil material referable to *Neohelos tirarensis* Stirton, 1967, a middle Miocene zygomaturine from the Kutjamarpu Local Fauna of South Australia, enables the genus to be distinguished from *Nimbadon*. The chronostratigraphic significance of the new zygomaturines is considered and found to approximately correspond to current understanding of the relative ages of the deposits from which the specimens were obtained. □ *Diprotodontidae, Zygomaturinae, Nimbadon, Neohelos, Oligo-Miocene, Riversleigh, Bullock Creek Local Fauna, Henk's Hollow Local Fauna, Fig Tree Local Fauna.*

Rich, Palaeontology, Museum of Victoria, Russell St, Melbourne, Victoria 3000, Australia; N.S. Pledge, Palaeontology, South Australian Museum, North Terrace, Adelaide, South Australia 5000, Australia; 24 November, 1992.

Specimens representing a very small zygomaturine were collected between 1984 and 1986 by Archer, Godthelp and Hand from the Henk's Hollow Site, in an as yet unnamed freshwater limestone on the Gag Plateau of Riversleigh Station (Archer, Hand & Godthelp, 1986; Archer & Flannery, 1987; Archer et al., 1989, 1991). Referred material includes maxillary and dentary fragments and isolated teeth. A second, larger Riversleigh species, represented by a maxilla, was collected in 1986 by Pledge from Fig Tree Site Locality adjacent to Godthelp Hill, Riversleigh Station.

A small Bullock Creek zygomaturine is known from a palate collected in 1981, by Rich and colleagues, from Horseshoe West Locality (WV 113) in the Camfield Beds of Camfield Station, northwestern Northern Territory (Rich et al., 1982, 1991).

Estimates of the age of the Henk's Hollow, Fig Tree and Bullock Creek Local Faunas are based mainly on stage-of-evolution comparisons of particular diprotodontian marsupials with those of other northern and central Australian faunas (Rich et al., 1982, 1991; Archer & Flannery, 1983; Archer & Hand, 1984; Woodburne et al., 1985; Murray, 1990a; Murray & Megirian, 1990; Archer et al., 1989,1991). Recent reappraisal of the age of central Australian Tertiary mammalian faunas, based on the study of foraminifera (Lindsay, 1987), suggests that some of these faunas (e.g. the Ditjimanka, Pinpa and Ericmas Local Faunas) are appreciably older than once thought (e.g. Woodburne et al., 1985; but see Tedford, 1966), possibly late Oligocene. By comparison, the Bullock Creek Local Fauna is estimated to be ?middle Miocene in age, i.e. immediately post-Wipajiri (Murray, 1990a; Murray & Megirian, 1990). On-going studies (Archer et al., 1991) of the Riversleigh fossil faunas suggest that the Henk's Hollow Local Fauna is ?middle Miocene in age and the Fig Tree Local Fauna somewhere between late Oligocene and early Miocene in age.

The new zygomaturines described here are most similar to forms currently referred to the genus *Neohelos*. Their generic distinction, however, has been clarified by discovery at the type locality of new material referable to *Neohelos*

TABLE 1. Measurements of *Neohelos tirarensis* P^3 (AMF87625) and M^3 (AMF87626) from the Leaf Locality, Lake Ngapakaldi, South Australia. In mm. Abbreviations: ant, anterior; post, posterior; paramet, parametacone; protoc, protocone; parac, paracone.

P^3	Length	15.8
	width	13.9

tirarensis, the type and only named species of the genus. The original description (Stirton, 1967) of this Miocene zygomaturine from the Kutjamarpu Local Fauna of central Australia was based on five isolated teeth collected in 1962 at the Leaf Locality, Lake Ngapakaldi, Etadunna Station, South Australia. The holotype, a broken P^3, preserves only the posterior portion of the tooth. Though less complete than the other teeth, it was selected as the holotype because of the importance of premolar morphology in diprotodontoid systematics (Stirton, 1967; Stirton, Woodburne & Plane, 1967).

In 1982 two isolated teeth referable to *N. tirarensis* were collected from the type locality by Archer, Hand, T. Flannery, G. Hickie, J. Case and P. Bridge: a well-preserved RP^3 (AMF87625) and RM^3 (AMF87626). These add considerably to knowledge of this species. Additional materials referable to *Neohelos* from the Bullock Creek Local Fauna (Plane & Gatehouse, 1968; Plane, 1971; Murray & Megirian, 1992) and various Oligo-Miocene Riversleigh local faunas (Archer et al., 1989, 1991) are presently under study.

Institutional abbreviations used here are as follows: QMF, fossil collection of the Queensland Museum; AMF, fossil collection of the Australian Museum; SAMP, palaeontological collection of the South Australian Museum; NMVP, palaeontological collection of the Museum of Victoria; AR, research collection of the School of Biological Sciences, University of New South Wales. Cusp nomenclature follows Archer (1984) and Rich, Archer & Tedford (1978). The posterolingual cusp of the upper molars, conventionally called the hypocone (e.g. Stirton, Woodburne & Plane, 1967), is now called the metaconule following Tedford & Woodburne (1987) but the posterolingual cusp of P^3, following unchallenged convention, is called the hypocone. Cheektooth homology is that proposed by Archer (1978). Higher level systematic nomenclature follows Aplin & Archer (1987).

SYSTEMATICS

Superorder MARSUPIALIA Illiger, 1811
Order DIPROTODONTIA Owen, 1866
Family DIPROTODONTIDAE Gill, 1872
Subfamily ZYGOMATURINAE Stirton, Woodburne & Plane, 1967

Neohelos Stirton, 1967
(Fig. 1, Table 1)

Type species. Neohelos tirarensis Stirton, 1967

REVISED GENERIC DIAGNOSIS

The following combination of features appears to distinguish species of *Neohelos* from all other zygomaturines: P^3 with large, erect parastyle that is well isolated from the parametacone; parastyle is conical without tip developed as a blade; anterolingual basin well defined in P^3 by distinct basal cingulum extending between parastylar corner of tooth to anterolingual base of protocone; P^3 parametacone with an undivided tip; parametacone tip not developed into anterobucally oriented blade; line between protocone, parametacone and widest buccal point on crown is approximately rectilinear and divides crown either in half or leaves anterior division shorter than the posterior division; P^3 with well-developed hypocone or hypocone shelf; M^{2-3} with well developed parastyle and metastyle.

Nimbadon n.gen.
(Figs 2-5, Table 2)

Type species. Nimbadon lavarackorum n.sp.
Additional species. Nimbadon whitelawi n.sp., *Nimbadon scottorrorum* n.sp.

GENERIC DIAGNOSIS

Species of *Nimbadon* differ from those of all other zygomaturines (with special reference to *Neohelos*, the taxon to which they are otherwise most similar) in the following combination of features: small size (although they are larger than *Raemeotherium* Rich, Archer & Tedford, 1978); in having a molar gradient that does not appreciably increase posteriorly (in contrast to all other zygomaturines except *Raemeotherium*); posteriorly inclined parastyle on P^3 (rather than conical

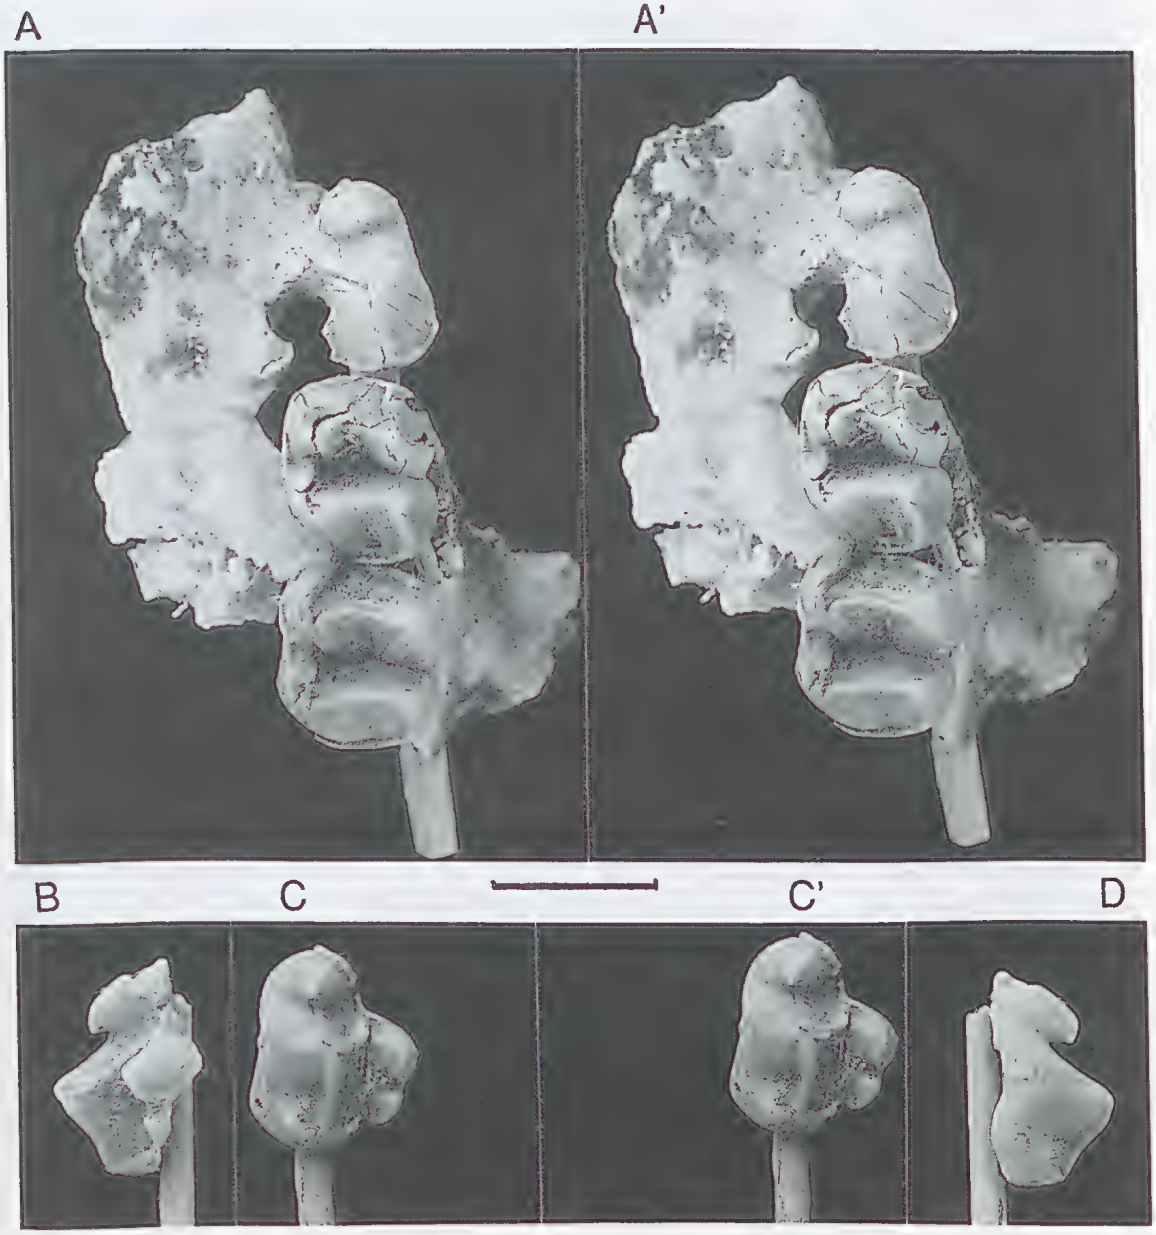

FIG. 2. *Nimbadon lavarackorum* n.gen., n.sp., Henk's Hollow Site, Riversleigh Station. A-A', QMF23141, holotype, left maxillary fragment with M^2, M^3 and buccal half of P^3, occlusal stereopair. B-D, QMF23143, RP^3: B, lingual view; C-C', occlusal stereopair; D, buccal view. Bar indicates 10mm.

pocone on P^3 (in contrast to *Alkwertatherium* and most but not all *Neohelos* and in contrast to all other zygomaturine P^3s where this cusp is large, including *Maokopia* Flannery, 1992); posterobuccal basal cingulum on P^3 (in contrast to most other zygomaturines except *Alkwertatherium* and *Neohelos* where this feature is variably developed); poorly developed to absent anterolingual basal cingulum joining base of parastyle to base of protocone (in contrast to most other zygomaturines except some *Neohelos* where there may be only a very small cingulum); an anterolingual crest on P^3 that extends from the parametacone towards the protocone but, veering

anteriorly, bypasses the buccal crest from the protocone and extends to the anterolingual basal cingulum (in contrast to directly connecting to the buccal crest from the protocone as occurs in most if not all other zygomaturines); a line extended buccally through the protocone and parametacone passes anterior to the position of the widest point on the buccal base of the crown (in contrast to intersecting this point as it does in *Neohelos* and *Alkwertatherium*, although this feature is variable in *Nimbadon whitelawi* n.sp.); this same line divides the crown such that the anterior moiety is longer than the posterior one (as it does in *Alkwertatherium* but in contrast to either dividing the crown into approximately equal lengths or into shorter anterior and longer posterior moieties as it does in *Neohelos*); poorly developed parastyles and metastyles on upper molars (in contrast to species of *Neohelos* but as in some anterior teeth of other zygomaturines such as *P. centralis*).

ETYMOLOGY

Nimba is a northwestern Queensland Aboriginal word (Wanyi language) meaning 'small'; *don* is Greek for 'tooth'. The name alludes to the small molars found in species of this genus and to the fact that the posterior molars do not increase markedly in size from M2 to M4 as they appear to do in the otherwise similar *Neohelos tirarensis*.

Nimbadon lavarackorum n.sp.
(Figs 2,3)

HOLOTYPE

The holotype is QMF23141, a left maxillary fragment containing M^2, M^3 and the buccal half of P^3.

ETYMOLOGY

The species is named after Sue and Jim Lavarack in recognition of their invaluable support in the field at Riversleigh and as founding members and hard working Councillors of the Riversleigh Society, a support group for Australian palaeontological research.

TYPE LOCALITY AND AGE

Henk's Hollow Locality (Archer & Flannery, 1987) occurs within the sequence of Tertiary limestones outcropping on Riversleigh Station, northwestern Queensland (Archer & Hand, 1984; Archer et al., 1989, 1991). It is stratigraphically near the top of the System C sequence as defined by Archer et al. (1989, 1991). This is interpreted to be stratigraphically higher than Site D (System A containing the Riversleigh Local Fauna; Archer et al., 1991), Microsite (containing the Nooraleeba Local Fauna; Sigé, Hand & Archer, 1982; Hand, 1993) and Gag Site (near the base of System C, containing the Dwornamor Local Fauna; Flannery & Archer, 1984; Hand, 1985; Archer et al. 1991), but is close to (though still above) the level of Two Trees Site (containing the Two Trees Local Fauna Flannery & Archer, 1987). On the basis of its stratigraphic position and stage of evolution comparisons of its fossil mammals (work in preparation), the Henk's Hollow Local Fauna is tentatively interpreted here to be middle Miocene in age (Archer et al., 1989, 1991).

REFERRED SPECIMENS AND THEIR LOCALITIES

QMF23142 from the Henk's Hollow Locality, a left dentary containing P_3-M_5, is tentatively referred to this species, as are the following isolated teeth from Henk's Hollow: QMF23143, a right P^3; QMF23144, a left P^3; QMF23145, a left M^2; QMF23146, a right M^3; QMF23147, a left M^4; QMF23148, a left ?M^4; QMF23149, a right M^4; QMF23150, a right M^5; QMF23151, a right P_3; QMF23152, a left P_3; QMF23153, a right P_3; QMF23154, a left ?M_2. QMF23155, a right M_2, and QMF23160, a right M^{2-3}, were collected from the Gag Site of the same plateau, Riversleigh Station.

REFERRED LOCALITIES AND AGES

The stratigraphic relationships of the Henk's Hollow Local Fauna and the Dwornamor Local Fauna are indicated above. At present, both are interpreted to be middle Miocene in age.

SPECIES DIAGNOSIS

This species is distinguished from *Nimbadon scottorrorum* n.sp. from Riversleigh's Fig Tree locality (see below) by its smaller size, relatively longer P^3, better developed hypocone on P^3, less well-developed parastyle on M^3 and probably more elongate posterior upper molars and less well developed postmetacrista but more discrete metastyle on M^2.

It is distinguished from the similar-sized *N. whitelawi* n.sp. by its almost square (rather than rectangular) upper molars.

DESCRIPTION

P^3 is represented by three specimens: a LP^3 from the holotype, QMF23141; an isolated RP^3, QMF23143; and an isolated LP^3, QMF23144. The tooth is widest across the protocone, sharply pinching in anteriorly and smoothly rounding posteriorly. It is subtriangular and is comprised

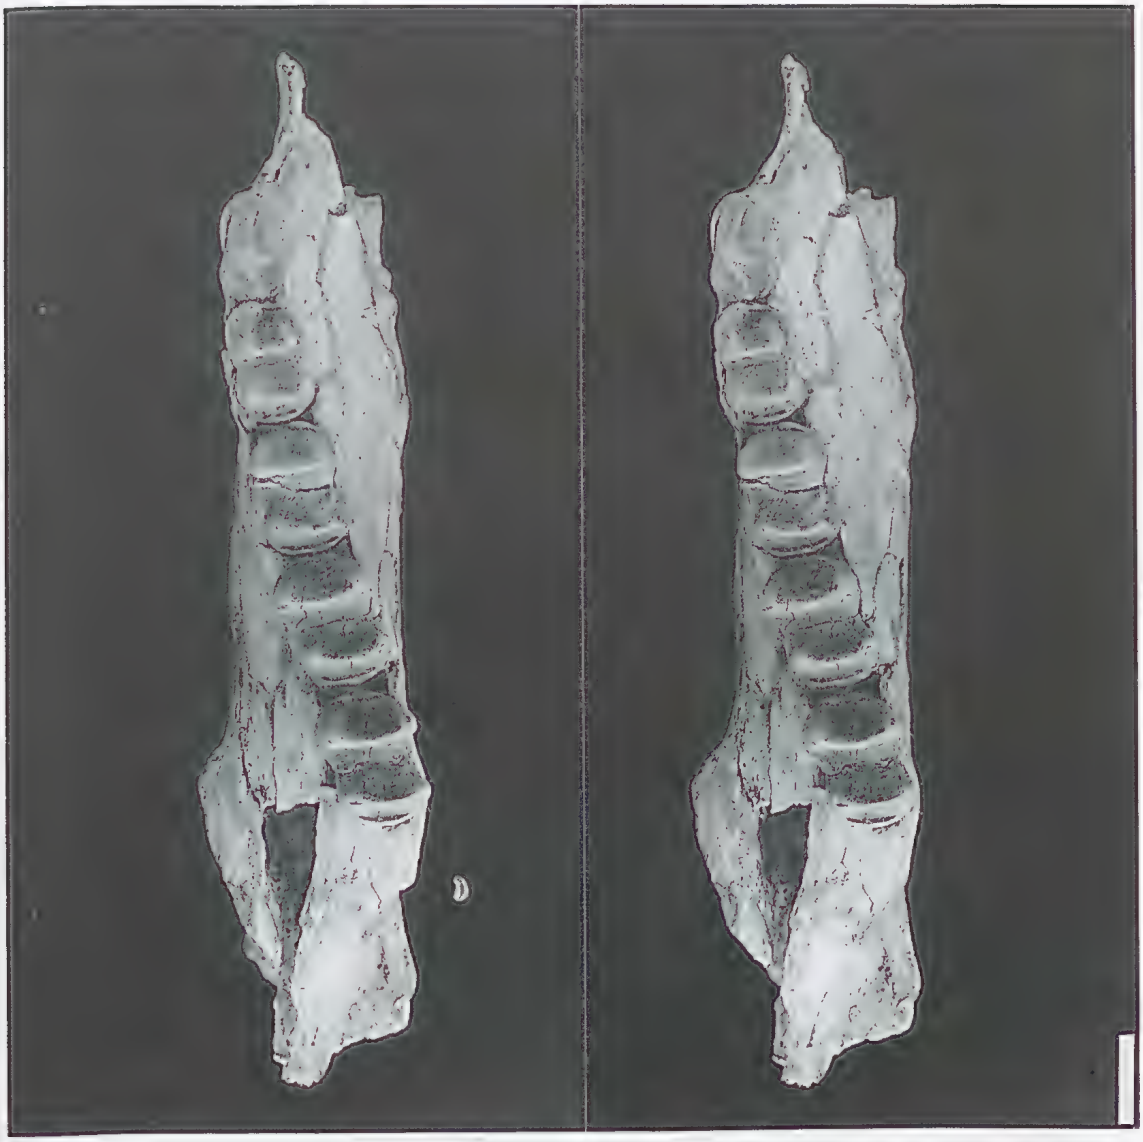

FIG. 3. *Nimbadon lavarackorum* n.gen., n.sp., Henk's Hollow Site, Riversleigh Station. QMF23142, left dentary with P_3, M_2, M_3, M_4 and M_5, occlusal stereopair. Bar indicates 10mm.

of four cusps: the parastyle, parametacone, protocone and hypocone (the latter however being variably developed). The parametacone is the highest cusp. It is blade-like with a strong shearing crest on the posterior edge and a short anterobucally oriented apical crest. The protocone and parastyle are subequal to each other in size. The hypocone is the smallest cusp and is even absent in one specimen (QMF23144). There is no suggestion of a division in the parametacone which is pyramid-shaped having relatively flattened anterior, buccal and lingual faces. The protocone is lingual to the parametacone and the hypocone lies posterobuccal to the protocone. The hypocone is more sharply separated by deep fissures from the buccal cusps than is the protocone. The parastyle is posteriorly inclined with a short anterolingually oriented apical blade. This large conical cusp forms a strong anterobuccal projection in the occlusal outline of the crown. It is separated from adjacent cusps by a chevron-shaped transverse cleft that is better-developed lingually than buccally. Posterior to this cleft, and on the anterior flank of the parametacone, a con-

spicuous ridge extends anterolingually from the tip of the parametacone to the anterolingual cingulum at a point anterobuccal to the base of the protocone. From the tip of the protocone, a poorly-defined transverse crest runs buccally until it almost meets (but does not) the parametacone ridge, its counterpart, at the commisure that separates the protocone and parametacone. Anterolingually, a very poorly developed (to ?absent) cingulum extends from the anterobuccal base of the protocone to the lingual base of the parastyle but does not continue up the flank of the parastyle. A cingulum is also developed posterobuccally from the buccal flank of the parametacone to the most posterior point of the crown (but is better-developed in some specimens than in others) and appears to be developed posterolingually from this point to at least the base of the hypocone. There is no evidence of an anterobuccal cingulum. From the tip of the parametacone, a prominent crest runs to the posterior margin of the tooth, dividing the posterolingual and posterobuccal cingula. A small crest runs posteriorly from the tip of the protocone to a swelling or cuspule. Another thin crest on the posterior face of the hypocone appears to converge with the posterolingual cingulum (at least in QMF23144). The tooth is two-rooted. The anterior root is conical and slightly anteriorly sloping; the larger posterior root is anteroposteriorly flattened and anteriorly convex. Many of the medial surfaces of the four crowns are covered in fine, poorly developed crenulations. There are two roots: one anterior oval one beneath the parastyle; and a much longer anteroposteriorly compressed root that extends transversely beneath the whole width of the posterior part of the crown.

M^2. The first upper adult molar is known from the holotype, QMF23141, and ?an isolated left M^2, QMF23145. It is a low-crowned almost square transversely lophodont tooth that is only slightly longer than wide. It is comprised of an anterior moiety, the protoloph, and a posterior moiety, the metaloph. Both are anteriorly convex. The paracone and metacone are similar in size as are the slightly shorter protocone and metaconule. The metaconule is slightly higher than the protocone and more lingually-situated. The metaloph is thus wider than the protoloph. The paracone and metacone are slightly closer together than are the protocone and metaconule. In the anterobuccal corner of the tooth a weak parastyle is developed at the buccal end of the short anterior cingulum. There is no metastyle although there is a prominent postmetacrista that extends from the tip of the metacone to the posterior cingulum with which it merges. A weakly developed postparacrista on the posterior flank of the paracone extends toward the midvalley but stops short of contacting similar premetacristae that extend from the metacone and from just lingual to the metacone towards the midvalley. From the protocone and metaconule, wide but very faint crests extend posterobuccally across the posterior flanks of the protoloph and metaloph. From the protocone, this crest extends to the transverse valley near the midline; from the metaconule this crest extends to the posterior cingulum also near the midline of the tooth.

Wear facettes on these crests exhibit polish and parallel striations (particularly in QMF23145) suggesting that their function was maintained by thegosis against (respectively) the entoconid of M_2 and the metaconid of M_3. The anterior cingulum extends from the parastyle around the lingual base of the protocone where it is interrupted and then continues across the lingual end of the transverse valley to the anterolingual base of the metaconule where it is interrupted and then continues around to the metastyle. There is no buccal cingulum. The M^2 may have been three-rooted with a cylindrical root beneath the paracone and another beneath the protocone and a single wide root beneath the metaloph. Precise thegotic facettes occur on the anterior trailing edges of the protoloph and metaloph blades. The anterior flanks of the protoloph and metaloph are "hollow-ground" in anticipation of the thegotic sharpening of the blades. Fine vertical crenulations on the flanks of the protoloph and metaloph produce secondary, vertical ?beta thegotic blades as the tooth sustains abrasive and thegotic wear.

M^{3-5}. M^{3-5} are similar to M^2 in basic morphology but are slightly larger and higher-crowned. The paracone is larger and more buccally- situated than the metacone. The protoloph and metaloph increase slightly in width from M^{2-4}. The parastyle and postmetacrista are markedly reduced in M^{3-5} such that in M^3 they are represented by terminal swellings in the anterior and posterior cingula respectively and are absent in M^4 and M^5. In some specimens (e.g. M^3 in QMF23160), however, there is a very tiny cuspule on the posterior flank of the metacone of posterior molars. The postparacrista is less well-developed as are the crests from the protocone and metaconule. The mesostyle appears to be lacking. The part of the crown anterior to the protoloph is shorter and the swelling in the transverse valley better developed. The metaloph is much more strongly curved in

M^{3-5} and is more lingually offset with respect to the protoloph.

Dentary. QMF23142, a dentary containing P_3, M_{2-5}, is tentatively referred to this species. It is of a size appropriate for some of the referred upper molars of this species and in its suite of plesiomorphic zygomaturine features (e.g. its lack of a posteriorly increasing molar size gradient), is analogous to the phylogenetic state of the upper molars of *N. lavarackorum*. However, because the specimen appears to be approximately 10% larger than the holotype, there is still some slight doubt about the propriety of referring this dentary to *N. lavarackorum*.

The dentary is badly fractured and is missing the incisor, medial symphysis, angle and ascending ramus. It is deepest below the hypolophid of M_4. The ventral border slopes posteriorly upward from this point and anteriorly upward to at least the hypolophid of M_2. The anterior edge of the coronoid process leads posterodorsally from the body of the horizontal ramus. The postalveolar process is missing. There is no distinct digastric fossa and the area beneath the leading edge of the coronoid process is smooth suggesting that the masseteric fossa was not deep. The mental foramen is located approximately 4mm in front of a vertical line marking the most anterior edge of the P^3 crown. It is round in lateral view and opens anterodorsally onto the buccal surface of the diastemal region. Although the mandibular foramen is not preserved, the mandibular canal is represented by a sulcus at about the level of the tooth row.

The P_3 is preserved in QMF23142 as well as QMF23152, an isolated LP_3, QMF23153, an isolated RP_3 and QMF23151, an isolated RP_3. The tooth is longer than it is wide and more narrow anteriorly than posteriorly. It bears a central principal cusp, the protoconid, and a much smaller medially positioned posterior cingular cusp. These are joined by a prominent longitudinal shearing crest that also extends anteriorly from the protoconid to terminate as a cuspule or cingular swelling at the anterior edge of the crown. Lingual to the principle central cusp there is a variably distinguished cuspule (stylid or vertical cristid). This structure is the apex of a vertical flanking crest that extends ventrally to a point just posterior to the lingual base of the protoconid. This crest is most conspicuous in posterior view. A posterolingual cingulum leads posteriorly from the base of this crest to the base of the posterior cusp. A similar but much less well-developed vertical cristid extends ventrally from the buccal apex of the protoconid. Taken together, these flanking cuspules and their associated vertical cristids comprise a transverse structure that intersects the crown at its apex at right angles to the main longitudinal shearing cristid. The posterior cingulum is much better developed than the anterior cingulum which is present only at the anterolingual tip of the crown. The posterior cingulum extends from the lingual base of the protoconid to the posterior cuspid where it is met by the buccal base of the protoconid but is best developed in the region of the posterior cuspid where it is met by the main longitudinal crest of the crown. In this area of intersection, the posterior cingulum is conspicuously crenulated in some specimens (i.e. QMF23152 and QMF23153) and slightly less so in others (i.e. QMF23151). In QMF23152, a wear facette on the posterobuccal cingulum, possibly produced by the P^3 parametacone, is developed which is not seen in other specimens. In this same specimen, just anterior to the crenulated posterior cingulum, a transverse crest extends anterolingually from the tip of the posterior cusp to the posterolingual cingulum. In all specimens, a wear facette for M_2 is developed at the tallest point of the posterior cingulum. The tooth is double-rooted, the anterior root being conical in shape, the posterior root being anteroposteriorly flattened.

Specimens QMF23152 and QMF23153, although similar in morphology, are considerably smaller than the P_3 preserved in the dentary. The P_3 in this species might be sexually dimorphic.

M_2. The M_2, known from QMF23142 and QMF23154? (and the Gag Site QMF23155), is an elongate, subrectangular tooth that is narrower anteriorly than posteriorly. The trigonid of M_2 is represented by a transverse protolophid and an arcuate anterolingually directed paracristid that extends to the anterior margin of the tooth. From the protoconid a short indistinct crest (?protocristid) appears to extend posterobuccally to terminate in a slight swelling which is perhaps the protostylid. From the metaconid, a crest extends anteriorly a short distance. From the entoconid, a short entocristid extends anterolingually.

In occlusal view, the paracristid is convex buccally, the protolophid is transverse or very slightly posteriorly convex and the hypolophid is markedly posteriorly convex. The protolophid is narrower than the hypolophid. An anterior cingulum is present both buccal and lingual to the anterior end of the paracristid. The cingulum on the buccal side is not preserved in QMF23142, is distinct (between the protolophid and hypolo-

phid) in QMF23155 but not in QMF23154. There is no lingual cingulum or cristid obliqua in QMF23142 but there is a lingual cingulum in QMF23155 (again between the protolophid and hypolophid). The posterior cingulum connects the posterior base of the hypoconid to that of the entoconid. A wear facette is developed at the midpoint of the posterior cingulum. Distinct wear facettes extend along the posterior lengths of the protolophid and hypolophid. In lingual view, the floor of the transverse valley is U-shaped. The protoconid is taller than the subequal metaconid, hypoconid and entoconid. The tooth is double-rooted but these are not well preserved in the isolated teeth QMF23154 and QMF23155.

QMF23154 (M_2?) has a paracristid and premetacristid that are much less distinct than those preserved in the dentary and Gag Site specimen. Only the paracristid extends to the anterior cingulum of the tooth. In this specimen, the enamel on the posterior face of the protolophid has prominent vertical crenulations. The cristid obliqua is also distinct although low and extends as a minor vertical crenulation on to the posterior flank of the protolophid.

M_{3-5}. Unlike M_2, trigonids of the posterior molars lack a prominent paracristid and are more rectangular in appearance with the protolophid being slightly wider than the hypolophid in M_{3-5}.

In M_3, the protolophid and hypolophid are approximately the same width. The paracristid forms a poorly-defined vertical crest that extends only partly down the anterior face of the protolophid. The premetacristid is also poorly defined and extends approximately the same distance. Protolophids and hypolophids become more posteriorly convex from M_2 to M_5. In M_{4-5}, the protolophids are markedly wider and the hypolophids are lingually displaced. M_4 and M_5 are larger than M_3.

Nimbadon whitelawi n.sp.
(Fig. 4)

Holotype
The holotype and only known specimen is NMVP186506. It preserves the palate, RP^3-M^5 and LP^3-M^3. All teeth except LP^3 are damaged and LM^3 and RM^5 are missing parts of their posterior halves.

Etymology
This species is named after Michael Whitelaw who assisted in the collection and processing of specimens from Bullock Creek.

Type Locality and Age
The type locality is fossil vertebrate locality WV 113 in Bultitude (1973) (17°7'S, 131°32'E), the Horseshoe West locality of the Camfield Beds at Bullock Creek, Camfield Station, northwestern Northern Territory. The Bullock Creek Local Fauna (Plane & Gatehouse, 1968; Archer & Bartholomai, 1978; Rich et al., 1991; Archer & Hand, 1984; Murray & Megirian, 1990, 1992) is currently interpreted to be ?middle Miocene, i.e. immediately post-Wipajiri, in age (Woodburne et al., 1985; Murray, 1990a; Murray & Megirian, 1990, 1992).

Species Diagnosis
This species is distinguished from *N. lavarackorum* and *N. scottorrorum* by its markedly more elongate (i.e. less square) upper molars and relatively more anteriorly situated buccal swelling on P^3. It is also distinguished from *N. scottorrorum* by its relatively much longer P^3 and markedly convex anterior and posterior molar crown margins such that these teeth have a much reduced area of interdental contact.

Description
The species is described insofar as it differs from *Nimbadon lavarackorum*.

The palate preserves most of the right and a large part of the left maxillae and small fragments of the left and right palatines. Anteroventrally, the palate is fractured at or behind the premaxillo-maxillary suture. Posteroventrally, it preserves the maxillo-palatine suture. The latter extends anteriorly to a point medial to the posterior part of M^3. Palatal ridges extend longitudinally and anteriorly along the length of the palate from the level of M^3. The right diastemal crest runs anterolingually. The tooth rows are parallel to slightly convex buccally. Anteriorly, doming of the median region of the palate is marked. It extends posteriorly to the level of the rear of M^2 and, though shallowing perhaps, anteriorly to at least just behind the premaxillo-maxillary boundary. There is a pair of nutrient foramina on the right side of the palate medial to P^3 and on the left side a single foramen. Medial to the hypoloph of M^2, is another tiny foramen on each side of the palate. The infraorbital foramen canal is about 30mm in length. The infraorbital canal opens onto the face 14mm above the anterior edge of the P^3 alveolus. Sutural relationships of the palatine, lacrimal, jugal and maxillary bones are unclear. There is no evidence for maxillary or palatal vacuities although the anterior and posterior ex-

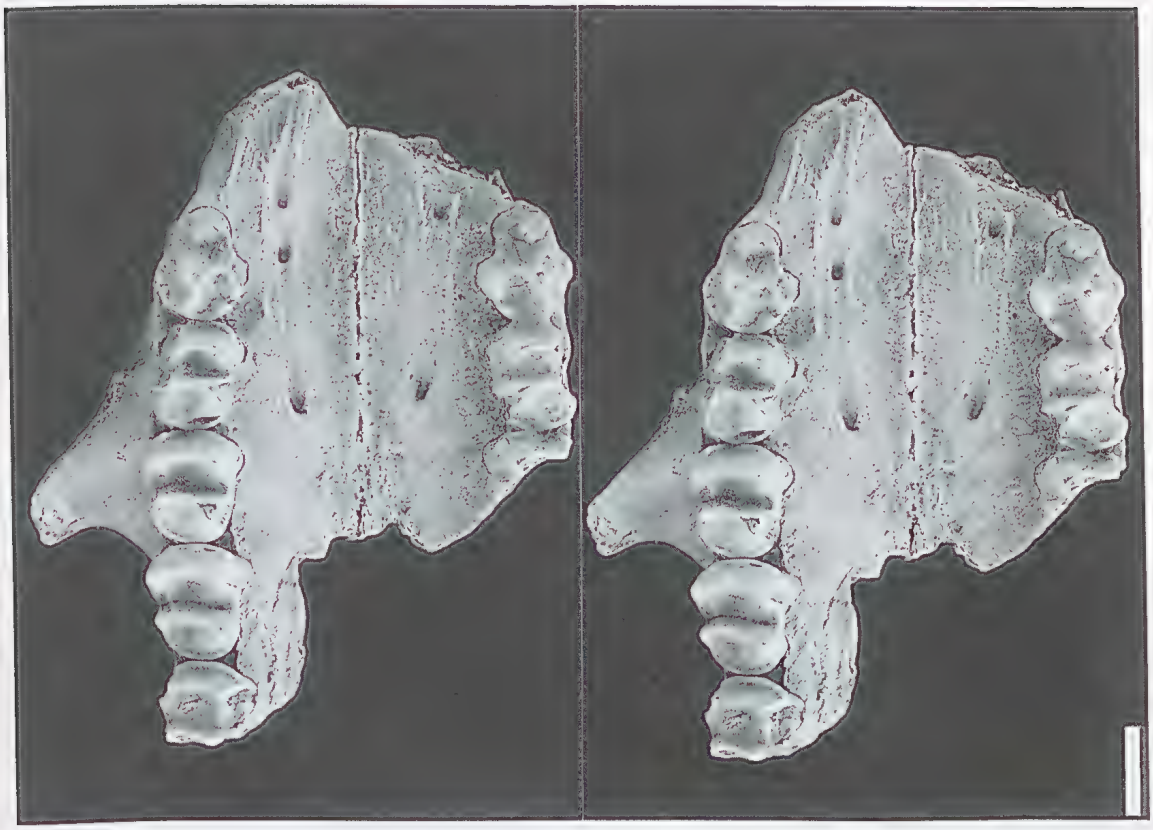

FIG. 4. *Nimbadon whitelawi* n.sp., Bullock Creek, Northern Territory. NMVP186506, palate with RP^3-M^5 and LP^3-M^5, occlusal stereopair. Bar indicates 10mm.

tremities of the palate are missing. The maxillary process near the roof of the zygomatic arch, although damaged, is down-turned and conspicuous but does not extend ventrally below the level of the palate. There appears to have been a very reduced orbital wing of the maxilla, although bone boundaries in this region are unclear.

Upper dentition. The P^3 differs from most specimens (all except QMF23144 AR5513) of *N. lavarackorum* in the greater degree of development of the hypocone. In *N. whitelawi* the parastyle appears to be less posteriorly inclined and the anterolingually-directed crest that extends from the parametacone to the anterolingual cingulum is less distinct although it is possibly diminished by wear. It nevertheless approaches the buccal crest from the protocone at a steep angle rather than perpendicular.

The M^2 on both sides of the holotype is damaged buccally and lingually. However, it appears to differ from both Riversleigh species of *Nimbadon* in being longer relative to P^3 and in appearing to be rectangular rather than square.

The M^3 appears to differ from the Riversleigh species in a similar way as M^2, but it appears to be relatively even more elongate. M^2 and M^3 are approximately equal in length.

The M^4 differs less from that tooth in the other species of *Nimbadon*.

All of the cheekteeth of *N. whitelawi* appear to differ from those of *N. scottorrorum* in having anteriorly and posteriorly markedly convex tooth margins so that the crowns abut with limited contact.

Nimbadon scottorrorum n.sp.
(Fig. 5)

HOLOTYPE

The holotype and only known specimen is QMF23157 (formerly SAMP27815), a right maxillary fragment containing P^3, M^2, M^3, M^4 and M^5. While P^3 and M^2

are intact, M^{3-5} are missing the buccal margins of the crown.

Etymology

The species is named after Sue and Don Scott-Orr, in recognition of their long-term support for the Riversleigh Palaeontological Research Project. With the Lavaracks, they are also founding members and Councillors of the Riversleigh Society.

Type Locality and Age

The type locality, Fig Tree Site, is adjacent to Godthelp Hill, Riversleigh Station, northwestern Queensland. It is laterally adjacent to units regarded by Archer et al. (1989, 1991) to be part of System B although it may actually be from the basal part of System B or even upper part of System A, hence stratigraphically below Henk's Hollow (upper part of System C; Archer, Hand & Godthelp, 1986) and Gag Site (lower part of System C; Flannery & Archer, 1984; Hand, 1985) and possibly above or equivalent to Microsite (?System A; Sigé, Hand & Archer, 1982; Archer et al., 1989, 1991) and Site D (System A; Tedford, 1967; Archer et al., 1989, 1991). On this basis and stage of evolution comparisons of the marsupials in these faunas, the Fig Tree Local Fauna is interpreted to be ?late Oligocene-early Miocene in age.

Species Diagnosis

This species is distinguished from *Nimbadon lavarackorum* and *N. whitelawi* by its larger size, anteroposteriorly compressed P^3 (which is much shorter than any upper molar), its more robust cingula on all cheekteeth and its greater parastylar development in M^{2-3} (contributing to the squared appearance of these teeth). It also has less convex anterior and posterior molar crown margins which therefore have much wider interdental contact with each other.

It is further distinguished from most (but not all) *N. lavarackorum* by its much smaller hypocone on P^3.

Description

Nimbadon scottorrorum differs from *N. lavarackorum* and *N. whitelawi* as follows:

The P^3 is markedly anteroposteriorly compressed such that it is almost as wide as it is long and is subrounded in shape. Unlike *N. lavarackorum*, in which P^3 is equal in length or longer than any adult upper molar, in *N. scottorrorum* this tooth is the shortest in the tooth row. The hypocone appears to have been very poorly developed.

The anterobuccal corner of M^2 has a much squarer appearance due to greater parastylar development in the anterior cingulum. This is true also of the posterobuccal corner of the tooth where metastylar development occurs mid-way along the postmetacrista.

Parastylar development in M^3 is relatively marked compared with its condition in *N. lavarackorum*. The teeth are buccally fractured in M^{3-5} making it impossible to determine the degree of development of the buccal cusps in M^{4-5}.

DISCUSSION

The three diprotodontids described here appear to comprise a new clade of zygomaturines. As species of the new genus *Nimbadon*[1], they may be distinguished from other zygomaturines by, among other features, a combination of upper premolar attributes. Premolar morphology was extensively used by Stirton (1967) and Stirton et al. (1967) to help resolve distinctions between diprotodontid lineages and has subsequently been used by most workers. Few other character systems have been found to be as useful in distinguishing probable inter-relationships among Tertiary diprotodontids.

Since Stirton et al.'s (1967) review of Tertiary diprotodontids, diverse diprotodontoid materials have been collected from Oligo-Miocene fossil sites at Riversleigh, Bullock Creek, Alcoota and Beaumaris and from Pleistocene sites in New Guinea (e.g. Flannery, 1992) and many areas of Australia. This material includes specimens representing new genera and probably new diprotodontoid subfamilies. Murray (1986, 1990a,b) has named several new Tertiary taxa but the bulk of the material, particularly from Riversleigh sites, is yet to be described. As a result of the new discoveries, the superfamily Diprotodontoidea is in need of major revision.

At present (e.g. the reviews of Archer, 1984; Aplin & Archer, 1987; Marshall, Case & Woodburne, 1989; Murray, 1990b) two diprotodontoid families are recognised: the Palorchestidae; and the Diprotodontidae with two subfamilies, the

[1] The generic name *Nimbadon* was used by Murray (1990b) in a cladogram of hypothetical phylogenetic inter-relationships among Miocene diprotodontids. However Murray did not designate a species of *Nimbadon* in the cladogram or in the ensuing discussion, and, as outlined in Article 13B of the Code of Zoological Nomeneclature, '*Nimbadon*' was thus used as a *nomen nudum*.

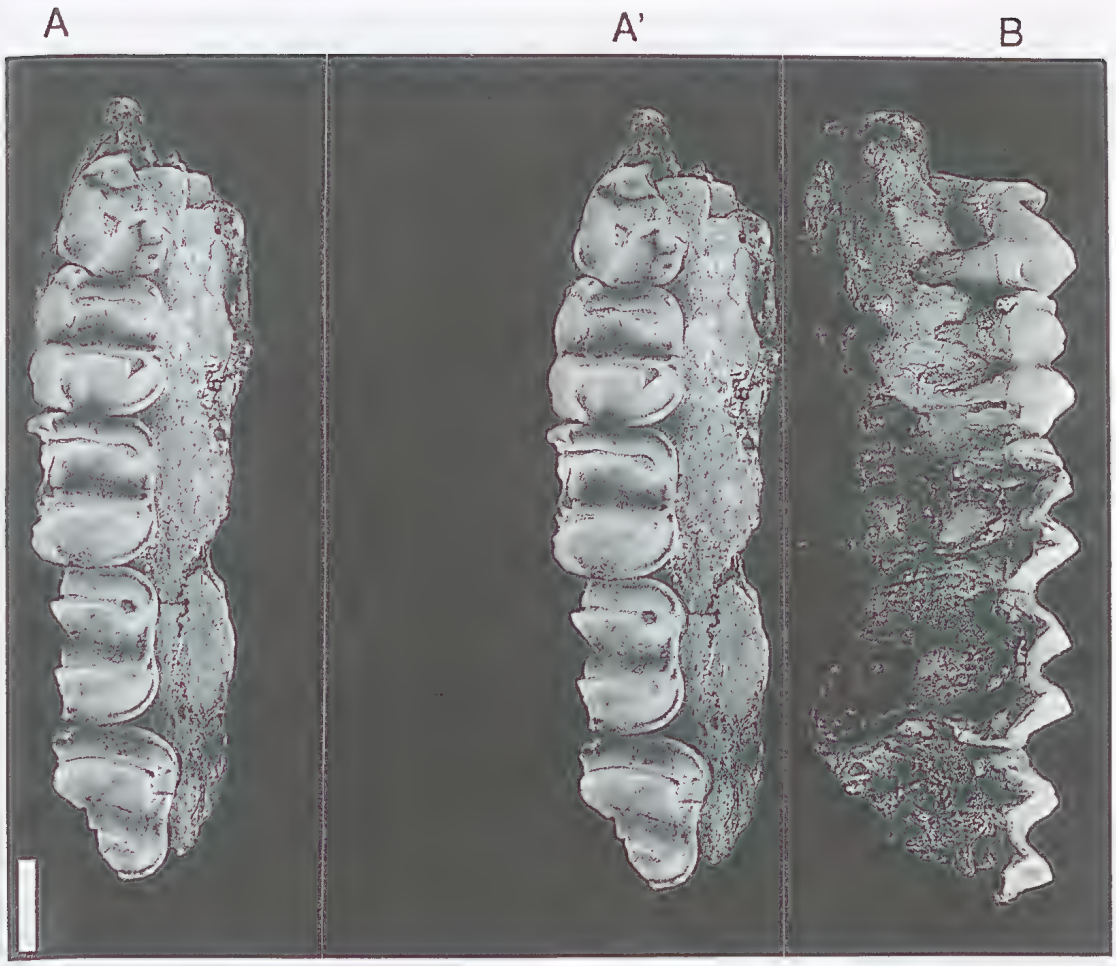

FIG. 5. *Nimbadon scottorrorum* n.sp., Fig Tree Site, Riversleigh Station. QMF23157, right maxillary fragment with RP^3- M^3, A-A', occlusal stereopair; B, buccal view. Bar indicates 10mm.

Diprotodontinae and the Zygomaturinae. Although zygomaturines have traditionally (e.g. Stirton et al., 1967) been considered to be among the most primitive of diprotodontoids, it is by no means certain that this is so (Murray, 1990b). It is not clear what might be used as an appropriate outgroup in a phylogenetic analysis of zygomaturines nor, consequently, are polarities of character state morphoclines within the Zygomaturinae confidently determined.

Murray (1990b) has discussed other difficulties in analysing diprotodontid phylogenetics. He notes that despite the fact that many Tertiary diprotodontids are represented by almost-complete skull and dentary material, discontinuities in some character complexes and the continuously varying nature of others tend to obfuscate clarification of relationships between taxa. Considerable variability in cranial morphology has been observed in some zygomaturines (e.g. in a *Neohelos* sample from the Bullock Creek Local Fauna; P. Murray, pers.comm.), and the molar dentitions of the zygomaturines *Plaisiodon centralis* Woodburne, 1967 and *Alkwertatherium webbi* Murray, 1990b and the diprotodontine *Pyramios alcootense* Woodburne, 1967 have been found to overlap in size and morphology (Murray, 1990b).

It is perhaps a measure of the difficulties encountered in determining species and generic boundaries for diprotodontids that *Nimbadon* is one of few non-monotypic Tertiary zygomaturine genera, the others being *Kolopsis* Woodburne, 1967 and *Zygomaturus* Owen, 1859.

Recognition of the genus *Nimbadon* has been facilitated by re-diagnosis of *Neohelos* Stirton,

1967 based on new material obtained by Archer and colleagues 20 years after the original material was collected by Stirton and colleagues from the Leaf Locality of Lake Ngapakaldi, South Australia. This provides novel information about the anterior morphology of P^3, which exhibits, among other distinctive features, a large, erect parastyle. This feature is also present in specimens referred to *Neohelos* from the Bullock Creek and Riversleigh Tertiary faunal assemblages (Plane & Gatehouse, 1968; Plane, 1971; Rich et al., 1982; Murray & Megirian, 1990, 1992; Archer et al., 1989, 1991).

In his review of Oligo-Miocene diprotodontid taxa, Murray (1990b) postulates a number of phylogenetic hypotheses, only one of which is expressed in his cladogram (fig. 14). The latter is based primarily on analysis of dental characters (in particular, P^3), using species of the Oligo-Miocene palorchestid genera *Ngapakaldia* and *Pitikantia* as outgroups. In it, Murray identifies species of *Kolopsis* and *Zygomaturus* as the most derived diprotodontids and *Neohelos tirarensis* as their closest relative. Species of *Nimbadon* form the sister-group to the *Neohelos–Kolopsis–Zygomaturus* clade, with *Plaisiodon centralis* being the sister-group of a *Nimbadon–Neohelos–Kolopsis–Zygomaturus* clade, *Kolopsoides cultridens* Plane, 1967 the sister-group of a *Plaisiodon—Nimbadon—Neohelos—Kolopsis—Zygomaturus* clade and *Alwertatherium webbi* the most plesiomorphic of zygomaturines. Species of *Pyramios*, *Euryzygoma*, *Bematherium* and *Diprotodon* form a separate (diprotodontine) clade. *Raemeotherium yatkolai* Rich, Archer & Tedford, 1978 from the ?late Oligocene Namba Formation of Lake Pinpa, South Australia, is interpreted to be the most plesiomorphic member of the family Diprotodontidae.

On the basis of his broader study of dental and cranial characters, however, Murray (ibid.) concludes that there are probably two minor zygomaturine lineages: one represented by species of *Nimbadon*, *Neohelos* and *Kolopsis*, a group he suspects may consist of taxa related largely by symplesiomorphies; the other lineage possibly containing species of *Alkwertatherium*, *Plaisiodon* and *Kolopsoides*, although for this clade he can find even less concrete evidence. He suggests that these two lineages might be related through common ancestry in *Nimbadon*. He also suggests in the text, but not the cladogram, that *Nimbadon* species could represent basal zygomaturines with some specific affinity to *Plaisiodon centralis* and *Neohelos tirarensis*, and that *Plaisiodon centralis* is more closely related to *Alkwertatherium webbi* than to any other zygomaturine.

A phylogenetic hypothesis of diprotodontid inter-relationships, including the three new *Nimbadon* species and broadly based on Murray's cladistic analysis of dental characters, is given in Fig. 6. The polarity of some characters has been interpreted differently from Murray (1990b) but basic intergeneric relationships remain unchanged except for the position of *Plaisiodon centralis*.

In Fig. 6 and Murray (1990b), the Zygomaturinae are clustered on the basis of a large parastyle on P^3 which is separated from the parametacone by a deep cleft. The *Kolopsoides-Plaisiodon-Nimbadon-Neohelos-Kolopsis-Zygomaturus* clade shares as a synapomorphy development of a hypocone in P^3. The basic proportions of P^3 are apomorphically shared by species of the *Nimbadon, Plaisiodon, Neohelos* and Kolopsis clade (but see Murray, 1990b), with a division in the parametacone interpreted to have occurred subsequently in the *Kolopsis* lineage. Retraction of the mesostyle towards the cingulum in P^3 clusters species of *Neohelos* and *Kolopsis* (Murray, 1990b).

In both cladograms, the posteriorly inclined (or hooked) parastyle of P^3 in species of *Nimbadon* is regarded to be apomorphic. Only one other zygomaturine exhibits this feature — *Plaisiodon centralis*. Although species of *Nimbadon* are readily distinguished from *P. centralis* by aspects of upper premolar morphology (including in *P. centralis* the very large hypocone and the lingual crest from the parametacone linking to the protocone rather than the anterolingual cingulum) as well as by their small size, lack of a posteriorly increasing molar gradient and absence of metalophids on lower molars, sharing of the distinctively shaped parastyle may indicate an albeit distant phylogenetic relationship.

Although the three taxa described here as species of *Nimbadon* may, when better known, prove not to be monophyletic, all exhibit the distinctive crest on P^3 running lingually from the parametacone to the protocone then anteriorly to the anterolingual cingulum, a feature not previously noted in any other diprotodontoid taxa. Other features that characterise the new taxa include their small size and an M_2:M_4 length ratio which approaches 1.0. The latter are interpreted here and generally (see below) to be plesiomorphic features among diprotodontids, but they might equally be interpreted to represent apomorphic reversals within certain zygomaturine lineages.

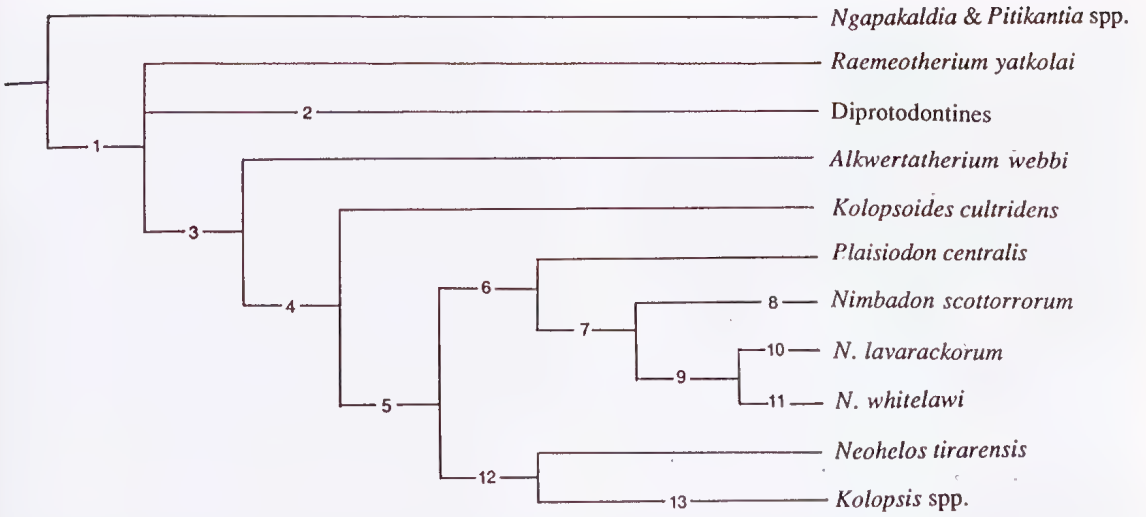

FIG. 6. A phylogenetic hypothesis of zygomaturines, broadly based on Murray's (1990b) cladistic analysis of dental characters in the Diprotodontidae. Apomorphies are as follows: 1, loss, incorporation or suppression of stylar cusps C and D with respect to the lophs on upper molars; 2, reduction of paralophid crest on M_2; 3, large parastyle on P^3 separated from parametacone by a deep cleft; 4, development of a hypocone on P^3; 5, basic proportional similarity of P^3; 6, hooked parastyle on P^3; 7, apical blade and diagonal crest on P^3; 8, shortening of P^3; 9, elongation of posterior molars (i.e. at least M3-4); 10, hypertrophy of P^3 hypocone; 11, elongation of anterior molars, i.e. M2; 12, mesostyle on P^3 retracted towards cingulum; 13, division in P^3 parametacone.

We can, however, find no pressing evidence to closely align individual species of *Nimbadon* with any previously known zygomaturine taxa.

Most zygomaturines — including species of *Zygomaturus*, *Kolopsis*, *Kolopsoides* and *Plaisiodon* — exhibit a marked increase in molar size from M2 to M4 (with an M_2-M_4 length ratio of 0.85 or less) with M5 generally decreasing in size (see also Rich, Archer & Tedford, 1978). Whether this is also true of topotypical *Neohelos tirarensis* is not known but *Neohelos* specimens from Bullock Creek and most from Riversleigh exhibit this feature.

A molar gradient of M2:M4 length approaching 1.0 is regarded by Rich, Archer & Tedford (1978) to be plesiomorphic in zygomaturines. *Raemeotherium yatkolai*, commonly considered to be the most primitive of known zygomaturines (but see Murray, 1990b, and below) and represented by a dentary, isolated lower teeth and an upper incisor from the Oligo-Miocene Namba Formation of Lake Pinpa, also has uniformly sized molars (with a ratio of M_2:M_4 length of 0.96). Palorchestids and diprotodontines variably exhibit this feature and one of the oldest known diprotodontoids, represented in the early Miocene Geilston Bay Local Fauna by a maxilla preserving part of M^2 and M^3, also has uniformly sized molars. The latter is similar in size to *R. yatkolai* but is tentatively considered by Tedford et al. (1975) to be a palorchestid. Apart from its slightly larger size, *Nimbadon lavarackorum*, the only species of the genus so far represented by lower molars, like all other zygomaturines differs from *R. yatkolai* in its reduction of anterior entocristids. *Nimbadon* species further differ from *Raemeotherium yatkolai* in being larger; in having a more massive dentary which, in transverse width, is approximately twice the width of M_3; in having less well developed cristids obliqua; relatively wider trigonids on all molars; trigonid of M_2 nearly the same width as the talonid (in contrast to *R. yatkolai* where it is markedly narrower); metaconid of M_2 as high as the protoconid and associated with a prominent, steeply inclined, swollen anterior buttress; metacristid of M_2 transversely oriented (in contrast to *R. yatkolai* where it is posterobuccally oriented); "arcuate" (rather than anteroposteriorly rectilinear) paracristid on M_2; and lophids of lower molars less occlusally concave.

It is possible that molar size gradients in zygomaturines are allometrically related to body-size, with larger animals exhibiting relatively larger posterior molars. From Oligo-Miocene deposits on Riversleigh Station, small diprotodontines have been found with M2:M4 length gradients approaching 1.0. Equally, however, the

larger of the Riversleigh species of *Nimbadon* described here (*N. scottorrorum*) appears to have been similar in overall size to at least one undescribed Riversleigh *Neohelos* that shows a marked progressive increase in molar size from M2 to M4. It seems, therefore, that the feature is not always dependent on absolute size although it may vary allometrically within lineages. In Fig. 6 it has been interpreted to be autapomorphic within various clades.

Intrageneric relationships within *Nimbadon* are not much easier to interpret. *Nimbadon whitelawi* differs from both *N. lavarackorum* and *N. scottorrorum* in its markedly more elongate upper molars (particularly with respect to *N. scottorrorum*) and relatively more anteriorly situated buccal swelling on P^3. *Nimbadon lavarackorum* differs from *N. scottorrorum* in its smaller size, less well-developed parastyle on M^3 and probably more elongate posterior upper molars and less well developed postmetacrista but more discrete metastyle on M^2. *Nimbadon scottorrorum* is larger than both *N. lavarackorum* and *N. whitelawi*, has more robust cingula on all cheek-teeth and greater parastylar development in M^{2-3} (contributing to the squared appearance of these teeth). Within *Nimbadon*, features such as the hypertrophy of the P^3 hypocone in some specimens of *N. lavarackorum* and the shortening of P^3 in *N. scottorrorum* appear to be autapomorphic features unique to those species. The most striking differences between the taxa lie in the degree of squaring (or conversely elongation) of the upper molars.

There are two quite different phylogenetic interpretations of *Nimbadon* species, depending on whether elongation (versus squaring) of the upper molars is considered to be plesiomorphic or apomorphic. Commonality would indicate squared upper molars to be plesiomorphic among diprotodontian marsupials including phalangeridans, vombatimorphians and even plesiomorphic kangaroos. However, within the Diprotodontidae the otherwise 'plesiomorphic' (i.e. simple) *Raemeotherium yatkolai* has relatively elongate lower molars and, although no uppers molars are yet known, they too would probably have been relatively elongate, using as a guide the relative proportions of the upper and lower molars of *N. lavarackorum*. It should be noted that the presumption that *R. yatkolai* is the most plesiomorphic diprotodontid is based on its simplicity. Simplicity, however, often characterises the smaller members of some diprotodontian lineages (e.g. pseudocheirids and macropodids) and all members of other lineages with ubiquitously small members (e.g. burramyids and acrobatids).

Because so few dental character systems have been found to be useful in diprotodontid systematics, polarity swings of this kind greatly influence the interpreted relationships of taxa and their biostratigraphic significance. If elongation is plesiomorphic among diprotodontoids, then *N. whitelawi* would be the most plesiomorphic of the three *Nimbadon* species. Its presence in the middle Miocene Bullock Creek Local Fauna and the presence of what would then be interpreted to be the most apomorphic in the older Fig Tree Local Fauna, would not be support for the currently understood stratigraphic relationships. If, on the other hand, elongation is interpreted to be apomorphic, then the most derived species (*N. whitelawi*) occurs in one of the younger faunas and the most plesiomorphic (*N. scottorrorum*) in the oldest of the faunas (Fig Tree).

The stratigraphic relationships of the fossil assemblages have been discussed in the Systematics section above. The Fig Tree Site occurs adjacent to units regarded to be part of Riversleigh's System B sequence as defined by Archer et al. (1989, 1991), though it may actually be basal System B or upper System A, and is interpreted to be late Oligocene to early Miocene in age. The Henk's Hollow Site occurs near the top of Riversleigh's System C sequence and the Gag Site near its base. Both lie stratigraphically above the Fig Tree level. On the basis of their positions and stage of evolution comparisons of their fossil mammals, they are interpreted to be middle Miocene in age and are probably similar in age to the Bullock Creek assemblage. The Bullock Creek Local Fauna has been interpreted by Woodburne et al. (1985), Murray (1990a) and Murray & Megirian (1990) to be middle Miocene, i.e. immediately post-Wipajiri, in age.

On balance, we consider the phylogenetic relationships of *Nimbadon* species (Fig. 6) to approximately correspond to current understanding of the relative ages of the deposits from which the specimens were obtained but conclude that for the moment at least caution is appropriate in attempts to use zygomaturines to correlate northern Australian Tertiary mammal- bearing faunas.

ACKNOWLEDGEMENTS

Grants to P.V. and T.H. Rich from the Australian Research Council and the National Geographic Society made possible the collection and preparation of *Nimbadon whitelawi*. The South

Australian Museum enabled N. Pledge to collect and prepare the holotype of *N. scottorrorum*. Work at Riversleigh has been supported by the Australian Research Council, the Department of the Arts, Sport, the Environment and Territories, National Estate Programme Grants (Queensland), the Australian Geographic Society, ICI, the Queensland Museum and the University of New South Wales. During the course of this work, S. Hand and H. Godthelp were supported by a University of New South special research grant. The authors thank Dr Peter Murray for his constructive criticism of the manuscript, and Dr David Ride who provided helpful nomenclatural advice. The photos were taken by Ross Arnett of the University of New South Wales.

DESCRIPTION OF A NEW SPECIES OF *CHAMA* FROM THE GULF OF CARPENTARIA WITH COMMENTS ON *PSEUDOCHAMA* ODHNER (MOLLUSCA: BIVALVIA: CHAMIDAE)

JOHN M. HEALY, KEVIN L. LAMPRELL AND JOHN STANISIC

Healy, J.M., Lamprell, K.L. & Stanisic, J. 1993 06 30: Description of a new species of *Chama* from the Gulf of Carpentaria with comments on *Pseudochama* Odhner (Mollusca: Bivalvia: Chamidae). *Memoirs of the Queensland Museum* **33**(1): 211-216. Brisbane. ISSN 079-8835.

A new species of Chamidae, *Chama isaacooki* sp.nov., is described from northern Australia and a key to the Australian Chamidae presented. In addition, the phenomenon of left versus right valve attachment in chamids is discussed, particularly in relation to recognition of the genus *Pseudochama* Odhner, 1917. It is concluded that the identity of valve attachment is not a reliable, sole basis for distinguishing *Pseudochama* from *Chama*.□ *Mollusca, Bivalvia, Chamidae, new species, taxonomy, Pseudochama.*

John M. Healy, Department of Zoology, University of Queensland, Queensland, 4072, Australia; Kevin Lamprell, John Stanisic, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; 4 January, 1993.

The Chamidae (Superfamily Chamoidea) is a widespread and common family of (typically) attached heterodont bivalves, characterized by pronounced leaf-like or spinose ornamentation, coiled umbones and often marked disparity in valve size. The living chamids of Australia have most recently been treated by Lamprell & Whitehead (1992), but the family has yet to be formally revised. During our recent investigations we have had the opportunity to examine numerous specimens from the various Australian State museums as well as material from a number of large private collections. This work revealed the existence of many synonyms as well as a new species from the Arafura Sea and the Gulf of Carpentaria. In the present paper we describe this species of *Chama* and compare it to other chamids from the Indo-Pacific region. We also take the opportunity to discuss Odhner's (1917) claim that *Pseudochama* Odhner can be separated from *Chama* solely on the basis of the valve of attachment (left versus right valve).

Abbreviations used in text: AM = Australian Museum; QM = Queensland Museum; WAM = Western Australian Museum; MV = Museum of Victoria; Q = Queensland; lv = left valve; rv = right valve; pv = paired valves; L = length; H = height; W = width..

MATERIAL AND METHODS

This study is based primarily on material held in the Australian Museum (Sydney), Museum of Victoria and Queensland Museum as well as numerous specimens in private collections including the Lamprell collection. All measurements were made with Vernier callipers.

SYSTEMATICS

Superfamily CHAMOIDEA Lamarck, 1809
Family CHAMIDAE Lamarck,1809
Chama Linnaeus,1758

Type species: *Chama lazarus* Linnaeus,1758; SD Children, 1823

Chama isaacooki sp.nov.
(Figs 1-4, Table 1)

ETYMOLOGY

The name honours the memory of Isaac Cook, son of Mr Steve Cook who provided the material for this study.

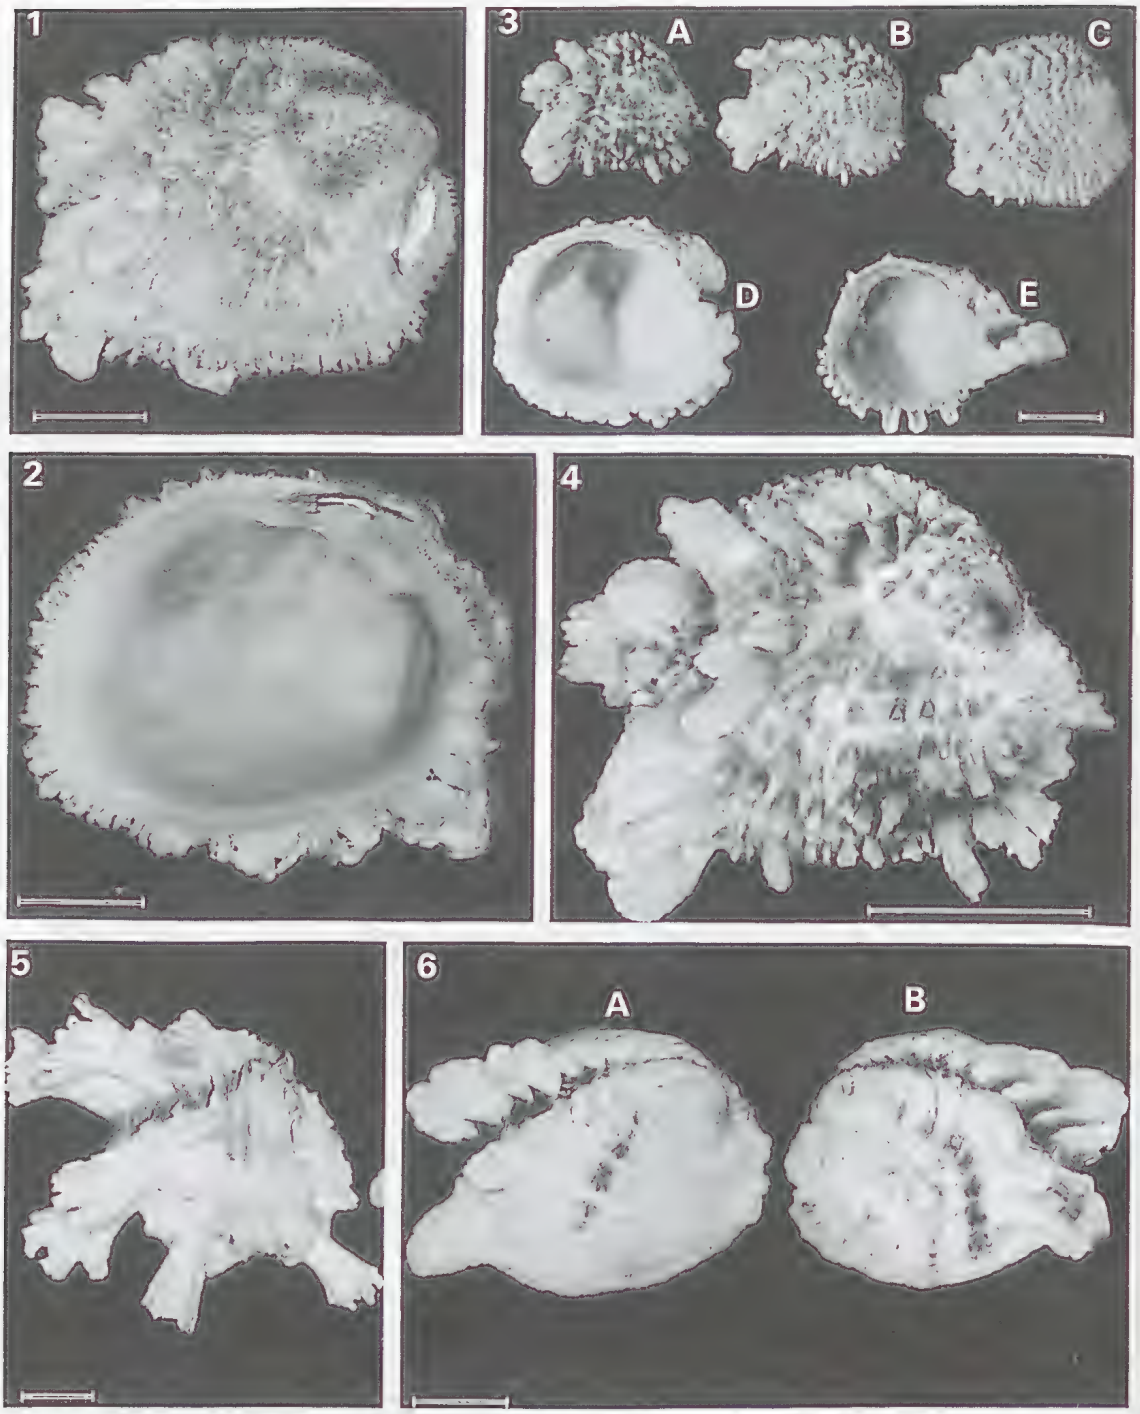
MATERIAL EXAMINED

HOLOTYPE: QMMO38412, 1 pv,Gulf of Carpentaria, 12°23.7'S, 140°41.1'E, dredged 58m, 26 Nov. 1991, S. Cook.

PARATYPES: AMC171008, 1 pv, Gulf of Carpentaria, 10°07.09'S, 141°48.36'E, dredged 47m, 1989, K Colgan; WAM83.92, lpv, Timor Sea, 12°12'S, 129°15'E, dived 37m, 17 Nov. 1989, K. Colgan; QMMO38410, QMMO38411, 2pv, Gulf of Carpentaria, 13°07'S, 141°41'E, dredged 53. 5m, 29 Nov. 1991, S. Cook.

DIAGNOSIS

Shell elongate-ovate; solid; small to moderately large; valves unequal and inequilateral; umbones prosogyrate. Externally, top (right) valve



FIGS 1-6. 1-4, *Chama isaacooki* sp.nov. 1, holotype (QMMO38412), external view of rv showing two broad bands of foliaceous spines posteriorly. 2, holotype (QMMO38412), internal view of lv showing teeth, crenulate margins and ligament. 3A,B,E, external (rv) and internal (lv) views of paratypes (A,E, WAM83.92; B, AMC171008); 3C,D, external and internal of specimen from Lamprell Collection. 4, external view of paratype (AMC171008) showing ribbed sculpture of broad spines. 5, *C. lazarus* Linnaeus, external view of rv, showing broad, foliate spines, Gove, NT. 6, *C. pulchella* Reeve. A, external view of top valve (rv), Torres Strait, NQ; B, external view of top valve (lv), Hervey Bay, SEQ. All scale bars = 10mm.

TABLE 1. Measurements (mm) of type series.

	L	H	W
Holotype: QMM038412, lpv	36.8	37.5	25.1
Paratype: AMC171008, lpv	28.5	21.4	16.5
Paratype:WAM83.92, lpv	26.9	21.1	14.6

convex, densely ornamented with rows of hollow spines radiating from the umbonal area. Spines erect or curved, ribbed and broad terminally. Posteriorly the spines become leaf-shaped and organized into two loosely defined rows, separated by smaller, vaulted spines. Externally, bottom (left) valve deeply convex and densely ornamented with vaulted spines which frequently fuse laterally to form concentric foliations. Posterior margin with small non-fused spines. Internally, margins of both valves finely crenulate. Adductor scars elongate-ovate, prominent, anterior larger than posterior. Hinge plate featuring one large, broad cardinal and one posterior (remote) lateral tooth per valve. External colouration white with orange to purple-brown blotches; spines white, purple or pink with a dark spot at the base. Internal colouration white, often with large purple blotches, particularly in young specimens. Ligament brown, elongate, parivincular.

Sample size: 8 pv. Length:height ratio — range 1:1-1:0.73; mean 1:0.86. Length:width ratio — range 1:0.75-1:0.51, mean 1:0.65.

Habitat and Distribution

Attached to living *Spondylus, Cardita* and *Crassostrea* in the Arafura Sea, Torres Strait and Gulf of Carpentaria at depths of 10 to 58m.

Remarks and Comparisons

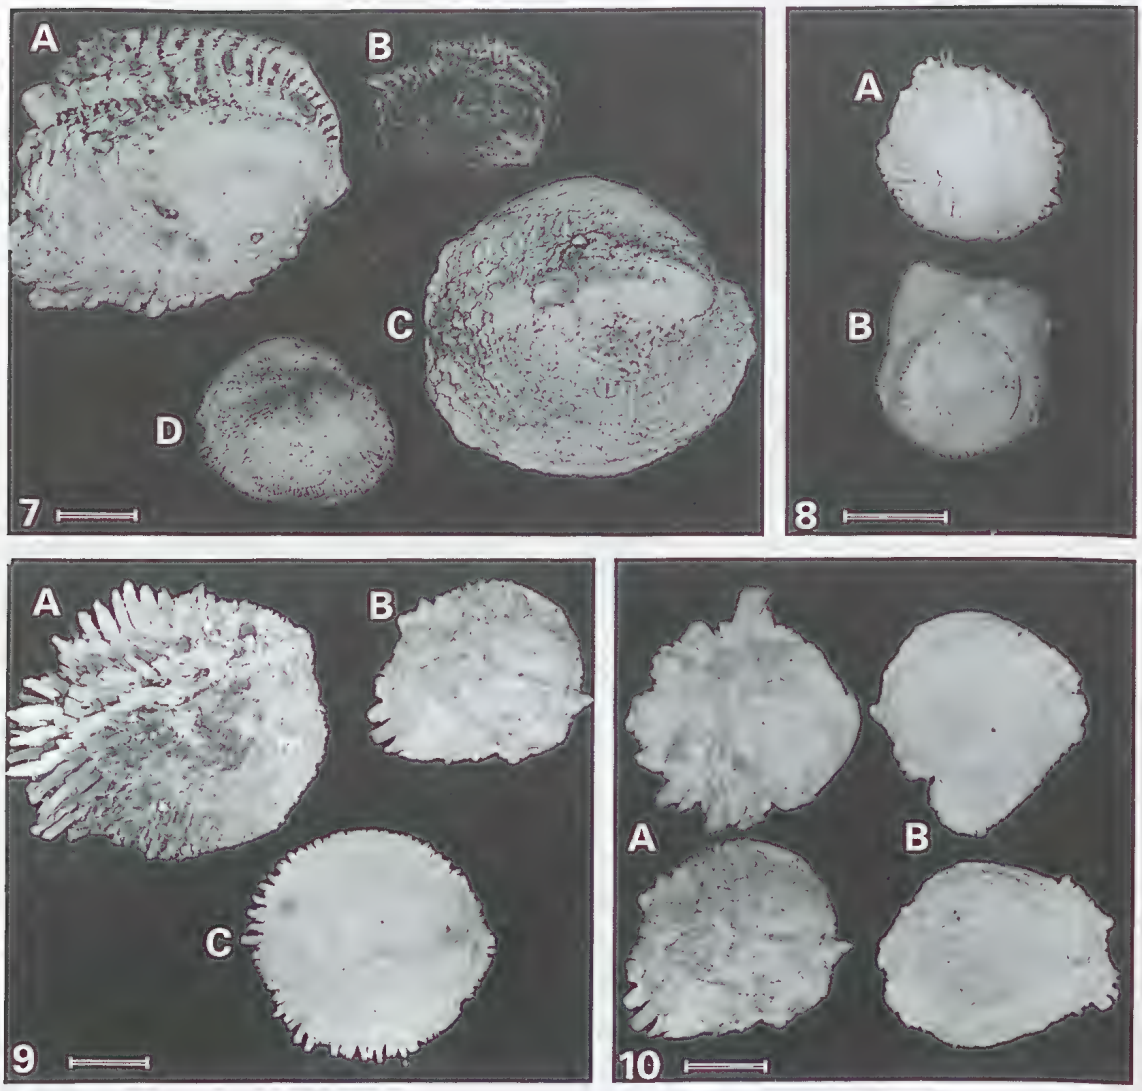
Valve ornamentation, particularly the shape and arrangement of the spines, and the consistent presence of a dark spot at the base of each spine (spot frequently absent near margin) immediately distinguish *Chama isaacooki* from others of the genus. The degree of spine preservation in exposed reef dwelling species is often poor, hence unworn juvenile material has been examined in addition to adult shells. Two prominent, posterior rows of broad spines are also present in *C. pulchella* Reeve, 1847 (Fig. 6), *C. limbula* Lamarck, 1819 (Fig. 7B), *C. fibula* Reeve, 1846 (Fig. 8) and *C. plinthota* Cox, 1927 (Fig. 7A) but not in *C. lazarus* Linnaeus, 1758 (Fig. 5), *C. pacifica* Broderip, 1834 (Fig. 9A), *C. asperella* Lamarck, 1819 (Fig. 9C) or *C. ruderalis* Lamarck, 1819 (Fig. 9B). *C. lazarus, C. pulchella* and *C. ruderalis* differ from *C. isaacooki* and other Australian chamids by totally or almost totally lacking sharp spines.

KEY TO THE AUSTRALIAN CHAMIDAE

1a. Spines broad only, often fused to form lamellae 2
Spines sharp or a mix of broad and sharp, broad spines never fused to form lamellae . . . 3
2a. Spines equally developed across valve . . . . . *C. lazarus*
Spines inequally developed across valve . . . . . *C. pulchella*
3a. Two prominent rows of broad spines dorso-posteriorly 4
Two dorso-posterior rows of spines poorly developed or not distinguishable 5
4a. Valve with strong transverse corrugations dorso-posteriorly . . . . . *C. plinthota*
Valve without strong transverse corrugations 6
5a. Spines equally developed across valve 7
Spines inequally developed across valve 8
6a. Valve margin finely crenulate. . . . *C. isaacooki*
Valve margin smooth . . . . . *C. limbula*
7a. Valve white, almost circular, strongly conex usually with rose-coloured umbone . . . . . *C. asperella*
Valve usually purple dorso-posteriorly, slightly elongate, weakly convex, umbone purple . . . . . *C. fibula*
8a. Spines raised, organized into clearly defined radial rows . . . . . *C. pacifica*
Spines prostrate, not organized into well defined rows . . . . . *C. ruderalis*

NOTES ON THE GENUS *PSEUDOCHAMA* ODHNER, 1917

Within the family Chamidae, attachment to the substrate may involve either the left valve (often referred to as the 'normal' condition) or the right valve (the 'inverse' condition) (Odhner, 1919; Cox, 1969). Early workers such as Broderip (1835) and Reeve (1846-7) indicated that both conditions may occur in the same species (for example *Chama pulchella).* Odhner (1917) disagreed and erected the genus *Psuedochama* for chamids attaching via the right valve, thereby reserving the genus *Chama* exclusively for species showing left valve attachment. He supported this division by drawing attention to differences in hinge teeth, the nepionic shell and anatomy between *Pseudochama* and *Chama* (see Odhner, 1919 for details). Although a number of recent authors have since accepted Odhner's opinion



FIGS 7-10. 7A, external view of top valve (rv) of *Chama plinthota* Cox (note strong transverse corrugations), Palm I., NEQ; 7B,C, external views of top valves (rv) of *C. limbula* Lamarck (B, immature, Fantome I., NEQ; C, One Arm Point, NWA); 7D, external view of top valve rv) of *C. fibula* Reeve, Turkey Beach, MEQ. 8A, external view of top valve (rv) of *C. fibula*, Turkey Beach, MEQ; 8B, top valve (lv) of *C. fibula*, Redcliffe, SEQ. 9A, external view of top valve (rv) of *C. pacifica* Broderip, Swain Reefs, MEQ; 9B, external view of top valve (rv) of *C. ruderalis* Lamarck, Spencer Gulf, SA; 9C, external view of top valve (rv) of *C. asperella* Lamarck, Gloucester I., MEQ. 10A, top valves (rv) of two specimens of *C. ruderalis*, Spencer Gulf, SA; 10B, top valves (lv) of two specimens of *C. ruderalis*, Spencer Gulf, SA. All scale bars = 10mm.

that the valve of attachment can be used to determine generic placement (e.g. Keen, 1969; Delsaerdt, 1986), others have maintained the earlier Broderip-Reeve view that left and right valve attachment may occur in the same species (Lamy, 1927; Cotton, 1961; Lamprell & Whitehead, 1992).

During the present study we observed both left and right valve attached specimens in *Chama pulchella, C. fibula, C. limbula* and C. *ruderalis*. Typically the left valve is favoured but in *C. limbula* the ratio of left versus right attached specimens may approach 1:1 (Cotton, 1961). Although Odhner (1919: 11,17) accepted that certain chamids showing right valve attachment and

those showing left valve attachment may appear strikingly similar to each other in external colouration, sculpture and even attached valve dentition, he maintained that such similarity was due to covergence (pp.21,22) and that right valve attachment consistently differentiated *Pseudochama* from *Chama*. He therefore held that no species of Chamidae exhibited both left and right valve fixation. Odhner stressed differences in dentition between *Pseudochama* and *Chama*, but dismissed the possibility that any similarity in the arrangement of teeth between left and right attached valves could be the result of hinge teeth 'inversion' (= transposition). According to Cox (1969: N57) transposition of the hinge teeth in chamids 'goes hand-in-hand with reversal of the valve of fixation'.

Cox cited other examples of hinge teeth transposition in living and fossil taxa and in fact recommended that the Bernardian system of tooth notation (used throughout Odhner's work) not be applied in cases of tooth transposition at least until shell ontogeny has been examined in these taxa. In fact even Odhner stated that in various species of *Chama* (sensu Odhner) the details of hinge teething may vary significantly through accentuation, suppression or addition of teeth (Odhner, 1919: 11). Yonge (1967), who made a detailed study of chamid anatomy, shell dentition and shell growth patterns, concluded that the process of cementation determined the morphology of the hinge teeth and valve profile in this family (significantly, Yonge examined both left and right valve attached specimens of *Chama pellucida* and *Pseudochama exogyra*). He supported the claim of Munier-Chalmas (1882) that free and attached valves of left valve attached specimens were mirror-images of the valves of right valve attached specimens. For this reason Yonge, like Munier-Chalmas, suggested recognizing 'free' and 'attached' valves rather than 'left' and 'right' and the application of non-Bernardian notation for Chamidae. Subsequently Yonge (1979) reverted to useage of 'left' and 'right' valves in discussing cementation in chamids (among other bivalves), but reiterated his earlier conclusion that genera within the family cannot be recognized by the valve of attachment (Yonge, 1979:100, in fact stating that 'There is no valid reason for separating the species into two genera'). By strict application of Odhner's valve of attachment rule (that is, all *Pseudochama* attach via the right valve), it would be necessary to hypothesize that left valve attached *Chama limbula, C. ruderalis, C. pulchella* and *C. fibula* each coexist with a conchologically similar, but right valve attached species of *Pseudochama*. However, in view of the fact that hinge teeth transposition has now been well demonstrated in a number of heterodont groups (Cox, 1969), and after considering Yonge's (1967, 1979) findings that cementation has had an overriding effect on hinge teeth and valve morphology in the Chamidae, we conclude that a number of chamid species are truly capable of attaching by the left or the right valve. Any observable differences in dentition between left and right 'free' valves and left and right 'attached' valves should therefore be viewed as the result of transpositional effects.

The remaining features cited by Odhner (1917, 1919) as being diagnostic of *Pseudochama* — nepionic shell sculpture and morphology and/or position of the stomach caeca and the nephridia — seem worthy of detailed investigation. It would, for example, be interesting to determine whether such features occur in right valve attached specimens of *Chama limbula, C. fibula, C. ruderalis* and *C. pulchella,* particularly the latter which Odhner (1917) named *Pseudochama similis*. Should this not be the case, then the basis for the genus *Pseudochama* would have to be reassessed.

ACKNOWLEDGEMENTS

We would like to thank Mr Steve Cook, Queensland Museum for providing specimens of *Chama isaacooki* for this study. Mr Ian Loch (Australian Museum) and Ms Sue Boyd (Museum of Victoria) provided access to collection material in their charge. Mr and Mrs Ivan Marrow (Melbourne) also allowed one of us (KL) the opportunity to examine specimens in their collection. This study was supported financially by an Australian Research Fellowship (to JH).

A NEW CAVERNICOLOUS HARVESTMAN FROM LAVA TUBE CAVES IN TROPICAL AUSTRALIA (ARACHNIDA: OPILIONES: PHALANGODIDAE)

GLENN S. HUNT

Hunt, G.S. 1993 06 30: A new cavernicolous harvestman from lava tube caves in tropical Australia (Arachnida: Opiliones: Phalangodidae). *Memoirs of the Queensland Museum* **33**(1): 217-219. Brisbane. ISSN 0079-8835.

Zalmoxis lavacaverna sp.nov. is from lava tube caves in the Mt Surprise area, north Queensland. It is the first cave-adapted harvestman to be described from tropical Australia. Troglomorphies include depigmentation, eye reduction, and elongation of appendages and spines on pedipalp. □ *Arachnida, Opiliones, Phalangodidae, Zalmoxis lavacaverna, new species, cavernicolous, tropics, Australia.*

Glenn S. Hunt, Australian Museum, PO Box A285, Sydney South, New South Wales, 2000, Australia; 13 July, 1992.

Hitherto, no harvestmen displaying cave adaptations (troglomorphies) have been described from caves in tropical Australia. *Zalmoxis lavacaverna* sp.nov. inhabits lava tubes in inland northern Queensland and shows depigmentation, some eye regression, elongation of spines on the pedipalp and elongation of appendages.

Elsewhere in Queensland, a cave adapted species has been recorded from Hercules Cave in the limestone tower karst region of Chillagoe (Howarth, 1988). This has proved to be another species of *Zalmoxis* but its description will await the discovery of a male.

Z. lavacaverna belongs to the family Phalangodidae, a group with many cavernicolous representatives in the Northern Hemisphere (e.g. Vandel, 1965; Briggs, 1968), though these are not closely related to *Zalmoxis*. Two troglomorphic phalangodids in the genus *Chrondrobunus* have, however, been recorded from a limestone cave in New Guinea (Smith, 1980). The Phalangodidae, together with the Assamiidae, are tropical elements that replaced the older, more temperate families as Australia drifted northwards and established biological contact with Asia.

The temperate caves of southern Australia are populated by species of Triaenonychidae, predominantly the genera *Hickmanoxyomma, Holonuncia* and *Lomanella* (Hunt, 1990, 1992; Hunt and Hickman, in press). These southern caves seem to support higher numbers of cavernicolous harvestmen, though this may be a consequence of more collecting and research.

Environmental parameters and faunal diversity of the lava tube caves are discussed by Howarth (1988) and Howarth & Stone (1990). He (1988) believed the biospeleological potential of tropical caves in Australia was only just beginning to be appreciated.

MATERIAL EXAMINED

HOLOTYPE: QM S20731, Queensland, Collins Two-Ten Cave, Spring Creek Station, Mt Surprise, 21 Jan 1989, M. Ashe, F.G. Howarth & H. Hoch, male.

PARATYPES: QM S20732, same data, female; BMH, same data, male & female.

OTHER MATERIAL: QM S20733, Queensland, Long Shot Cave, Spring Creek Station, Mt Garnet, 20 Jan 1989, F.G. Howarth, M. Asche, H. Hoch & D. Irvin, male; QM S20734, same data, juvenile.

DIAGNOSIS

Cavernicolous. Depigmented, eyes reduced, 5 segments in tarsus IV.

DESCRIPTION

Male. Body. BL 3.10-3.15, SL 2.97-3.11, CW 1.01-1.10, BW 1.92-2.03. Depigmented, colour straw yellow to yellow-orange, appendages likewise. Anterior margin below with a process between chelicerae and between each chelicera and pedipalp, anterior margin above with 2 tubercles above each pedipalp coxa. Eyemound well developed, rising steeply a short distance behind anterior margin, armed with 1-3 tubercles, sloping less steeply posteriorly. Eye small, set low on

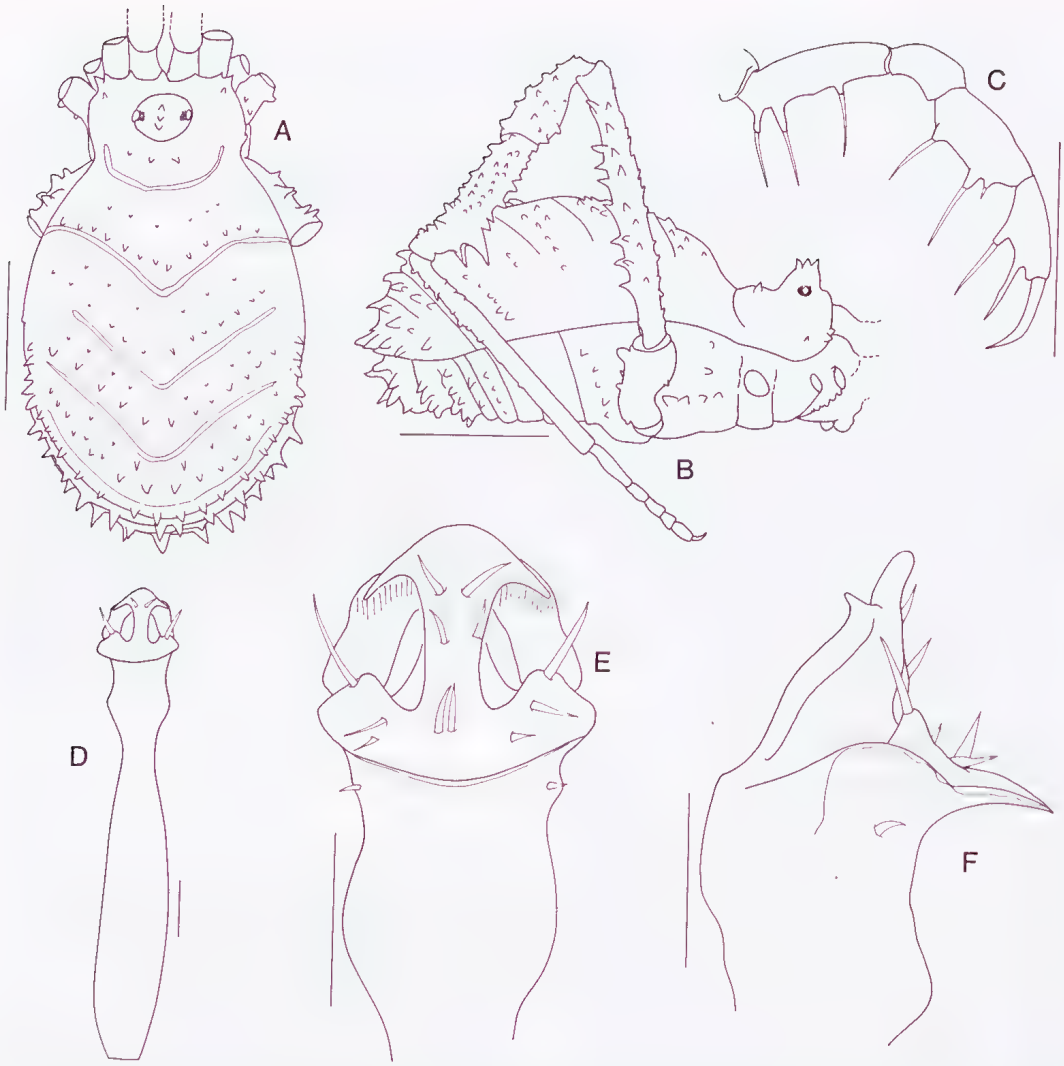

FIG. 1. *Zalmoxis lavacaverna* sp.nov., holotype male. A, body, dorsal; B, body, lateral, with leg IV; C, pedipalp, retrolateral; D, whole penis, ventral; E-F, apical part of penis, ventral and lateral. Scale bars: A-C = 1.0mm; D-F = 0.1mm.

eyemound, surrounded by small halo of pigmentation. Carapace with a few small tubercles as shown (Fig. 1A). Tergal areas 1-5 bearing a transverse row of tubercles or spines near their posterior margin, spines on TA 4 and 5 largest; TA1 - TA4 with second more anterior row composed of granules; TA5 narrow and without secondary row. The 3 free tergites each with row of strong spines; anal operculum and posterior sternites also carrying strong tubercles/spines (Fig. 1B).

Chelicera. Second segment with tiny setose granulations; CSL 0.80-0.84.

Pedipalp. PFL 0.64-0.66; femur with a two closely spaced proximoventral spines (Fig. 1C), a smaller spine ventrally at about 0.66 femur length, and a prolateral spine at about 0.75 femur length. Patella with a prolateral spines in distal half; tibia with 3 pro- and 3 retrolateral spines, most distal retrolateral spine small, remaining two retrolateral spines larger than prolateral spines. Tarsus with two pro- and two larger retrolateral spines. Setae of all spines very long. Claw subequal to tarsus.

Legs. FIV 2.20-2.34 Femora with granules enlarging to tubercles/spines on ventral surface; spines particularly strong on femur IV. Tibia IV with strong subdistal ventral spine, spines distal to it may be subequal to or stronger than other

ventral spines; otherwise patella IV to metatarsus IV coarsely tuberculate. Tarsal formula 3,5-6,5,5.

Penis. A marked ventral shelf-like projection bears 4 pairs of setae, 1 mesial pair placed close together, 2 pairs more laterally, and 1 seta inserted on each side in dorsolateral projection of shelf. 2 mesial pairs of setae are placed more distally, setae further apart than proximal mesial pair. One small pair placed below (proximal to) shelf on ventrolateral margin of penis.

Female. Differs from male in the following: much smaller, BL 2.23-2.53, SL 2.12-2.31, BW 1.54-1.57, PFL 0.53-0.57, FIV 1.52-1.54. Body and legs with more subdued spination, large distal spine on tibia IV lacking. Tarsal formula 3,5,5,5.

Variation

Spination of the eyemound varies — eyemounds with 1 spine appear more conical. The strong spine on tibia IV in males varies in strength.

Comments

On the basis of penis structure and spination of the body, *Z. lavacaverna* seems closely related to *Z. cardwellensis* Forster, 1955, which occurs in the coastal ranges directly to the east. It differs from *Z. cardwellensis* in being depigmented, having much longer appendages, a less bulbous femur IV, and 5 instead of 6 segments in tarsus IV. The female of both species is much smaller than the male. The undescribed troglomorphic species from Hercules Cave, Chillagoe, differs from *Z. lavacaverna* in having a more conical eyemound, more subdued spination of body and legs, and 6 rather than 5 segments in tarsus IV.

Etymology

The specific epithet is formed by a latinised combination of two nouns, lava and cavern, descriptive of the species habitat.

Natural History

The species was taken well inside the lava tube caves where 98-100% humidities prevail (Howarth, 1988). Howarth regarded the species as 'possibly a troglobite'. The caves support a very large troglobitic and troglophilic fauna because tree roots and bat guano provide a steady flow of energy and nutrients to the community.

Distribution

North Queensland: Long Shot and Two-Ten Caves, Collins lava tube system, Mt Surprise area. It does not seem to occur in the Bayliss lava tube, 30km to the NW, despite this cave having a rich troglobitic fauna (Howarth & Stone, 1990). This supports the view that *Z. lavacaverna* is an obligate cavernicole incapable of long dispersals across the surface.

ACKNOWLEDGEMENTS

I thank Dr Frank Howarth, Bishop Museum, Hawaii, for making the material available to me. Dr Michael Gray, Australian Museum, commented on the manuscript and Mr Roger Springthorpe did the illustrations.

NEW RECORD OF *LERISTA ALLANAE* (SQUAMATA: SCINCIDAE). *Memoirs of the Queensland Museum 33(1): 220. 1993:-* *Lerista allanae* (Longman,1937) was described from 3 specimens from Retro Station, near Capella. Additional material (Greer,1987; Ingram & Raven,1991) indicated a range through much of central and central eastern Queensland. However, Couper & Ingram (1992) recognised two species, the more widespread *L. colliveri* Couper & Ingram,1992 and *L. allanae* restricted to a small area between Clermont and Capella (30km in N-S direction) and 32km west of Capella. The latter was known from 9 specimens at 3 localities; it had been collected most recently in 1960 and recent searches in the same area have not added to these numbers. They concluded that the species was endangered, using the criteria of Ingram & Raven (1991:337).

In the South Australian Museum I located a specimen of *L. allanae* (R2823) from Logan Downs Station (22°23'S, 147° 56'E), 56km NE of the previously known range. It was collected by H. Womersley and registered on 16 November 1948, The collection date is not preserved with the specimen.

The specimen, an adult male (snout-vent length 72mm) with turgid testes 4.5mm long and opaque deferent ducts, agrees closely with the description of Couper & Ingram (1992) in most aspects of size and scalation, although some differences are: left hind limb missing; right hindlimb monodactyle with 6 subdigital lamellae; nuchals (paravertebral scales on nape overlapping 4 or more scales) absent; second supraocular on right side fused with right frontoparietal; superciliaries 6 in an unbroken row; infralabials 5; primary temporal present. Apparant differences in numbers of subdigital lamellae supraciliaries may reflect different reference points rather than real differences. The specimen is faded and the colour pattern only faintly discernible.

I thank Mark Hutchinson for allowing access to South Australian Museum facilities.

COMMON NAMES FOR QUEENSLAND FROGS

G.J. INGRAM, A.E.O. NATTRASS AND G.V. CZECHURA

Ingram, G.J., Nattrass, A.E.O. & Czechura, G.V. 1993 06 30: Common names for Queensland frogs. *Memoirs of the Queensland Museum* 33(1): 221-224. Brisbane. ISSN 0079-8835.

In Queensland, there has been a great increase in public interest in frogs. However, communication about frogs has been hampered by the lack of common, or English, names for the species. This checklist attempts to rectify the problem of communication by allocating a distinct common name to each species. The names are based on our experience of the frogs in the wild and familiarity with common names already in use. □ *Anura, frog, common name, nomenclature, checklist, Queensland.*

Glen Ingram & Greg Czechura, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; Ric Nattrass, 25 Warwick Court, Bellbird Park, Queensland 4300, Australia; 29 April, 1993.

In recent years there has been a great increase in public interest and concern regarding Queensland's native frogs. Several amateur societies have now been established throughout the State to watch, study or restore populations of frogs. Disappearance and possible extinction of several species in the wild and wider declines of others as a result of urban-sprawl have catalysed growing public fascination. 'Frog experts' are now in great demand to provide information about Queensland's frog fauna to both the public and media. However, scientists and naturalists are experiencing difficulties in communication because most frogs are only known by their scientific names: the media and public are reluctant to use these.

Some attempts have been made to introduce common, or English, names for popular usage (Moore, 1961; Clyne, 1969; Barker & Grigg, 1977; Ingram, 1983; Cogger, 1992 & earlier editions; Tyler, 1992). Not all of these efforts were comprehensive or not all the suggested names were adopted. Most suggestions have been based on literal translations of the latin nomenclature and this has often led to common names that are inappropriate, unwieldy or obscure. For example, *Litoria rubella* has been assigned the names 'Purple Treefrog' and 'Red-purple Treefrog' even though very few individuals are purple. And, inappropriately, it has also been called 'Desert Treefrog' even though it is commonly found in habitats other than desert. For many general users, the names recommended by scientists simply lack the 'colour' and 'descriptiveness' of the common names assigned to, for example, hummingbirds as in Sibley & Monroe (1990).

The following list — which has been developed from field experience, common names already in use and discussions with interested parties — attempts to redress this imbalance by allocating a distinct common name to each species that occurs in Queensland. Common names should reflect some distinctive attribute of a taxon, or the place where they live, so that it is appropriate in most, if not all, contexts. As well, it should not create a misleading preconception of appearance. Furthermore, we feel it is desirable that designations using 'toad' only refer to the introduced *Bufo marinus*. Thus species of *Uperoleia* are herein referred to as 'gungans' from an aboriginal name (see Ingram & Corben, 1975) and not as 'toadlets'. 'Toadlet' should only be used to describe juvenile *B. marinus*.

In choosing and framing English names, we have followed the principles of Royal Australasian Ornithologists Union (R.A.O.U., 1978). Scientific names follow Ingram (1991) with addition of *U. altissima* Davies, Watson, McDonald, Trenerry & Werren, 1993.

CHECKLIST OF QUEENSLAND FROGS

TOADS
BUFONIDAE

Bufo Laurenti, 1768
CANE TOAD *B. marinus* (Linnaeus, 1758)

TREEFROGS AND RELATIVES
HYLIDAE

SPERMATOLOGICAL EVIDENCE FOR THE TAXONOMIC STATUS OF *TRAPEZIA* (CRUSTACEA: BRACHYURA: HETEROTREMATA)

B.G.M. JAMIESON

Jamieson, B.G.M. 1991 06 30: Spermatological evidence for the taxonomic status of *Trapezia* (Crustacea: Brachyura: Heterotremata). *Memoirs of the Queensland Museum* 33(1): 225-234. Brisbane. ISSN 0079-8835.

Features of the spermatozoon of *Trapezia* which are general for heterotremes and endorse its inclusion in the Heterotremata are: extension of the subacrosomal chamber almost to the anterior apex of the sperm; division of the acrosome contents into inner and outer zones; presence of an acrosomal ray zone at the periphery of the inner acrosomal zone; and presence of a thickened ring where the acrosomal capsule surrounds the base of the subacrosomal chamber. A feature shared with 'higher' heterotremes is the restriction of cytoplasm to the periacrosomal region, the arms being nuclear only; and loss of a posterior median process, containing chromatin, which is present in raninids and majids. Additional features which *Trapezia* shares with the Xanthidae (exemplified by Xanthinae and Chlorodiinae) and Panopeidae (exemplified by *Eurytium*) include the structure of the perforatorium, tapering anteriad, with a fibrous core; and extension of the chromatin around the operculum, leaving only a raised central area of this exposed. Peculiar features of xanthids (Xanthinae, Chlorodiinae) and panopaeids which separate them from all other heterotremes, including *Trapezia*, are the dense 'xanthid ring' around the base of the subacrosomal chamber and, in xanthids, the additional peripheral zone outside the outer acrosomal zone. Presence of a presumed derivative of the xanthid ring in thoracotremes indicates that the Xanthidae s. strict. and panopaeids are near the base of the Thoracotremata and absence of the ring in *Trapezia* suggests that it (in the Trapeziidae) is the plesiomorphic sister- or neighbouring-taxon of the xanthid-panopaeid assemblage. An apomorphy of *Trapezia* is restriction of the acrosome ray zone to an annulus around the anterior region of the perforatorium. Presence of the ring or its derivatives indicates that although the xanthids, panopaeids, and such thoracotremes form a monophyletic group, the Xanthoidea is a paraphyletic group. □ *Crustacea, phylogeny, spermatozoa, ultrastructure, Trapezia, Pilodius, Eurytium, Mictyris.*

B.G.M. Jamieson, Zoology Department, University of Queensland, Queensland 4072, Australia; Honorary Associate, Queensland Museum; 7 May, 1992.

Trapezia Latreille, 1825, is a genus of heterotreme crabs, the species of which are obligate symbionts of corals (Abele & Felgenhauer, 1982). The 'trapézides' of A. Milne Edwards, 1862, were given subfamilial rank, as the Trapeziinae, by Miers (1886) in the family Xanthidae of Macleay, 1838. This allocation of *Trapezia* was widely accepted. However, Guinot (1978) revived Ortmann's (1893) idea, subsequently abandoned, that a family Trapeziidae should be recognised. Within her Xanthoidea, Guinot (1978: 275) considered the Trapeziidae Miers to be a distinctive family equal in rank to the Xanthidae, and other xanthoid families (the Carpiliidae, Menippidae, Platyxanthidae, Pilumnidae, Panopeidae and Geryonidae), a view supported by specialists on the genus *Trapezia* (e.g. Clark & Galil, 1988).

Despite objections that classification on larval characters conflicts with that on adult characters (Gurney, 1938; Lebour, 1944), studies of larval development have been considered to confirm relationship of *Trapezia* with other xanthoid genera (Hyman, 1925; Wear, 1970; Rice, 1980; Martin, 1984). The classifications of Hyman (1925) and Wear (1970) suggested a special relationship of *Trapezia* to menippines and pilumnines (Menippidae and Pilumnidae sensu Guinot, 1978). Nevertheless, Guinot (unpublished) considers that the distinctive morphology of *Trapezia* may justify recognition of a distinct superfamily Trapezoidea.

The present study examines the ultrastructure of the spermatozoa of *Trapezia coerulea* with a view to providing evidence of its relationships. For comparative purposes, micrographs are included of the sperm of the xanthid *Pilodius areolatus* and the thoracotreme *Mictyris longicarpus* (Mictyridae) and brief reference (in the Discussion) is made to the sperm of the panopaeid *Eurytium limosum* (Say) (Jamieson & Abele, unpublished). Published descriptions of xanthoid sperm are limited to a brief description for *Menippe mercenaria* (Menippinae) by Brown

(1966) in an unpublished doctoral thesis; a diagram of the sperm of *Atergatis floridus* (Linnaeus) in a discussion of malacostracan phylogeny by Jamieson (1989c); detailed description of the sperm of *Atergatis floridus* (Xanthidae, Zosiminae), *Etisus laevimanus* Randall (Xanthidae, Etisinae), *Liagore rubromaculata* De Haan (Carpiliidae, incertae sedis) and *Pilodius areolatus* (H. Milne-Edwards) (Xanthidae, Chlorodiinae) by Jamieson (1989a); brief mention of *Eurypanopeus depressus* (Smith) and an SEM micrograph for *Eurytium limosum* (Say) (both Panopeidae) by Felgenhauer & Abele (1990) and a description for *Geryon fenneri* and *G. quinquedens* (Geryonidae), by Hinsch (1988). It is unfortunate that no descriptions of spermatozoal ultrastructure exist for Pilumnidae and that the brief description for *Menippe mercenaria* by Brown (1966) in an unpublished doctoral thesis does not give sufficient detail for purposes of comparison, in view of the supposed relationship of these to *Trapezia*.

MATERIAL AND METHODS

Species examined for sperm ultrastructure are: *Trapezia coerulea* Rüppell, from Heron Island, Great Barrier Reef; the xanthid *Pilodius areolatus* (H. Milne-Edwards), from One Tree Island, Great Barrier Reef; the panopaeid *Eurytium limosum* (Say) (see Discussion only) from the vicinity of Talahassee, Florida, USA; and the thoracotreme *Mictyris longicarpus* Latreille (Mictyridae), from Moreton Bay, Queensland. The specimen of *Trapezia* used has been lodged in the collections of the Queensland Museum.

Small portions of testes of were fixed in 3% glutaraldehyde in 0.1M phosphate buffer (pH 7.4), with 6% sucrose, at 4°C, washed in buffer, post-fixed for 80 min in similarly buffered 1% osmium tetroxide, washed in buffer, dehydrated through an ascending ethanol series, and infiltrated and embedded in Spurr's epoxyresin. Thin sections were cut with a diamond knife on an LKB 2128 UM IV ultrotome, collected on carbon stabilised colloidin-coated 200 mesh copper grids, and stained by the Daddow method: for 0.5 min in Reynolds' lead citrate, 1 min in 6% aqueous uranyl acetate and a further 0.5 min in lead citrate, before rinsing in distilled water. Specimens were examined with a Hitachi 300 and a Jeol 100S transmission electron microscope operated at 80kV and 60kV respectively.

RESULTS AND COMPARATIVE REMARKS

The terminology adopted by Jamieson (1989a,b, 1991) will be employed in this account with the modification that the inner zone of the acrosome and the acrosome ray zone will be recognised as distinct layers, rather than being combined under the term inner dense zone. This modification of terminology will accommodate the condition in paguroid anomurans where the acrosome ray zone may form the widest layer of the acrosome. Although in Brachyura the acrosome ray zone is sometimes poorly delimited from or forms part of an inner dense zone, the two layers will therefore be recognised as the 'inner acrosomal zone' and the 'acrosome ray zone'. To minimise repetition of data from *Trapezia* in the Discussion, some comparison with archaeobrachyuran and other heterotreme crabs will be made in the Results. Comparison with thoracotremes will chiefly be reserved to the Discussion.

GENERAL MORPHOLOGY

The spermatozoon of *Trapezia coerulea* is illustrated from transmission electron microscopy in a line drawing (Fig. 1) and in micrographs (Fig. 2). For comparison with a xanthid and a thoracotreme, these are illustrated by micrographs of the sperm of *Pilodius areolatus* (Fig. 3) and the thoracotreme *Mictyris longicarpus* (Fig. 4).

The spermatozoon of *Trapezia coerulea* (Fig. 1) is spheroidal but slightly depressed anteroposteriorly and, like all decapod sperm, lacks a flagellum (Fig. 2B). This simple form is modified by the presence of broadly based lateral projections or 'arms'. From light micrographs, there are four arms, each with a length considerably surpassing the diameter of the sperm body. A plesiomorphic, chromatin-containing 'posterior median process', seen in *Ranina* and some majids, is absent. As is usual for brachyurans, the nucleus consists of diffuse, fibrous chromatin, and forms a cup surrounding the acrosome, a thin layer of cytoplasm intervening between nucleus and acrosome. The cytoplasm contains sparse mitochondria, some membranous (lamellar) structures of probable mitochondrial origin and, basal to the perforatorium, the two centrioles (Figs 2B,C,D).

ACROSOME

The subspheroidal core of the *Trapezia* spermatozoon consists entirely of the complex

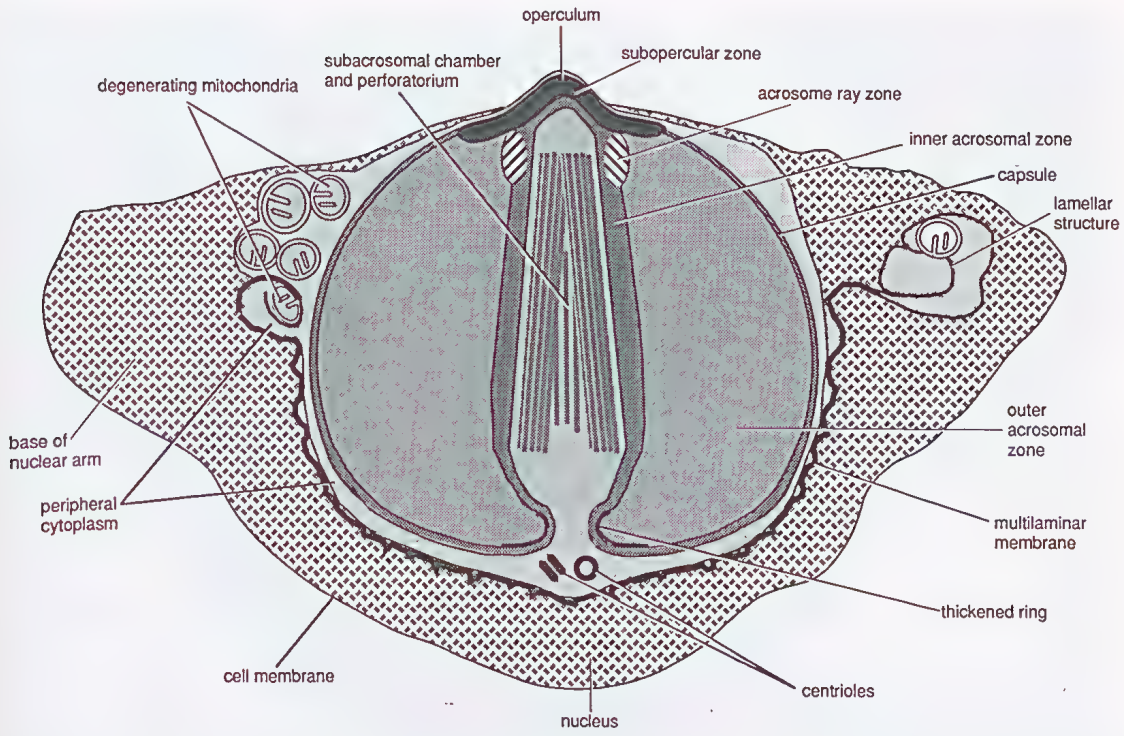

FIG. 1. *Trapezia coerulea*. Diagrammatic representation of a longitudinal sagittal section of the spermatozoon.

acrosome. This is composed of a number of components identifiable with, and presumably homologous with, those described for other higher brachyuran sperm (Jamieson, 1989a,b, 1991).

The acrosome (Figs 2B,D) is invested by an acrosomal membrane underlain by an electron dense sheath, the 'capsule'. The length of the acrosome, from the apex of the operculum to the base of the thickened ring, is 2.4-2.9μm (mean of 3 = 2.6μm); the width is 2.6-3.0μm (mean of 3 = 2.8μm). The acrosomal membrane is separated by a very thin, pale layer, from the capsule and, like the capsule, is invaginated at the posterior pole to cover a columnar subacrosomal chamber (Fig. 2B), the contents of which are the perforatorium. The anterior tip of this chamber extends almost to the anterior apex of the sperm. As in most other crabs, this central, subacrosomal axis of the acrosome is surrounded by a wide electron dense sheath, the 'inner acrosomal zone' (Figs 2B, D). Unlike xanthoids for which sperm descriptions are sufficiently detailed (*Pilodius areolatus*, Fig. 3, *Atergatis floridus*, *Etisus laevimanus* and *Liagore rubromaculata*) there is no differentiation of the posterior part of the inner acrosomal zone as an electron dense prominent annulus, the 'xanthid ring'.

As in xanthids of the Xanthinae and Chlorodiinae, but in this case in the absence of the xanthid ring, the inner acrosomal zone in *Trapezia* is surrounded by an 'acrosome ray zone' (Fig. 2A,B) seen also in other heterotremes and in paguroid anomurans (Jamieson, 1991). In xanthids (Fig. 3), the dorippid *Neodorippe*, and portunids, the acrosome ray zone extends for much of the length of the inner layer (being especially wide in portunids), but in *Trapezia* (Fig. 2A,B) it is limited to a slightly convex annulus restricted to, and embedded in, the anterior region of the inner acrosomal zone, from which it is poorly demarcated.

In *Trapezia* as in xanthids, portunids and other heterotremes, the inner acrosomal zone, with the ray zone, is in turn surrounded by a broad layer, the outer acrosomal zone (Figs 2B,D). In *Trapezia*, as in heterotremes excepting xanthids, this zone is the only additional concentric layer and continues to the capsule. In xanthids, in contrast, it is differentiated into an outer dense zone, next to the inner acrosomal zone and ray zone, and a further, peripheral zone (Fig. 3). The external

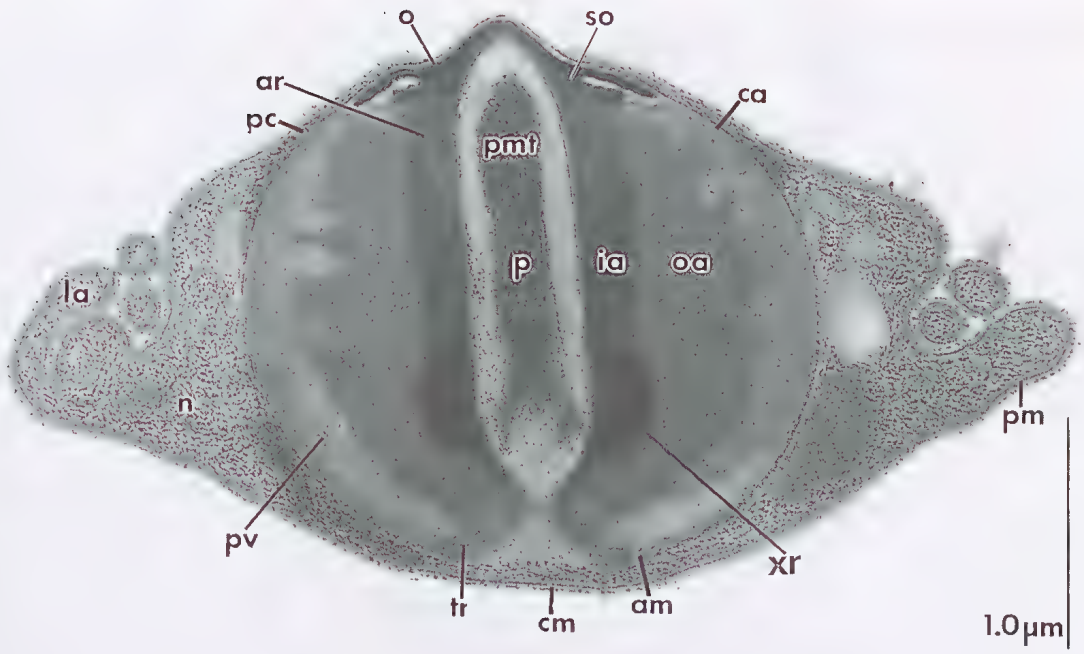

FIG. 3. Transmission electron micrograph of a longitudinal sagittal section of the spermatozoon of the xanthid *Pilodius areolatus*. Abbreviations: am = acrosome membrane; ar = acrosomal rays; ca = capsule; cm = cell membrane; ia = inner acrosomal zone; la = base of lateral arm; n = nucleus; o = operculum; oa = outer acrosomal zone; p = perforatorium; pc = vestigial periacrosomal cytoplasm; pmt = microtubules of perforatorium; so = subopercular zone; tr = thickened ring; xr = xanthid ring.

margin of the outer dense zone peculiar to xanthids is ragged and deeply dissected (*Atergatis* and *Pilodius*) or slightly crenulated (*Etisus*) or almost smooth (*Liagore*).

At the anterior pole of the *Trapezia* acrosome, as in all other brachyurans and paguroids with the doubtful exception of *Pagurus bernhardus* (see Chevaillier, 1968), there is a dense caplike structure, the operculum (Fig. 2B), 1.3- 1.5µm wide (mean of 3 = 1.4µm). As in *Portunus*, the operculum is imperforate whereas in *Ranina* and the majid *Menaetheus monoceros* it is perforate (see Jamieson, 1991), although in some individual xanthid sperm it appears weakened apically (it is also perforate but is closed by an apical button in most of the investigated thoracotremes, Fig. 4A, see Discussion).

Below the operculum, as in many other crabs, a further, caplike structure of moderately electron dense material, the subopercular zone, separates the operculum and adjacent region of the capsule from the summit of the inner acrosomal zone and acrosome ray zone (Fig. 2B). In *Trapezia*, as in xanthids, the operculum extends laterally slightly beyond the acrosome ray zone. In contrast the operculum is limited in *Calappa* to the width of the ray zone while in portunids and dorippids it is more extensive as it also caps the outer acrosomal zone (see Jamieson, 1991).

At the opposite, posterior, pole the capsule is perforated by invagination of the acrosome membrane and capsule as a narrow orifice which opens into the columnar subacrosomal chamber. Unlike the *Ranina* sperm but like that of *Calappa*, portunids, *Neodorippe* and xanthids, a thickening of

FIG. 2. *Trapezia coerulea*. Transmission electron micrographs of the spermatozoon. A. Detail of acrosome ray zone. B. Longitudinal sagittal section. C. Detail of centriolar region. D. Transverse section shortly below the equator of the acrosome. E. Detail of the cytoplasmic layer in transverse section, showing mitochondria in various stages of degeneration. Abbreviations: am = acrosome membrane; ar = acrosomal rays; c = centriole(s); ca = capsule; cm = cell membrane; ia = inner acrosomal zone; ine = multilayered inner nuclear envelope; la = base of lateral arm; lm = contorted (lamellar) membranes; m = degenerating mitochondrion; n = nucleus; o = operculum; oa = outer acrosomal zone; p = perforatorium; pc = vestigial periacrosomal cytoplasm; pmt = microtubules of perforatorium; so = subopercular zone; tr = thickened ring.

the capsule forms a 'thickened ring' on each side of the subacrosomal invagination (Fig. 2B).

Subacrosomal Region

In *Trapezia*, as in xanthids and other heterotreme (and thoracotreme) Brachyura, the subacrosomal material consists of a highly differentiated stout perforatorium that extends from the posterior perforation in the capsule to the vicinity of the operculum at the apex of the acrosome (Fig. 2B). The perforatorium in *Trapezia* is a stout cylinder, slightly tapering anteriad, with a bluntly pointed tip and a posterior stalk constricted at the thickened ring. This form, together with differentiation of the perforatorium into a central dense fibrous core, is indistinguishable from that stated to be distinctive of xanthids (see *Pilodius*, Fig. 3) by Jamieson (1989a). In cross section, the perforatorium is seen to contain, as in xanthids and portunids (Jamieson, 1991) many circular profiles resembling microtubules though differing from typical microtubules in varying in size and in sometimes being irregular in section (Fig. 2D).

Cytoplasm

A thin layer of spermatozoal cytoplasm surrounds the acrosomal capsule. As in portunids, dorippids and xanthids the cytoplasm does not extend into the arms. In majids, in contrast, the cytoplasm extends into the lateral arms together with contained microtubules which are not discernible in the other heterotremes mentioned. In *Trapezia* the cytoplasm is enlarged anterolaterally on one side of the capsule and contains several subspheroidal and apparently degenerating mitochondria with sparse cristae (Figs 2D,E). The degree of representation of mitochondria is variable in other heterotremes, usually being negligible, though it is similar to that in *Trapezia* in the thoracotreme *Macrophthalmus crassipes* and the archaeobrachyuran *Ranina ranina* (see Jamieson, 1991). The postacrosomal cytoplasm, typical of brachyurans and well developed in *Trapezia*, contains two centrioles (Figs 2B,C), a plesiomorphic condition seen in majids, parthenopids, calappids, portunids, dorippids and *Macrophthalmus* but absent in xanthids (Fig. 3) and, usually, in thoracotremes (see Jamieson, 1991).

Contorted membranes are present among the mitochondria of the dilated region of the cytoplasm and in extensions of the cytoplasm into the chromatin (Fig. 1, 2B). These membranes are the equivalent of the sometimes better developed lamellar structure seen in other brachyuran sperm. In *Trapezia* some of the membranes are continuous with the multilaminar prenuclear membrane (see below) and also appear to be continuous with membranes of disintegrating mitochondria. It seems possible, therefore, that the multilaminar membrane is at least partly derived from mitochondrial membranes.

Nucleus

In *Trapezia*, as in xanthids, and other brachyurans, the nuclear material is located in the lateral arms and their branches (Fig. 2B) and in the cup-shaped structure around both the acrosome and its cytoplasmic sheath. The chromatin extends around the operculum, leaving only the raised central area of this exposed (Fig. 2B), as in xanthids, whereas in portunids and *Neodorippe* the operculum is not covered. The envelope between the chromatin and the basal cytoplasm is unusually well developed in *Trapezia* and is represented by a dense double membrane bounding the cytoplasm (the nature of which is obscure as it cannot be the plasma membrane). Posterior to this membrane, bounding the anterior face of the nucleus, a series of six or more dense membranes (inner nuclear membrane in Fig. 2B), make up a multilaminar membrane. In xanthids and *Portunus*, for instance, the nuclear envelope though retained is disrupted and is not multilaminar. Nevertheless, the multilaminar membrane in *Trapezia* is incomplete, as it ends anteriorly at the lamellar structures. The external, basal surface of the cell, is bounded by a dense membrane, which may represent fused nuclear and plasma membranes, here termed the cell membrane (Fig. 2B). The general chromatin consists of electron dense filaments in a pale matrix, as in most brachyurans, but is less densely packed than in xanthids (see Discussion).

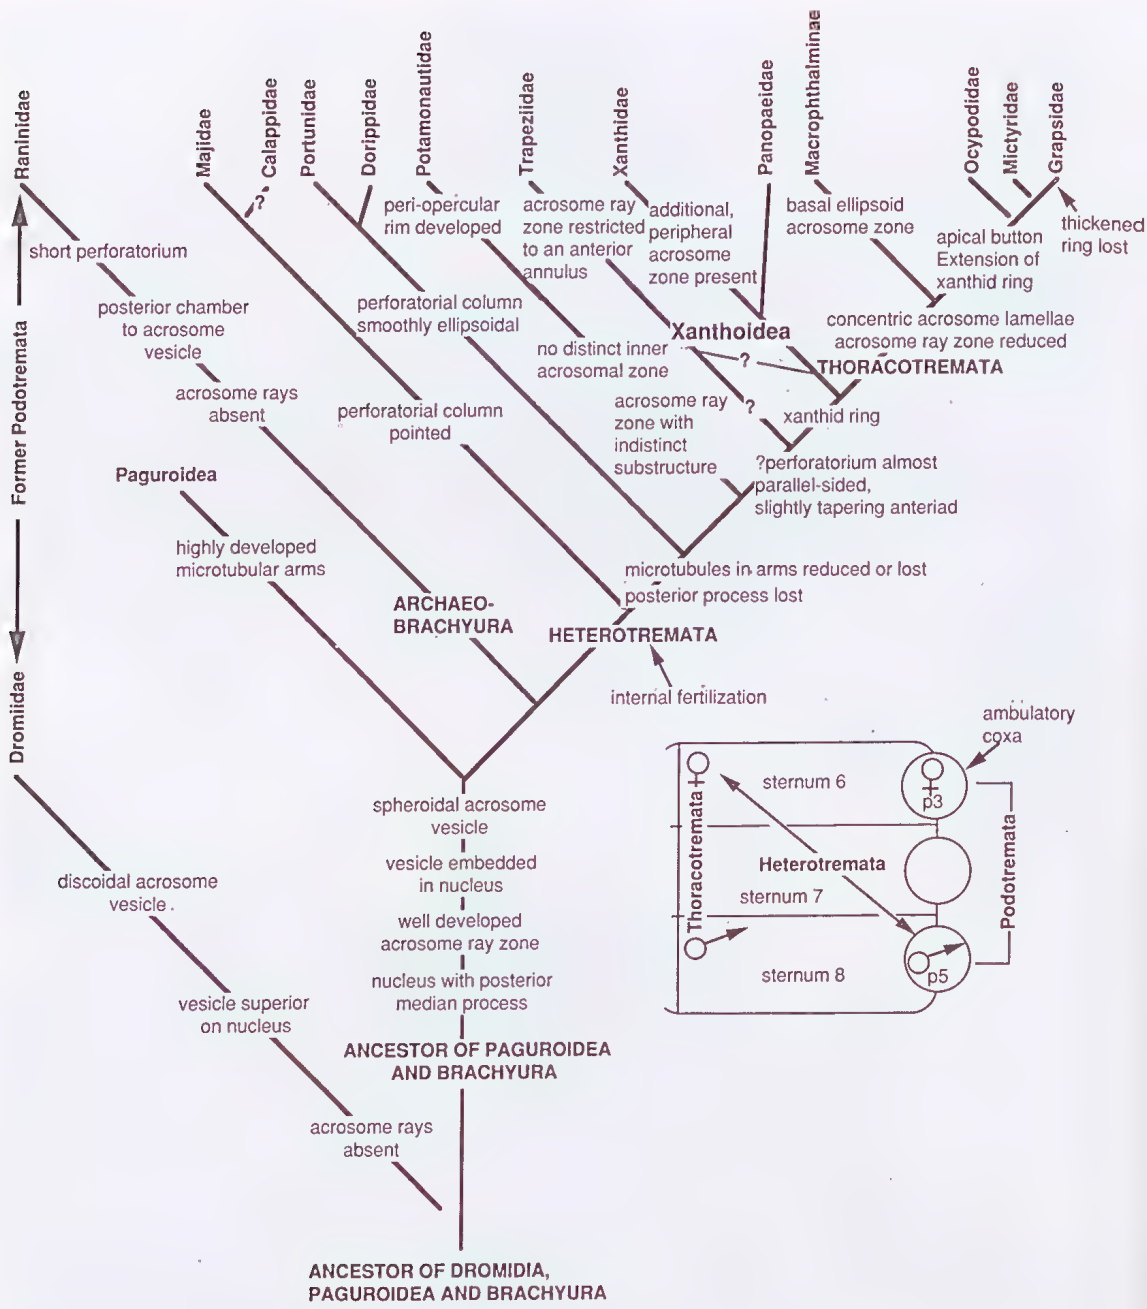

FIG. 5. Tentative phylogeny of the Brachyura based on apparent trends in the evolution of spermatozoal ultrastructure (modified from Jamieson, 1991). The chart of taxonomic features of location of gonopores is after Guinot (1978). The basal position of the Dromiidae, below the Paguroidea, which was tentatively suggested as an alternative to a brachyuran relationship by Jamieson (1991), is supported by evidence from rRNA (Spears et al., in preparation, cited in Abele, 1991). The position of the Potamonautidae is based on description of the sperm of *Potamonautes* by Jamieson (1993).

DISCUSSION

We may now consider the relationships of *Trapezia* as indicated by spermatozoal ultrastructure. These are tentatively indicated in Figure 5 within the context of a phylogeny of the Brachyura based on apparent trends in spermatozoal evolution

The following are features of the spermatozoon of *Trapezia* that are general for heterotremes: extension of the subacrosomal chamber almost to anterior apex of the sperm whereas it reaches only to the approximate equator of the acrosome in the archaeobrachyuran *Ranina*; division of the acrosome contents into inner and outer zones; presence of an acrosomal ray zone at the periphery of the inner acrosomal zone; presence of a thickened ring where the capsule surrounds the base of the subacrosomal chamber; and absence of thoracotreme features mentioned below. A feature shared with 'higher' heterotremes is the restriction of cytoplasm to the periacrosomal region; unlike majids, for instance, it does not extend into the arms. The sperm of *Trapezia* thus confirms its heterotreme status and endorses separation from thoracotremes (Guinot, 1977, 1978) on the basis of the arrangement of the genital pores.

Features of the spermatozoon of *Trapezia* that are shared with the Xanthidae (compare Figs 2B & 3), at least as exemplified by investigated Xanthinae and Chlorodiinae , and the Panopeidae, exemplified by *Eurytium limosum*, include all of the above general heterotreme features but also the following apparently apomorphic xanthid features: the structure of the perforatorium, tapering anteriad, with a fibrous core; and extension of the chromatin around the operculum, leaving only the raised central area of this exposed, the latter feature less developed in *Eurytium* than in the xanthids. These features are of questionable significance and could possibly arise homoplasically. Nevertheless, the form of the perforatorium is shared only with xanthids and *Eurytium* and, bearing in mind differences in sperm structure from the latter family outlined below, is not inconsistent with recognising relationship of *Trapezia* with xanthids though in a separate family.

Peculiar features of xanthids (Xanthinae, Chlorodiinae) (Jamieson, 1989a, and this study) and panopaeids (Jamieson & Abele, unpublished) which separate them from all other investigated heterotremes are the dense 'xanthid ring' around the base of the subacrosomal chamber and, in xanthids only, the additional peripheral zone outside the outer acrosomal zone (Fig. 3). A presumed derivative of the xanthid ring occurs in thoracotremes (see *Mictyris*, Fig. 4A) and this fact suggests that the Xanthidae are an advanced heterotreme group near the base of the Thoracotremata (see Jamieson, 1991). Presence of the ring or its derivatives indicates that although the xanthids and such thoracotremes form a monophyletic group, the Xanthoidea, as it is currently understood, is a paraphyletic group. The absence of the ring in *Trapezia* may parsimoniously be taken to be plesiomorphic rather than due to loss because loss would involve one extra evolutionary step. This, with the xanthid-like perforatorium and undoubted somatic similarities of *Trapezia* and xanthids, suggests that *Trapezia* is the plesiomorphic sister- taxon or, at least a neighbouring taxon, of the xanthid-panopaeid assemblage in so far as they are represented spermatologically by xanthines, chlorodiines and panopaeids. In *Geryon* the ring is also absent (Jamieson, 1991, from micrographs by Hinsch, 1988). The condition in other xanthoids is unknown.

Whereas the sperm of *Trapezia* shows clear heterotreme features, it lacks thoracotreme features, well exemplified by *Mictyris* (Fig. 4A,B), which include the perforate operculum with apical button (excepting *Macrophthalmus*); absence of the acrosome ray zone; absence of the thickened ring; and presence of concentric 'onion ring' lamellation of the outer acrosome zone (excepting *Uca*).

In conclusion, spermatologically *Trapezia* confirms its heterotreme position, shows features (especially the form of the perforatorium) linking it with xanthids and panopaeids, but warrants separate familial status in lacking the xanthid ring. It remains to be seen whether examination of sperm ultrastructure in further xanthoids will confirm this conclusion.

ACKNOWLEDGEMENTS

I am deeply grateful to Dr Danièle Guinot for providing information on the taxonomic status of *Trapezia*. I am also indebted to Miss Jenny Munoz for making some observations, Mrs L. Daddow, Mr C Tudge and Mr D. Scheltinga for technical assistance, to Mr P. Davie and Mr J. Short for identifying *Trapezia coerulea*, and to to Mr C. Tudge and an anonymous reviewer for constructive comments on the manuscript. The computer-generated line drawings are by the

author. This work was made possible by Australian Research Council funding.

A TAXONOMIC REVISION OF THE EASTERN AUSTRALIAN EARTHWORM GENUS *PERISSOGASTER* FLETCHER (MEGASCOLECIDAE: OLIGOCHAETA)

B.G.M. JAMIESON

Jamieson, B.G.M. 1993 06 30: A taxonomic revision of the eastern Australian earthworm genus *Perissogaster* Fletcher (Megascolecidae: Oligochaeta). *Memoirs of the Queensland Museum* 33(1): 235-244. Brisbane. ISSN 0079-8835.

The three species assigned to *Perissogaster* by Fletcher are redescribed. Of these *P. nemoralis* and *P. queenslandica* are shown to have on each side in caudal segments a median nephridium with preseptal funnel flanked by astomate meronephridia, all nephridia being exonephric. This dichogastrin condition of the nephridia, coupled with multiplication of gizzards, is considered to warrant placing the two species in the genus *Digaster* Perrier. The trigastric condition is verified for *P. nemoralis* but *P. queenslandica* is shown to have only two gizzards. It is demonstrated for the first time that *P. excavata*, the trigastric type species of *Perissogaster*, has at least 100, mostly preseptal, nephrostomes on each side per segment caudally, a condition attributable to the Tribe Megascolecini. It is nevertheless argued that this species is closely related to *Digaster*. Parsimony analysis is equivocal between origin of *P. excavata* within *Digaster* or a sister-group relationship to the *Digaster-Didymogaster* assemblage. The latter derivation is compatible with (though not necessitating) parallel development in *P. excavata* of multiple gizzards from a monogastric ancestor with or without multiple nephrostomes. A monotypic genus *Perissogaster* is redefined for *P. excavata*.
☐ *Perissogaster, Digaster, Didymogaster, nephridia, taxonomy, parsimony analysis.*

B.G.M. Jamieson, Department of Zoology, University of Queensland, Queensland 4072, Australia; 15 March, 1993.

Perissogaster was erected by Fletcher (1887) for a new species, *P. excavata*, which differed from all known Australian oligochaetes in possessing three gizzards. Subsequently, Fletcher 1889, included *P. nemoralis* and *P. queenslandica* on the grounds that they also were trigastric.

Beddard (1895) placed *Perissogaster* and *Didymogaster* in *Digaster* because the three entities shared lobate prostates, meronephridia and more than one gizzard and were restricted to Australia. Michaelsen (1900) again separated the three genera but Sweet (1900) and Jamieson (1963) included the three species of *Perissogaster* in *Digaster* while excluding *Didymogaster*. Jamieson (1970, 1971) showed that *P. queenslandica* had dichogastrin nephridia (a stomate exonephric meronephridium median to astomate meronephridia on each side in caudal segments) and could therefore be retained in *Digaster* which has the same nephridial condition. It was, however, suggested that *P. excavata* and *P. nemoralis* should be excluded from *Digaster* in a reinstated *Perissogaster* as only astomate nephridia were demonstrated. *Perissogaster* was formally restricted to these two species by Jamieson (1975) but it was stated that the existing material of the genus was not in sufficiently good condition to allow full characterisation of the genus. The kindness of Dr Courtenay Smithers in forwarding to the author a well preserved specimen which has proved to be *Perissogaster excavata* has allowed a reappraisal of the anatomy of this species revealing an unsuspected nephridial anatomy and has prompted redescription of the types of *P. nemoralis* and *P. queenslandica* which, again, are found to differ significantly from previous descriptions.

All figures are drawn by camera lucida. The following abbreviations are used in Figs 1&2: ♀, female pore; g.m. accessory genital marking; ♂ male pore; ♀ po, male porophore; pr.d, prostate duct; pr.g. glandular portion of prostate; sp. amp, spermathecal ampulla. sp. div, spermathecal diverticulum; sp.p, spermathecal pore; v.d, vas deferens. Roman numerals indicate respective segments. Registration numbers prefixed by AMW are housed in the Australian Museum.

TAXONOMY

Perissogaster Fletcher, 1887 emend.

Type species: *Perissogaster excavata* Fletcher, 1887.

DIAGNOSIS

Setae lumbricine. Gizzards 3, in V, VI and VII; extramural calciferous glands absent. Mero-

nephric; with numerous preseptal funnels on each side in each intestinal segment. Combined pores of a pair of tubuloracemose prostates and the vasa deferentia in XVIII. Spermathecae with pores at the anterior margins of their segments.

Detailed Definition

Setae 8 per segment; dorsal setal couple (*cd*) significantly wider than the ventral couple (*ab*). Clitellum anterior to the male pores. Combined male and prostatic pores a pair on XVIII. Accessory genital markings present. Female pores a minute pair presetally in XIV. Spermathecal pores 2 pairs, in 7/8 and 8/9.

Some preclitellar septa very strongly thickened. Dorsal blood vessel single, continuous onto the pharynx. Last hearts in XII, those in X-XII latero-oesophageal; preceding commissurals dorsoventral only; supra-oesophageal vessel oesophageal only; a pair of anterior lateroparietal trunks becoming latero-oesophageal and passing median to the dorsoventral commissurals to join the oesophageal plexus. Subneural vessel absent. Three oesophageal gizzards in V, VI and VII; extramural calciferous glands absent; intestine commencing in XVI, lacking muscular thickening, caeca and typhlosole.

Meronephric; enteronephric tufts in II-IV; astomate exonephric parietal micromeronephridia in succeeding segments but from XIV to the caudal extremity numerous preseptal nephrostomal funnels on each side in each segment; intestinal enteronephry not demonstrated. Holandric; gymnorchous; seminal vesicles in IX and XII. Prostates 1 pair, tubuloracemose. Fan shaped ovaries, and funnels, in XIII. Spermathecae short-stalked with small, sessile, lobed diverticulum.

Distribution

New South Wales: Hawkesbury to Hunter River districts.

Remarks

The presence of multiple nephrostomes here demonstrated for *P. excavata* for the first time, sets *Perissogaster* apart from *Digaster*, no other described characters necessitate separation of the two genera.

Perissogaster excavata Fletcher, 1887
(Figs 1A, 2A, B)

Perissogaster excavata Fletcher, 1887: 383-387.
Digaster excavata; Beddard, 1895: 486; Sweet, 1900: 123. Buchanan, 1909: 73; Jamieson, 1963: 85-90; 1971: 75.
Perissogaster excavata; Fletcher 1889: 1528; Michaelsen, 1900: 193; 1907: 162; Bage, 1910: 231; Jamieson, 1970: 44; 1975: 268-269.

Material Examined

'Tuglo' property, near Mt Royal, 48km north of Singleton, under a stone on very clayey muddy soil, collector C.N. Smithers, 8 February, 1976 – 1 clitellate specimen, AMW6644. Identification checked against a badly macerated much-dissected type specimen from Morpeth, AMW 1457.

Description

Length = 280mm, width (midclitellum) = 16mm, greatest width (forebody) = 18mm, 175 segments (69-334mm long, 3-15mm wide, 160-195 segments; Fletcher, 1887). Form circular in cross section. Segments II and III biannulate ; remaining segments to XIV triannulate, IV weakly, the others strongly; thereafter with a strong postsetal furrow. Pigmented grey, excepting the pale ventrum, in alcohol. Prostomium proepilobous, short and broad, it and the peristomium with many longitudinal furrows. Dorsal pores absent (sometimes about 20 rudimentary pores posteriorly, Fletcher, 1889: 1528). Setae in 8 regular longitudinal rows throughout, commencing on II; minute but distinctly visible; setae *a* and *b* not visible in XVIII. In XII *aa*:*ab*:*bc*:*cd*:*dd* = 2.96:1.00:1.60: 1.50:2.68; circumference = 55mm; *dd*:*u* = 0.19. Nephropores not externally recognisable. Clitellum annular, XIV-XVII, with weak development to 1/2XIII and 1/2XVIII dorsally; (1/3XIII-part or most XVIII; Fletcher, 1887) intersegmental furrows and setae retained. Male pores (Fig. 1A) , from internal examination, on small indistinct elliptical papillae equatorially in XVIII in *ab* (not visible externally; Fletcher, 1887). Accessory genital markings paired presetal eye-like markings in XVIII-XXII in *bc* and a transverse glandular trough similarly located in XXIII but continuous across the ventrum; the markings in XVIII also lying in a transverse elliptical trough which impinges on the posterior region of XVII; the troughs in XVIII and XXIII with numerous longitudinal stigmata; the accessory markings and male pores lying in a rectangular flattened and thickened area. (Accessory markings limited to XVIII-XXI; Fletcher, 1887). Female pores small but distinctly visible, a pair presetally and well median of *a* lines of XIV in a common whitish glandular area which interrupts the clitellum pre-

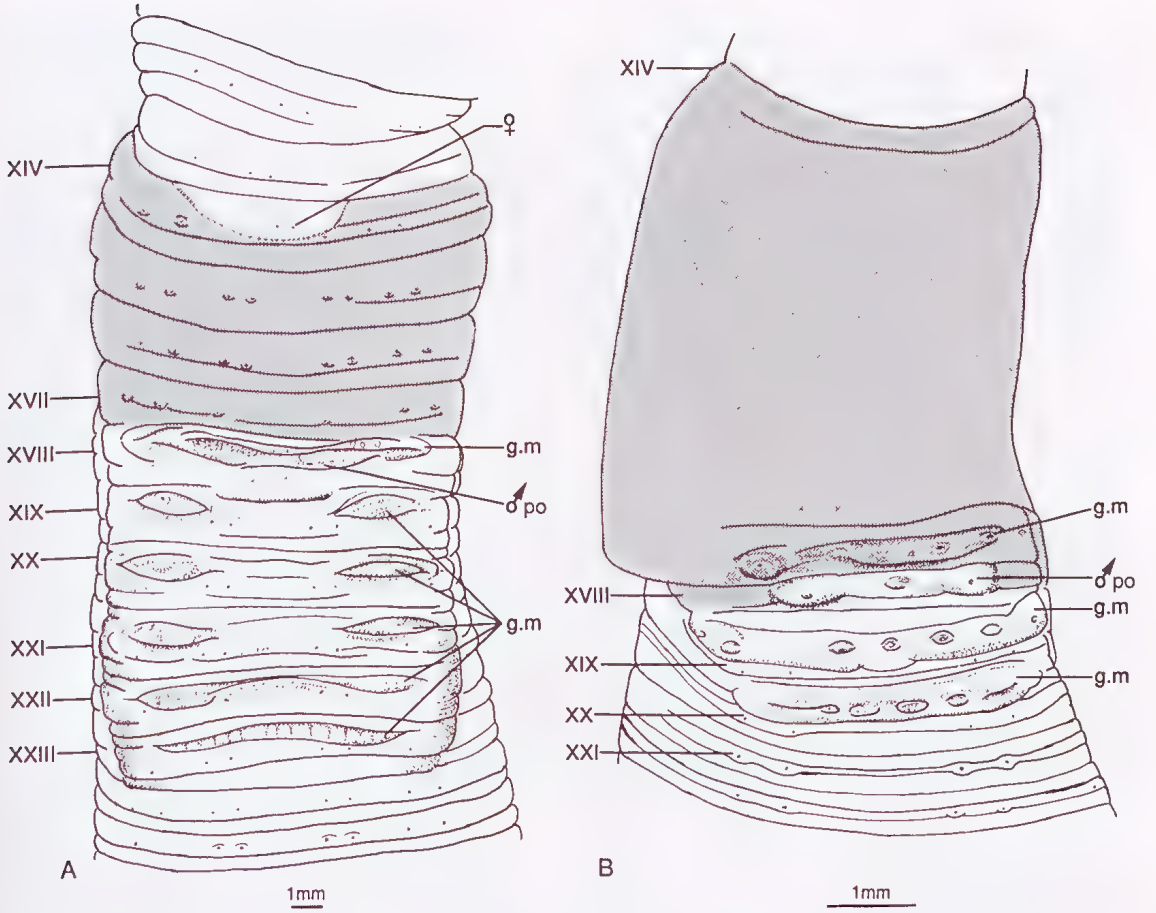

FIG. 1. Genital fields. A, *Perissogaster excavata* (TUGLO specimen); B, *Digaster nemoralis* (paralectotype). Clitellum shaded.

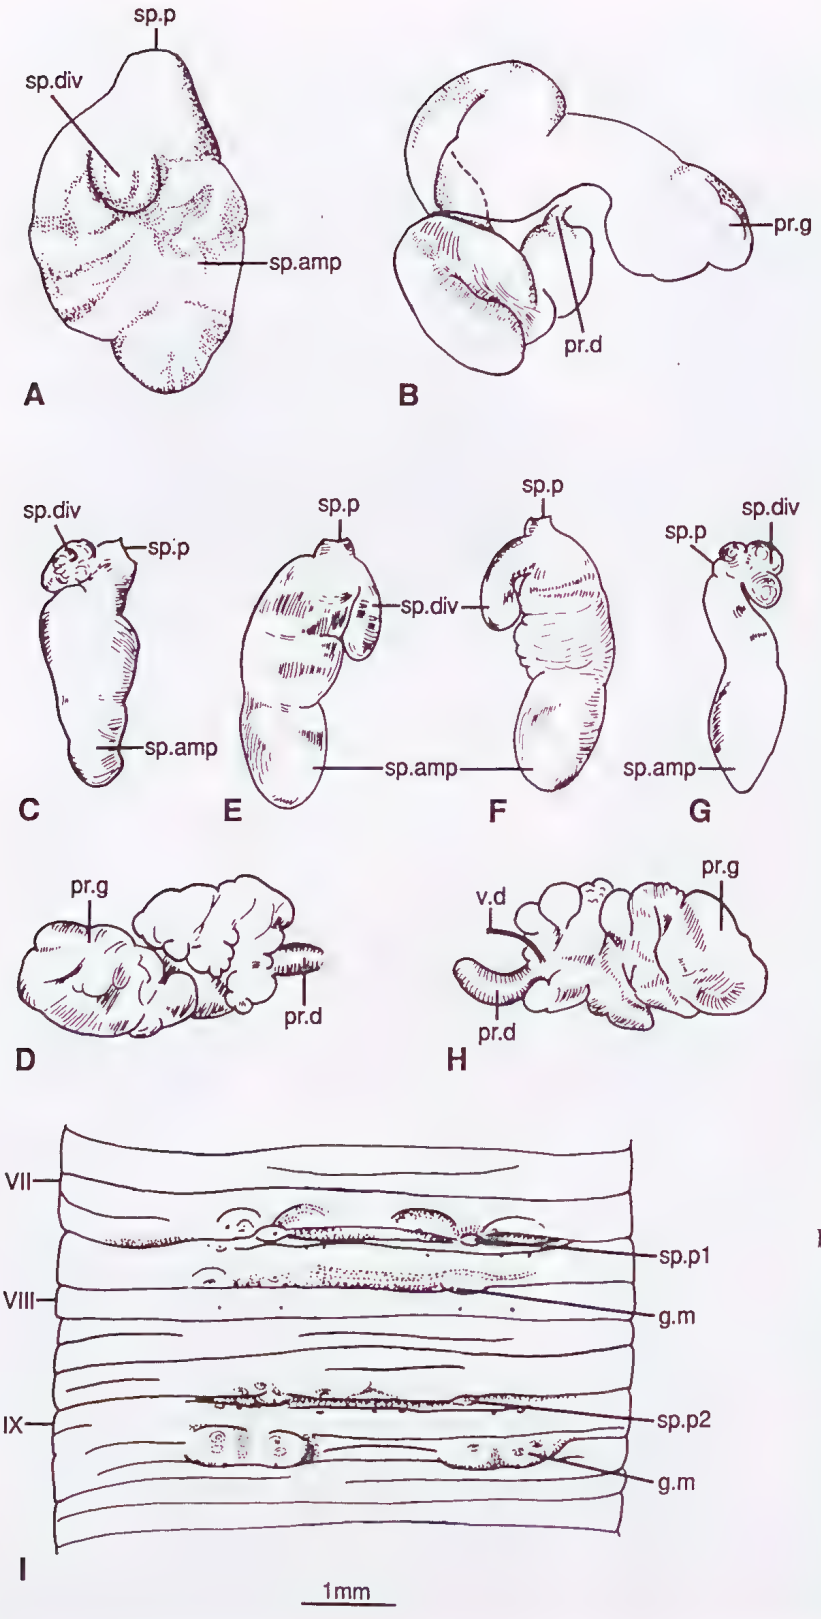
setally. Spermathecal pores not externally visible, in 7/8 and 8/9, appearing from internal examination to lie in *b* lines but stated by Fletcher (1887) to be in *a* lines.

Some preclitellar septa thickened; 9/10-12/13 (-13/14; Fletcher, 1887) immensely strong; tendons connecting the septa, of which those between septum 5/6 anteriorly are very strong. Dorsal blood vessel single, continuous onto the pharynx and passing under the brain. Last hearts in XII, those in X-XII large and latero-oesophageal, each receiving a broad short connective from the supra-oesophageal vessel and a longer slender connective from the dorsal vessel but otherwise unbranched; commissurals in V-IX (IV- IX; Buchanan, 1909) slender and dorsoventral only, though valvular, and each giving a lateral branch to the body wall before joining the ventral vessel. Supra-oesophageal from 3/4IX to XIII (VIII-XIII; Buchanan, 1909), rudimentary in the last segment; adherent to the oesophagus. A large, free latero-oesophageal trunk present on each side, median to the dorsoventral commissurals in V-IX, ending in the plexus on the floor of the oesophagus in IX and continuous in IV anteriorly as a thick longitudinal ventrolateral parietal trunk. Subneural vessel absent. Oesophagus forming 3 large subspherical strongly muscular gizzards, in V, VI and VII, decreasing in size posteriad, each constricted off from but abutting on the others without appreciable intervention of unmodified oesophagus (connected by short pieces of oesophagus; Fletcher, 1887). The oesophagus simple, lacking calciferous glands, in VIII-XV, though internally with low papillae. Intestine commencing in XVI, muscular thickening, caeca and typhlosole absent. Nephridia meronephridia: tufts of numerous astomate micromeronephridia



on and lateral to the pharynx in II, III and IV send composite ducts to the pharynx in III and IV and those of II to the buccal cavity; numerous minute astomate exonephric parietal micromeronephridia in V-XIII, becoming very dense in XIV in which many are, in addition, adherent to the posterior septum; very numerous shortly stalked nephrostomes present on the anterior face of septum 14/15 and apparently arising mostly from the dense bands of exonephric septal nephridia on the posterior face of this septum. Nephridia in XV and succeeding segments dense bands on the anterior and posterior septa, with numerous funnels restricted to the anterior face of the posterior septum; parietal nephridia few but at least some of them with funnels. By XIX the nephridial bodies are chiefly on the posterior face of each septum, with more than 100 stalked funnels on the anterior face of the septum on each side; parietal nephridia are very few. In the caudal region nephridia are dense on the anterior faces of the septa, co-

FIG. 2. A,B, *Perissogaster excavata* (paralectotype): A, left spermatheca of IX; B, right prostate. C, D, *Digaster queenslandica* (lectotype): C, left spermatheca of IX; D, left prostate. E-I, *Digaster nemoralis*: E,F, ventral and dorsal views of left spermatheca of IX (lectotype); G, right spermatheca of IX (paralectotype); H, right prostate (paralectotype); I, spermathecal genital field (paralectotype).

existing with numerous stalked funnels and less numerous, with very few evident funnels, on the posterior faces, parietal nephridia are absent; no enteronephry is demonstrable.

Testes and large iridescent funnels in X and XI; testis-sacs absent; seminal vesicles racemose, much divided, in IX and XII, the posterior pair the larger. Prostates (Fig. 2B) tubuloracemose, restricted to an enlarged segment XVIII (or unilaterally in XVIII and XIX; Fletcher, 1887) each basically a broad tortuous tube but with some portions, particularly at the ental end, fused so that the tubular form has in places been lost; almost sessile, the short duct being concealed in the body wall (vas deferens opening into the duct at the base of the gland; Sweet, 1900). Fan-shaped ovaries, and funnels, in XIII. Spermathecae (Fig. 2A) 2 pairs, in VIII and IX, each virtually sessile on the body wall, with flattened ovoid ampulla and short broad diverticulum on its anterodorsal surface, the diverticulum more or less bi- or trilobed.

Digaster Perrier, 1872

D. nemoralis must now be added to the genus, as redefined by Jamieson (1975), as it is here shown to have the dichogastrin condition of the nephridia seen in all species of *Digaster*. The following changes in the definition are necessitated by the present study: *P. queenslandica* must be excluded from the statement that there may be 3 gizzards (see account below). This number is now limited in *Digaster* to *D. nemoralis* and variant individuals (Jamieson, 1963) of *D. perrieri*. The intestinal origin in the genus is now XVI-XIX and absence of a typhlosole is no longer constant as a typhlosole is present in *D. nemoralis*.

Digaster nemoralis (Fletcher, 1889) (Figs 1B, 2E-I)

Perissogaster nemoralis Fletcher, 1889: 1527-1528.
Digaster nemoralis; Beddard, 1895: 486; Jamieson, 1963: 86; 1971: 75.
Perissogaster nemoralis; Michaelsen, 1900: 198; Jamieson, 1970: 44; 1975: 268-269.

Material Examined

Gosford, New South Wales, 2 clitellate, much dissected type specimens, AMW1438, here designated the lectotype (L) and paralectotype (P).

Description

Length = 90+, 105mm, width (midclitellum) = 5.5mm, greatest width (forebody) = 6mm (lectotype, paralectotype), segments (P) 192. Form circular in cross section. Segments I-III simple; IV biannulate with the setae on the anterior annulus; from V, segments quadriannulate with the setae on the second annulus, and often with faint additional furrows; postclitellar segments triannulate. Pigmentless buff in alcohol. Prostomium broad, prolobous or perhaps slightly proepilobous, it and the peristomium with many longitudinal furrows. Dorsal pores visible posteriorly, location anteriorly indeterminable owing to previous dissection (commencing after about X; Fletcher, 1889). Setae minute, in 8 regular longitudinal rows throughout, commencing on II; setae *a* and *b* replaced by penial setae in XVIII; in XII *aa*:*ab*:*bc*:*cd*:*dd* = 3.25:1.00:3.30:1.94:13.09; circumference = 15.4mm; *dd*:*u* = 0.47. Nephropores not externally recognisable. Clitellum annular, XIV-1/2XVIII; intersegmental furrows, dorsal pores and setae suppressed. Male pores in XVIII (Fig. 1B) on distinct ellipsoidal papillae, in *a* lines; the two papillae medianly conjoined by a transverse boss which widens medianly around a midventral oval pit-like glandular stigma. A median transverse pad present in each of intersegments 17/18, 18/19 and 19/20, each with a transverse series of similar stigmata. Numerous stigmata associated with tumescence (Fig. 2I) also present in VII, VIII and IX in association with the spermathecal pores. Female pores not visible. Spermathecal pores on distinct papillae in 7/8 and 8/9, in *a* lines.

Some preclitellar septa thickened: 5/6-9/10 very strong. Dorsal blood vessel single, anterior course indeterminable owing to previous dissection. Last hearts in XIII; those in X-XIII large and latero-oesophageal, each receiving a broad short connective from the supraoesophageal vessel and a longer slender connective from the dorsal vessel but otherwise unbranched; commissurals in VIII (and IX?; and further anteriorly?) slender and dorsoventral only and each giving a lateral branch to the body wall before joining the ventral vessel. Supraoesophageal vessel narrow and adherent to the oesophagus but limits indeterminable. Broken latero-oesophageal trunks observed in segment VI. Subneural vessel absent. Oesophagus forming 3 large strongly muscular gizzards, in V, VI and VII, each bowl-shaped and occupying the posterior half of the segment, the oesophagus in the anterior half being similarly dilated but only slightly muscularised. Oesophagus very short,

almost suppressed, in VIII; in IX and X short but laterally expanded and in XI-XIV forming paired,very conspicuous, strongly vascularised dilatations, increasing in size posteriorly to very large in XIV; these dilatations dorsolateral, internally with numerous low lamellae but not constricted off from the general oesophageal lumen. Oesophagus in XV and XVI narrow but invaginated into the dilatation in XIV in which it has the appearance of a rosette-like valve. Intestine commencing, with abrupt widening, in XVI; muscular thickening and caeca absent; a deep laminar dorsal typhlosole present. Nephridia meronephridia; large astomate tufts with many spiral loops in II-IV send a common (multiple?) duct forward on each side, traced anteriorly in II but further course indeterminable. Smaller aggregates with lateral outliers in V to VII are restricted to the posterior septum but are exonephric by separate individual ducts, one from each nephidium. By VIII the nephridia form a transverse exonephric band of several moderately large meronephridia at junction of posterior septum and body wall. By XII the band of several nephridia on each side is parietal with the forwardly directed ducts entering the body wall presetally; from XIII there is an increasing tendency for the median nephridia to form diffuse aggregations, though by about XXII these aggregations have reduced to 2 to 3 nephridia lateral to which are 4 smaller nephridia forming regular longitudinal rows; all nephridia are exonephric, avesiculate and apparently astomate. Towards the caudal end there are 3 well spaced nephridia on each side in very straight longitudinal rows lateral to what appear to be two or more aggregated nephridia. In the paralectotype which, unlike the lectotype, is complete posteriorly, the median-most nephridium in several posterior segments has a preseptal funnel and is enlarged as an exonephric megameronephridium. Finally in approximately 7 most posterior segments the regular arrangement of nephridia breaks down, nephridial loops filling the segments transversely and the median nephridium is further enlarged; the lateral nephridia appear to be interconnected by a medianly directed duct; the median nephridium retains the preseptal funnel but whether it and the lateral nephridia are exonephric or enteronephric is indeterminable. Testes and large iridescent sperm funnels in X and XI; testis-sacs absent; seminal vesicles racemose, large, in IX, XI and XII. Prostates (Fig. 2H) racemose: subrectangular deeply incised lobes, with stout moderately long muscular duct which branches within the gland and entally receives the vas deferens. Penial setae slender entally strongly curved needles, the ectal tip delicately pointed with recurved extremity; ectal region with a few fine apically directed spines; a mature seta (paralectotype) 0.96mm long; the shaft 21 µm wide at midlength. Bushy ovaries and funnels, in XIII; ovisacs not recognisable. Spermathecae (Fig. 2E,F,G) 2 pairs, in VIII and IX, each with elongate sacciform to pointed ovoid ampulla which is joined ectally and anteriolaterally by a clavate inseminated diverticulum, duct ectal to the ampulla very short. In the paralectotype the diverticulum is bi- or usually multi-loculate.

Digaster queenslandica (Fletcher, 1889) (Fig. 2C,D)

Perissogaster queenslandica Fletcher, 1889: 1529-1530.

Digaster queenslandica; Beddard, 1895: 485; Sweet, 1900: 124; Jamieson, 1970: 44; 1971: 75; 1975: 268-269.

Perissogaster queenslandica; Michaelsen, 1900: 199; 1916: 22-24.

Material Examined

Oxley, southeast Queensland, collector T.G. Sloane, AMW1408, two specimens here designated lectotype (L) and paralectotype (P).

Description

Length = 162mm, width at segment XV = 6.5mm, greatest width (forebody) = 8mm, segments 215. Form circular in cross section but with some ventral flattening posteriorly. Segments I to III simple; from IV biannulate with setae on the posterior annulus and sometimes with weaker further annulation; simple from approximately XX posteriorly. Pigmentless buff in alcohol. Prostomium prolobous though longitudinal furrowing of the peristomium perhaps includes a narrow dorsal tongue. Dorsal pores unusually obvious, first in 4/5 but with a rudiment in 3/4. Setae in 8 regular longitudinal rows throughout, *a* and *b* absent in XVIII; in XII, *aa*:*ab*:*bc*:*cd*:*dd* = 2.57:1.00:2.00:1.78:18.57; circumference = 21.5mm; *dd*: $u = 0.60$. Nephropores not externally recognisable. Clitellum not developed. Male pores in XVIII, in *a* lines, on small almost contiguous papillae. Female pore unpaired in XIV, midway between the setal arc and anterior margin. Spermathecal pores 2 pairs, minute but distinctly visible in VIII and IX, appreciably be-

hind the anterior margin; those in IX 0.55mm apart.

Septa 4/5 and 5/6 fairly strongly thickened; 6/7 and 7/8 slightly thickened; 8/9 moderately strongly; 9/10-13/14 strongly thickened, 11/12-13/14 especially so. Dorsal blood vessel single, continuous onto the pharynx. Last hearts in XII; those in X-XII large and latero-oesophageal, each receiving a broad short connective from the supra-oesophageal vessel and a slender connective from the dorsal vessel but otherwise unbranched; commissurals in (V?) VI-IX slender and dorsoventral only and each giving a lateral branch to the body wall before joining the ventral vessel. Supra-oesophageal vessel well developed in X-XII, weakly developed in IX and 1/2XIII. A large latero-oesophageal trunk on each side median to the commissurals joining the supra- oesophageal vessel in X and traceable forward at least to VI. Subneural blood vessel absent. Oesophagus with only 2 gizzards (contrary to Fletcher, 1889), in VI and VII, each very large, strongly muscular and subcylindrical, abutting on each other with almost inappreciable intervening oesophagus; that in VI preceded in the anterior portion of the segment by unthickenened oesophagus. The oesophagus in V dilated to almost the size of a gizzard but its musculature unthickened, a spurious impression of a gizzard being produced by the ensheathing muscular septum 5/6. Dilatation and vascularisation of the oesophagus in XIV-XVI but no calciferous glands. Intestine cornmencing in XVIII; muscular thickening absent; caeca and typhlosole not recognisable but maceration precludes certainty. Nephridia all avesiculate meronephridia: dense aggregations of meronephridial tubules on the parietes in II-IV appear exonephric but tubules adherent to the pharynx are possibly enteronephric; from V to the anterior intestinal region astomate, avesiculate micromeronephridia scattered on the parietes, the nephridia decreasing in size and becoming more numerous (many) posteriorly; never forming regular longitudinal rows. Caudally, in the last approximately 18 segments, with 15-20 astomate parietal micromeronephridia in transverse single file on each side lateral to an exonephric(?) megameronephridium with large preseptal funnel. Testes and funnels in X and XI, funnels in XI larger and iridescent; seminal vesicles large, racemose, in XI and XII. Prostates (Fig. 2D) depressed elongate tongue-shaped, sufficiently incised to be considered racemose but with a main, central canal from which many lesser side branches supply the lobes; ectal duct short, weakly muscular and largely concealed in loose parietal musculature. Penial setae absent. Ovaries presumably represented by a pair of large depressed lobes with no evident oocytes on the anterior septum of XIII; funnels on the posterior septum. Spermathecae (Fig. 2C) 2 pairs, in VIII-IX, each with conical-ovoid ampulla and short, wide duct: which is joined anterolaterally by a compact inseminated internally multiloculate and externally slightly lobed diverticulum.

Remarks

The demonstration above that Fletcher and Michaelsen were incorrect in recognising a third gizzard in this species gives unexpected support to the author's contention (Jamieson, 1970) that the previously described anatomy and the hitherto unrecognised dichogastrin condition of the nephridia warranted placing it in *Digaster*.

Michaelsen (1916) recorded this species from Brisbane, southeast Queensland.

CLADISTICS

As an adjunct to taxonomic considerations of the status of *Perissogaster* the relationships of the three species formerly placed in the genus to each other and to *Digaster* and *Didymogaster* have been investigated, using the PAUP program of Swofford (1990), version 3.0s, using 30 characters for 25 species (Jamieson, unpublished). Suffice to say the exhaustive and branch-and-bound search options gave a very large number of trees with grossly discordant topologies and that a consensus tree gave no resolution beyond separating the two *Didymogaster* species as the sister-group of the *Digaster-Perissogaster* assemblage. This assemblage formed a single polytomy. Many of the characters proved highly homoplasic.

A subset of 15 of the less noisy characters applied to only 11 taxa, consisting of a hypothetical ancestor (hypanc), the three *Perissogaster* species, the two *Didymogaster* species, and representatives of the *lumbricoides* and *perrieri* groups within *Digaster* (details below) produced a single tree (Fig. 3) in a branch-and-bound search. In view of the discordant results when the full character-taxon set is used, or when additional taxa are added to the reduced set, this single tree can be regarded as only one of many objective hypotheses of relationships. It is possible that the true phylogeny is not recoverable from the morphology of extant species of the total assemblage. The single tree obtained will, nevertheless be used in the following 'intuitive' discussion of

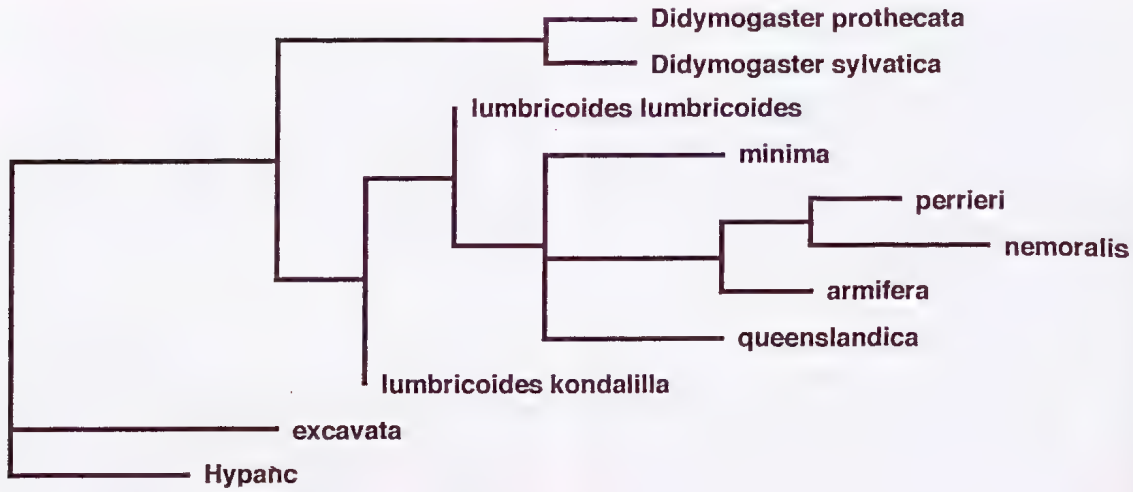


FIG. 3. Single tree obtained for 11 taxa indicated, and 15 characters, using the branch-and-bound option of the PAUP program. Tree length = 27. Consistency index (CI) = 0.778. Homoplasy index (HI) = 0.222. CI excluding uninformative characters = 0.667. HI excluding uninformative characters = 0.333. Retention index (RI) = 0.684. Rescaled consistency index (RC) = 0.532

relationships and in support of the taxonomic decision made.

An ancestor (hypanc) with a single gizzard and other characters indicated in the matrix was envisaged. Recourse, alternatively, to using the more objective out-group strategy, using *Didymogaster* as the outgroup, gave similar results.

Characters Employed

This list is a subset of those used in the more comprehensive analysis. As a result some of the characters (marked #) are uninformative or invariable. *Numbers are deducted from the states of some characters to limit their values to less than 10 and avoid hexadecimal notation.

#1. Male pore(s) unpaired 1; paired 2.
2. Female pore(s) unpaired 1, paired 2.
#3. Spermathecal pore(s) unpaired 1, paired 2.
4. First spermathecal segment.
5. Spermathecal pores, number of transverse sets.
6. Segment (-10) of last hearts.*
7. First gizzard segment.
8. Number of gizzards.
9. Caudal preseptal funnels 1, many 2.
10. Testes in X 1, X and XI 2, XI 3.
11. Seminal vesicles in IX, X, XI and XII 1, IX and XII 2, XI and XII 3, XII 4, IX, XI and XII 5.
12. Prostates tubular 1, tubuloracemose 2, racemose 3, racemose- bipartite 4.
13. Penial setae absent, 0 present 1.
#14. Number of diverticula per spermatheca.
15. Diverticula uniloculate 1, multiloculate 2.

Branch-and-Bound Search Settings

Initial upper bound: unknown (compute via stepwise).
Addition sequence: furthest.
Initial MAXTREES setting = 100.
Branches having maximum length zero collapsed to yield polytomies.
Topological constraints not enforced.
Trees are unrooted.
Multi-state taxa interpreted as uncertainty.
Outgroup = Hypanc.
Characters were all scored as unordered and unweighted.

DISCUSSION

From 'intuitive' taxonomic considerations, *Perissogaster nemoralis* and *P. queenslandica* are here included in *Digaster* because of the correlation of three points: general anatomy, multiplication of gizzards and dichogastrin nephridia. The dichogastrin nephridial condition occurs in earthworm genera of several zoogeographical regions of the world and has been accompanied by multiplication of the gizzard, from the usual monogastric condition, independently in the various regions. It has been argued (Jamieson, 1975) that the di- or trigastric condition in Australian earthworms originated in what is now the montane coastal province of the Eastern Sub-region, to which such forms are restricted, independently of evolution of this condition in other, non-Australian zoogeographic regions.

Multiplication of gizzards might have developed only once (strict monophyly) or in more than one lineage predisposed to this development by virtue of genetic similarity and relationship (parallelism or homoplasy). It is unlikely that a third hypothesis, development of the multigastric condition independently in unrelated taxa, is tenable as this would presuppose edaphic or other environmental factors favouring repeated development of the condition in the montane coastal province but absent from other provinces.

The taxa with multiple gizzards are (1) a large group of species, containing the type species, *D. lumbricoides* with two gizzards, in VI and VII, which is restricted to Queensland and northern New South Wales; (2) *D. perrieri* and *D. armifera*, with two gizzards, in V and VI, allopatric in New South Wales; (3) two species, comprising the genus *Didymogaster*, with the *lumbricoides* location of the gizzards, sympatric with *D. perrieri* and *D. armifera* in central New South Wales; and (4) the three species of *Perissogaster* s.lat., *P. excavata, P. nemoralis* and *P. queenslandica*.

With regard to the phylogenetic validity of these four groupings: on the basis of gizzard location the *lumbricoides* group might reasonably be assumed to form a monophyletic group. However, neither the restricted PAUP analysis (Fig. 3) nor analysis of the full taxon-character set supported monophyly.

Digaster perrieri and *Digaster armifera*, though sympatric with *Didymogaster*, differ from other *Digasters* and from *Didymogaster* in having gizzards in V and VI, and might be considered the sister-group of the *lumbricoides-Didymogaster* group. However, PAUP analyses do not support a monophyletic *perrieri-armifera* assemblage (Fig. 3).

Didymogaster has various conflicting positions in the PAUP analyses, including that of sister-group to *Digaster*, as shown in Fig. 3. Synapomorphies defining *Didymogaster* include intrasegmetal location of spermathecal pores and presence of testic-sacs (neither character used in the restricted analysis). Its generic status is accepted here.

The relationship of the three former *Perissogaster* species may now be further considered. It has been shown that *Perissogaster queenslandica* is digastric, contrary to previous descriptions, with the *lumbricoides* location of the gizzards, in VI and VII and is placeable in *Digaster*, as supported in Fig. 3 and advocated by Jamieson (1970, 1971). *P. nemoralis*, sympatric with *D. armifera* and *D. perrieri*, is here transferred to *Digaster* as its only trigastric species (excepting variant individuals of *D. perrieri*). Consideration has been given to the possibility that the *armifera-perrieri* condition (gizzards in V and VI) and *lumbricoides* condition (gizzards in VI and VII or their homeotic equivalent) have developed dichotomously from the trigastric condition seen in *nemoralis*. It has been shown above that cladistic analysis does not support recognition of either group. Conversely, the trigastric condition might be considered to reflect a further development of the propensity in *Digaster* to thicken the oesophageal musculature in two of segments V to VII. The PAUP analyses support the latter view, presenting the trigastric condition as an apomorphy of *nemoralis* developed from the digastric condition of an ancestral *Digaster* perhaps (Fig 3) shared with *D. perrieri*.

The relationships of the type species of *Perissogaster, P. excavata*, are especially uncertain. If multiple gizzards are evidence of relationship, it would appear that multiplication of nephrostomes characteristic of *P. excavata*, which would formerly have assigned it to the tribe Megascolecini sensu Jamieson (1971), has occurred in this species independently of acquisition of this condition in other genera of the tribe. This would support the author's contention that the Megascolecini may represent a grade rather than a clade. The anatomy of *P. excavata* is close to that of *P. nemoralis*, excepting the nephridial condition, extending to the origin of the intestine in XVI, unknown elsewhere in *Digaster*. However, an intuitive postulate of a sister-group relationship of *excavata* to the *Digaster-Didymogaster* assemblage is supported by the restricted PAUP

analysis (Fig. 3). It is equivocal as to whether the common ancestor of *excavata* and this assemblage had two or three gizzards despite indicating independent origin of three gizzards in *nemoralis* from the digastric condition. The common ancestor of *excavata* and the *Digaster-Didymogaster* assemblage is computed to have had the dichogastrin condition of nephridia (single preseptal funnel on each side), retained as a plesiomorphy in *Digaster* but changing to the multifunnelled condition in *excavata*. Some trees from the larger data set nevertheless do associate *excavata* and *nemoralis* as sister-species within the *Digaster* assemblage.

The PAUP analyses are not sufficiently extensive to rule out the alternative possibility that *Perissogaster excavata* is descended from a monogastric megascolecin ancestor with its nephridial condition of multiple preseptal nephrostomes in caudal segments, conditions seen in *Oreoscolex* Jamieson. Two *Oreoscolex* species from New South Wales, *O. illawarrae* (Fletcher, 1889) and *O. saccarius* (Fletcher, 1886) agree with *P. excavata* in having the intestinal origin in XVI. However, confinement of multiplication of gizzards to a single zoogeographical province favours the view that multiplication is a rare apomorphy more likely to occur in closely related forms than in forms as distinct as *Oreoscolex*.

In view of the logical and computational ambivalence as to the position of *P. excavata* it is here considered that taxonomic convenience is best served by retaining this species in the monotypic genus *Perissogaster*. This has been redefined in the taxonomic section.

ACKNOWLEDGEMENTS

The author is grateful to Dr C.N. Smithers for providing new material of *P. excavata*. This work was made possible by Australian Biological Resources Study and Australian Research Council support.

ON THE ALLEGED OCCURRENCE OF THE EARLY CRETACEOUS AMMONITE *SIMBIRSKITES* IN QUEENSLAND

SIMON R.A. KELLY

Kelly, S.R.A. 1993 06 30: On the alleged occurrence of the Early Cretaceous ammonite *Simbirskites* in Queensland. *Memoirs of the Queensland Museum* 33(1): 245-251. Brisbane. ISSN 0079-8835.

The two ammonite specimens that comprise the Australian records of the Early Cretaceous genus *Simbirskites* are reassessed. Formerly described as *S. morvenae* Whitehouse, they are re-identified here as Late Jurassic, *Galbanites galbanus* Buckman and *G. fasciger* Buckman. The Australian specimens were supposedly from Queensland, but are believed here to be exotic, brought from England probably in the late nineteenth century. Their limestone lithology contrasts with the local clastic sediments. They closely resemble the form and lithology of specimens from the Portland Stone of England. Furthermore they are associated with gastropods, *Leptomaria rugata* (Benett), and bivalves including *Laevitrigonia damoniana* (de Loriol) and oysters which are also comparable to Portland Stone forms. Simbirskitids are typically boreal in their distribution, occurring in mid-Hauterivian to Early Barremian deposits in northern Europe, parts of the USSR and North America. Most other austral occurrences have been previously discounted. The geographically isolated Australian occurrence now should be deleted from the record. □ *Late Jurassic, Early Cretaceous, ammonite, bivalve, gastropod, Portland Stone, Simbirskites, Galbanites, England, Queensland, Australia.*

Simon R.A. Kelly, British Antarctic Survey, Natural Environment Research Council, High Cross, Madingley Rd, Cambridge CB3 OET, England; 21 August, 1992.

In the Queensland Museum type collection, I recognised a moderately large, English, Portland Stone ammonite in characteristic limestone preservation. On reading the label, I was surprised to discover that this was reputedly from the Queensland Early Cretaceous. A smaller ammonite and three large gastropod internal moulds have been artificially attached with cement to the umbilicus. The two ammonites were placed in *Simbirskites* (Whitehouse, 1926) without sighting the specimens (Bryan & Whitehouse, 1926). Whitehouse (1927) described the smaller, Queensland Museum (QM) F16438, as type of *S. morvenae* sp. nov.; the larger (QM F1270) was made paratype. The ammonites are re-identified here, the larger one as *Galbanites (Galbanites) galbanus* (Buckman), and the smaller one as *G.* (*G.*) *fasciger* (Buckman). The gastropods (QM F21078-21081) originally determined as *Leptomaria* (?) (Etheridge, 1909) are identified here as '*Leptomaria*' *rugata* (Benett). In the matrix, Whitehouse (1927) identified fragments of '*Ostrea*' and '*Trigonia*'. The oyster may be *Liostrea* sp.; other undetermined oysters, possibly exogyrids, grew on the interior of the body chamber of the larger ammonite shell. The trigoniid shows an early commarginal ribbed phase, followed by later somewhat irregular tuberculation typical of *Laevitrigonia damoniana* (De Loriol, 1875). '*Leptomaria*' *rugata, Liostrea,* exogyrids and *L. damoniana* are present in the English Portland Stone; the last is restricted to it and French stratigraphic equivalents. Stratigraphically, the youngest occurrences of *Laevitrigonia* s.s. are undescribed specimens in the Berriasian of the Russian Platform, and close to the Jurassic-Cretaceous boundary in the Cinder Beds of southern England (Kelly, 1988). It is unknown in the Hauterivian. However, it is well known in the Late Jurassic of northern and western Europe, and is particularly common in the Portlandian/Tithonian Portland Limestones of southern England.

The composite specimen was originally acquired from a Mr Hurst or Mr Hunter (Rozefelds et al., 1990) and was catalogued in the Queensland Museum as D7710.12 in 1893. The cited locality is 'Victoria Downs, Morven' where extensive outcrops of the marine, Aptian, Roma Series, are placed in the Doncaster Member of the Wallumbilla Formation (Exon, 1971). However, despite detailed geological survey work in the area, no further *Simbirskites*, nor specimens of similar lithology have been collected (Day, 1969: 152).

Etheridge (1909) originally compared the ammonites to *Perisphinctes kayseri* Neumayr & Uhlig (1881), now recognised as *Simbirskites*, which occurs in the *seeleyi* zone, Hauterivian, of north

Germany (Rawson, 1971). Whitehouse (1926, 1927) initially appeared to accept a Queensland provenance. Whitehouse (1946: 3) intimated that the ammonites were exotic, stating 'a little uneasiness is felt about the locality record' and that preservation of the specimens was like that of simbirskitids of north Germany which last remark is not supported here. Whitehouse (1954: 9 footnote) reiterated his belief of an extra Australian provenance. This remark was supported by Day (1969: 152). Lithologies of the large German simbirskitids figured by Neumayr & Uhlig are ironstones (Rawson, 1971), whereas most other German occurrences are from paralic sandstones or offshore clay facies. Sediments of the Wallumbilla Formation are predominantly sandstones with minor mudstones, but the specimens, supposedly from Morven, are preserved as internal moulds in a pale creamy brown limestone with much bioclastic debris. The preservation exactly matches that of parts of the English Portland Stone.

The Simbirskitinae is a boreal group of Olcostephanidae, one of the youngest in the once widespread Perisphinctoidea. It is characteristic of the mid-Hauterivian to earliest Barremian of northern England, northern Europe, the Russian Platform, Spitsbergen and North America (Rawson, 1971). Possible Late Valanginian forerunners occur in Arctic Canada (Jeletzky & Kemper, 1988).

The Australian record of *Simbirskites*, discounted here, has been widely quoted, (Wright in Moore, 1957). Other records of simbirskitids outside the normal geographical range for the group were reviewed by Rawson (1971). Mexican (Burckhardt, 1912) and Himalayan forms (Uhlig, 1910, were re-identified (*Grayiceras*) (Spath, 1924). Leanza (1958) described four species of *Simbirskites* from Argentina, but these appear to be *Rogersites*. Kilian & Piroutet (1905) recorded *Simbirskites* from New Caledonia, but the record remains unsubstantiated (Whitehouse, 1926).

SYSTEMATICS

Class CEPHALOPODA
Superfamily PERISPHINCTOIDEA
Steinmann, 1890
Family PERISPHINCTIDAE Steinmann, 1890
Subfamily DORSOPLANITINAE Arkell, 1950

Galbanites Buckman, 1922

Type species. Galbanites galbanus Buckman, 1922, Portland Stone, Haddenham, Buckinghamshire, England.

REMARKS

Arkell (in Moore, 1957) synonymized *Galbanites* and *Titanites* Buckman, 1921 but Wimbledon & Cope (1978) recognised *Galbanites* as distinct. The specimens described below as *Galbanites* have predominantly biplicate to triplicate ribbing, but lack the coarseness of the primaries which characterises *Galbanites* (*Kerberites*). The genus is widespread in the *okusensis* and *kerberus* Zones of southern England.

Galbanites (Galbanites) galbanus
Buckman, 1922 (Figs 1,2A,3)

1909 *Perisphinctes kayseri* Neumayr & Uhlig; Etheridge, p.239, pl.68 [larger specimen only; non Neumayr & Uhlig, 1881].
1922 *Galbanites galbanus* Buckman, pl.355, figs A,B,C.
1926 *Simbirskites* spp. Whitehouse, p.200 [larger specimen only].
1927 *Simbirskites morvenae* sp.nov. Whitehouse, p.111, paratype only [non pl.16, fig. 1; non text fig. 5].
1938 *Galbanites galbanus* Buckman; Roman, p.297.
1946 *Simbirskites*; Whitehouse, p.8.
1972 *Galbanites galbanus* Buckman; Clark, p.82.
1974 *Galbanites galbanus* Buckman; Wimbledon, p.146, pl. 18.
1978 *Galbanites galbanus* Buckman; Wimbledon & Cope, p. 184.
1990 *Simbirskites morvenae* Whitehouse; Rozefelds et. al, p.701.

MATERIAL EXAMINED

HOLOTYPE: British Geological Survey, GSM47155, Haddenham Micritic Member (Blue and Cream Bed, Creamy Limestone), Portland Stone, works north of the railway station, Haddenham, Buckinghamshire, England (Buckman, 1922)

OTHER MATERIAL: QM F1270, originally catalogued as D7710.12 in 1893 and stated to be from Victoria Downs, Morven, Queensland. Donated by Mr Hurst or Mr Hunter. The provenance is believed here to be from the English Portland Stone.

DIAGNOSIS

Evolute perisphinctid with coarse biplicate to triplicate ribbing, branching just below mid-flank (Fig. 1). Whorl section rounded (Fig. 2A). Ribbing gently arched forward to rectiradiate, with only weak forward swing over the venter. Shell

FIG. 1. *Galbanites* (*Galbanites*) *galbanus* Buckman, 1922. Lateral view of internal mould of QM F1270 (larger specimen), showing QM F16438 (smaller specimen, *G.* (*G.*) *fasciger* Buckman) artificially attached to the umbilicus, together with four internal moulds of gastropods, QM F21078-21081, '*Leptomaria*' *rugata* (Benett); ×0.5. (See also Figs 2,3 for further detail).

septate up to a diameter of 330mm. Body chamber outer two thirds whorl; aperture not seen; suture in Fig. 3. Maximum diameter 365mm; septate diameter 244mm; maximum whorl height 112mm, width 85mm; no. of ribs 55 primary, 133±2 secondary.

REMARKS

The holotype of *Simbirskites morvenae* Whitehouse differs from the holotype of *Galbanites galbanus* Buckman by its larger size, and tendency towards triplicate as well as biplicate secondary ribs. It differs from *G. fasciger* by having rounded flanks, as opposed to flat sided, and the absence of fasciculation. *G. galbanus* occurs in the later *okusensis* and early to middle *kerberus* zones of southern England (Wimbledon & Cope, 1978).

Galbanites (Galbanites) fasciger Buckman, 1923 (Fig. 1, centre; Fig. 2, B,C,D).

1909 *Perisphinctes kayseri* Neumayr & Uhlig; Etheridge, 239, pl.68 [small specimen only; non Neumayr & Uhlig, 1881].
1923 *Galbanites fasciger* nov. Buckman, pl.451.
1926 *Simbirskites* spp. Whitehouse, p.200 [small specimen only].
1927 *Simbirskites morvenae* sp.nov. Whitehouse, p.111, pl.16, fig. 1; text fig. 5 only.
1946 *Simbirskites;* Whitehouse, p.8.
1972 *Galbanites fasciger* Buckman; Clark, p.82.

FIG. 2. A, *Galbanites* (*Galbanites*) *galbanus* Buckman, 1922, ventral aspect of QM F1270, ×0.5; B-D, *Galbanites* (*Galbanites*) *fasciger* Buckman, 1924; B, left lateral view, QM F16438, ×1. (Holotype of *Simbirskites morvenae* Whitehouse, 1926): C, right lateral view of QM F16438, ×1; D, ventral view of QM F16438, ×1.

1974 *Galbanites fasciger,* Buckman; Wimbledon, p.72.
1990 *Simbirskites morvenae* Whitehouse; Rozefelds et. al, p.701.

MATERIAL EXAMINED

HOLOTYPE: British Geological Survey, GSM37302, formerly S. Buckman Collection 295556, purchased 1924, 'Lower Witchett', Creamy Limestone, Portland Beds, Barrel Hill, Long Crendon, Buckinghamshire, England.

OTHER MATERIAL: QM F16438, cemented to umbilicus of QM F1270, information as for *G. galbanus* above.

DIAGNOSIS

Moderately involute perisphinctid (Fig. 2 B,C), with flattened, ventrally converging sides (Fig. 2D). Ribs straight and prorsiradiate, fasciculate, branching in mid- to just above the mid-flank into usually three secondary ribs. Intercalatory secondary ribs also present.

MEASUREMENTS

Maximum diameter 65mm; septate diameter 37mm; maximum whorl height 26mm, width 21mm; no of ribs c.27 primary, about 75 secondary.

FIG. 3. *Galbanites* (*Galbanites*) *galbanus* Buckman, 1922, internal mould showing detail of suture, QM F1270. At left are moulds of '*Leptomaria*' *rugata* (Benett, 1831) artificially cemented to the umbilicus. ×1.

REMARKS

The specimen of *G. fasciger* differs from *G. galbanus* by being smaller, more involute, flatter sided and having fasciculate ribs. The ribbing is more regularly prorsiradiate. Wimbledon (1974: 72) believed that *G. fasciger* represented the inner/juvenile whorls of *Briarites polymeles* Buckman or a closely related species.

Class GASTROPODA
Family PLEUROTOMARIIDAE Swainson, 1844

Leptomaria Eudes-Deslongchamps, 1864

Type species. Pleurotomaria amoena Eudes-Deslongchamps, 1849, Bajocian, Middle Jurassic, France.

'Leptomaria' rugata (Benett, 1831)
(Figs 1, 3) (Fig. 1, centre; Fig. 3, left)

1831 *Trochus rugatus* Benett, p.6, pl.16, upper right.
1888 *Pleurotomaria rugata* Benett; Damon, pl.8, fig. 6.
1909 *Leptomaria* (?) sp.; Etheridge, p.239, pl.68.
1927 *Leptomaria* (?) sp.; Whitehouse, p.111.
1946 *Leptomaria* (?) sp.; Whitehouse, p.3.
1989 *Trochus rugatus* Benett; Spamer, Bogan & Torrens, p. 141 [q.v. for further synonymy].

MATERIAL EXAMINED

SYNTYPE: Original of Benett (1831: pl.16) upper right figure, Academy of Natural Science, Philadelphia, 65710 (B.C. 506), fide Spamer et al. (1989), Portland Beds, Tisbury, Wiltshire.

OTHER MATERIAL: Four specimens: QM F21078-21081, artificially cemented to the umbilicus of QM F1270.

REMARKS

The smooth internal moulds have the apices broken off, but would have had a blunt apical angle; there are traces of a weak shoulder. The preservation is typical of '*L.*' *rugata* in the Portland Beds of England.

CONCLUSIONS

The two ammonites, reported to be from the Early Cretaceous of Victoria Downs, Queensland, formerly attributed to Hauterivian *Simbirskites* (Whitehouse, 1926, 1927, 1946), are confirmed, along with associated bivalves and gastropods, as English, Late Jurassic, Portland Stone forms. *Galbanites* (*Galbanites*) *galbanus* and *G.* (*G.*) *fasciger* suggest Portlandian/Tithonian faunas 3/4, the *okusensis/kerberus* zones of Wimbledon & Cope (1978) and Cope et al. (1980). The Cockly Bed of the former Okus Quarry in Swindon, Wiltshire, is probably the most likely original site, but is not proven. The gastropod '*Leptomaria*' *rugata* and the bivalves, including *Laevitrigonia damoniana* and oysters associated with the ammonites are also common in the Cockly Bed. The record of *Simbirskites* from Australia should now be deleted. The provenance of other material of the Hurst/Hunter bequest should be treated with caution.

ACKNOWLEDGEMENTS

I thank Peter and Annette Jell for hospitality in Brisbane; J.C.W. Cope (University College of Wales, Cardiff), J.A. Crame, D.I.M. Macdonald, M.R.A. Thomson (British Antarctic Survey), R.W. Day (Geological Survey of Queensland) and P.F. Rawson (University of London) for discussions and comments on early draft typescripts; R.M. Owens and S. Howe (National Museum of Wales, Cardiff) for access to the W.A. Wimbledon collection of Portland Beds ammonites; Ron Cleevely (British Museum of Natural History) for advice on the generic allocation of the gastropods; H.C. Ivimey-Cook (British Geological Survey) for loan of types from the Buckman Collection; E.D. McKenzie (Queensland Museum) for data on the specimens; and the Photographic Department of the Queensland Museum for the photographs.

NEW INFORMATION ON THE AUSTRALIAN SMALL BITTACIDS (MECOPTERA)

KEVIN J. LAMBKIN

Lambkin, K.J. 1993 06 30: New information on the Australian small bittacids (Mecoptera). *Memoirs of the Queensland Museum* 33(1):253-257. Brisbane. ISSN 0079-8835.

The unrecorded male and additional females of the small and little known scorpion-fly *Symbittacus scitulus* Byers have been found at three north Queensland montane rainforest localities. The male terminalia are similar to those of *Edriobittacus* Byers. New localities for the other small Australian bittacids show that *Austrobittacus anomalus* Riek occurs in the coastal zone between Bundaberg and Rockhampton, *Tytthobittacus macalpinei* Smithers extends into south-east Queensland, and *Edriobittacus microcercus* (Gerstaecker) is widely distributed between Bundaberg and Cairns. □ *Mecoptera, Bittacidae, Edriobittacus, Tytthobittacus, Austrobittacus, scorpion-fly, rainforest, Queensland, new records.*

Kevin J. Lambkin, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; 6 November, 1992.

The Australian bittacid fauna comprises 6 genera. The monotypic *Austrobittacus* Riek, *Edriobittacus* Byers, *Symbittacus* Byers and *Tytthobittacus* Smithers are small and delicate forms, which have AA_{3+4} (=*1A* of other notations) of the hindwing much reduced. *Bittacus* Latreille (1 species) and *Harpobittacus* Gerstaecker (9 nominal species) are large and robust scorpionflies with AA_{3+4} of the hind wing well developed. Byers (1986) provided a key to all genera except *Bittacus*, which was differentiated by Lambkin (1988).

Symbittacus was erected by Byers (1986) for *S. scitulus* Byers, which was based on one female from rainforest of Bellenden-Ker Range, north Queensland. Since then, further collecting by G.B. Monteith and colleagues in montane rainforest south of Bellenden-Ker has brought to light a further five specimens, including the first male. An examination of the collections of the Australian National Insect Collection, Canberra (ANIC) has also revealed a female specimen from another north Queensland rainforest locality. Herein I record this new material and describe the male. As well, new diagnostic characters and new localities are given for *Austrobittacus*, *Edriobittacus* and *Tytthobittacus*. No new localities have been published for these taxa since their original descriptions or since Riek (1954). Full reference lists for each have recently been given by Smithers (1987) and are not repeated here.

All measurements are in millimetres. Other abbreviations used are as follows: ICZN, International Code of Zoological Nomenclature; KJL, author's collection (to be deposited in Queensland Museum); LFW, fore wing length; MV, Museum of Victoria, Melbourne; QM, Queensland Museum, Brisbane; UQ, The University of Queensland Insect Collection, Department of Entomology, University of Queensland.

Symbittacus scitulus Byers
(Figs 1A-C,2)

Symbittacus scitulus Byers, 1986, pp. 166-168, figs 1-6.

MATERIAL EXAMINED

QUEENSLAND: QM: 1♂,1♀ (both teneral), Cardwell Range, Upper Broadwater Ck valley, 700-800m, RF [rainforest], 17-21.xii.1986, 3♀♀, Kirrama Range, Douglas Ck road, 800m, 9-12.xii.1986, all G.Monteith, G.Thompson and S.Hamlet. ANIC: 1♀, Davies Ck, 20km E by S Mareeba, 20.xi.1981, D.H.Colless, Malaise trap.

LFW

♂ 14.9, ♀♀ 14.1-14.6 (holotype recorded by Byers (1986) as 14.1).

MALE TERMINALIA (Fig.1A-C)

Epiandrium short, plate-like, articulated on the anterodorsal corners of sternum 9; in lateral view (Fig.1A) narrow, arched dorsally at c.⅔ length; in dorsal view (Fig.1B) posterior margin broadly incised to c.⅔ length, resultant lobate paired lateral regions each with 5 short black spines medioapically. Posterior margin of sternum 9 with a few long setae dorsally. Basistyles completely fused medially; in lateral view ventroposterior margin evenly curved; dististyle-bearing lobes strongly produced. Dististyle (Fig.1C) small and simple, with strongly sclerotised glabrous apical knob; distinct 'stylocavernula' (Tjeder 1970) basally. Aedeagus of moderate length, recurved, without a terminal

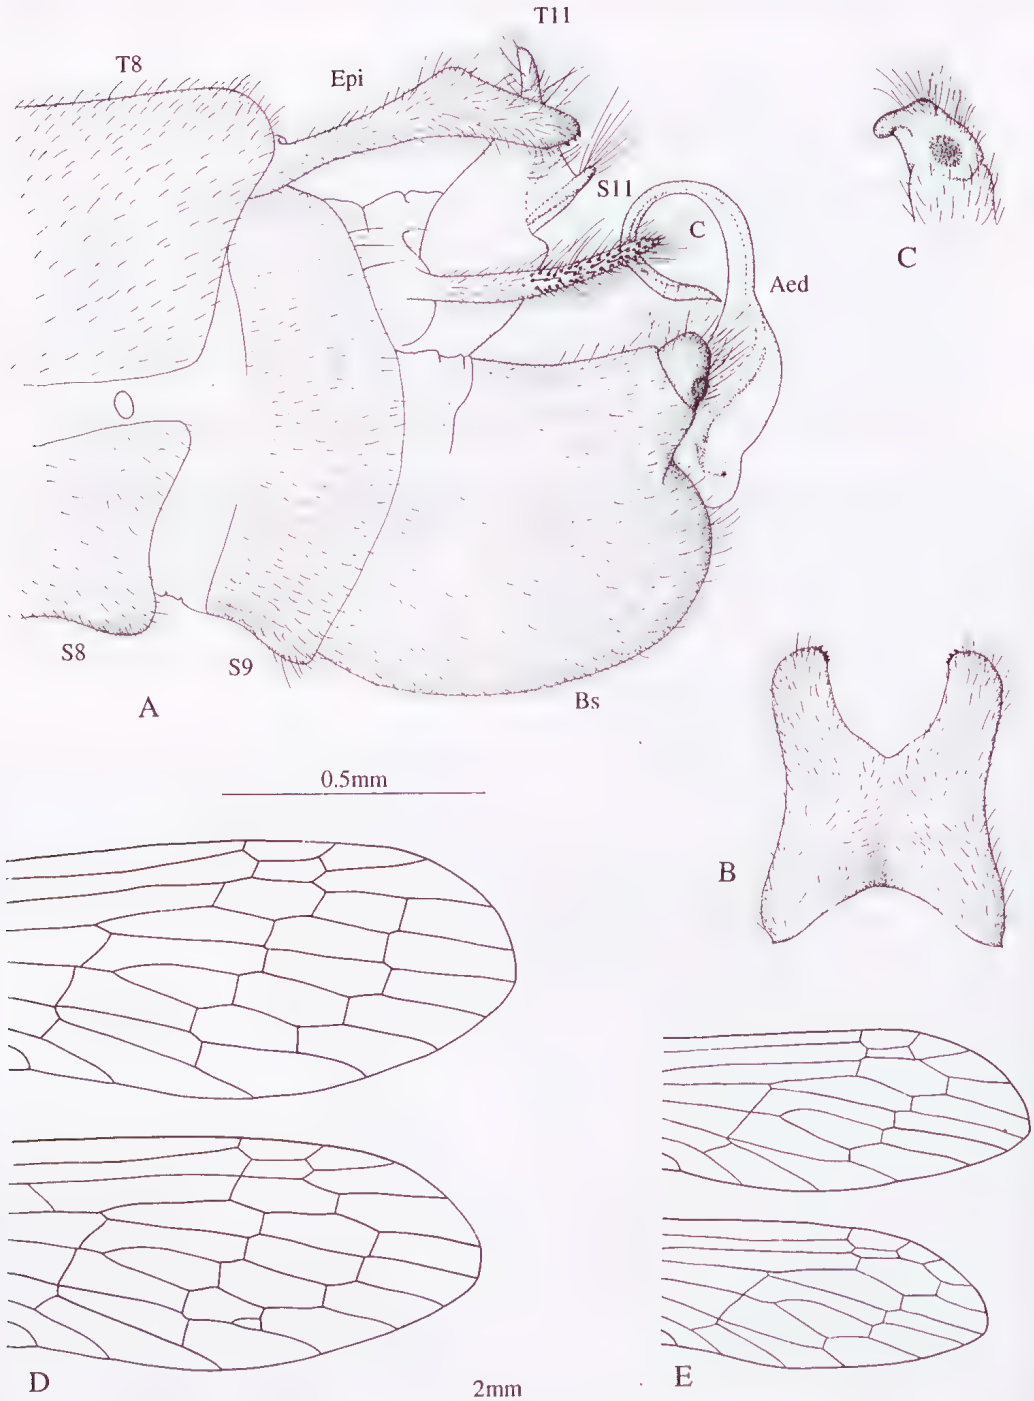

FIG. 1. A-C (0.5mm scale line). *Symbittacus scitulus*, male: A, apex of abdomen, left lateral; B, epiandrium dorsal; C, right dististyle, posteroventral (darker circular area is the 'stylocavernula'). D,E (2mm scale line Distal regions of right fore and hind wings (venation only shown): D, *Edriobittacus microcercus*; E, *Tytthobi tacus macalpinei*. Abbreviations: Aed, aedeagus; Bs, basistyles; C, cercus; Epi, epiandrium; S8,9,11, stern 8,9,11; T8,11, terga 8,11.

filamentous extension. Tergum 10 not detected (specimen teneral). Cercus elongate, reaching to level of dististyle; broadest at c.½ length, then tapering distally. Tergum 11 elongate, in posterior perpendicular view tapering to an acute apex. Sternum 11 much shorter than tergum 11, with apical margin truncate.

REMARKS

The new material compares well with Byers' (1986) description, but 2 minor variances can be noted. Byers recorded the ocelli as of uniform diameter. In all the new material (and, on re-examination, in the holotype as well) the lateral ocelli are slightly larger than the medial one. The number of thick black setae on each side of the 4th hind tarsomere, recorded as 1 by Byers, is variable. The holotype and one of the Kirrama females (both with fore wings 14.1 long) have 1 or 2, whereas the other specimens (which are larger) have 2. Unfortunately the male is teneral and not well preserved, but its non-genitalic structural features are similar to those of the female.

The male terminalia of *S. scitulus* are similar to those of *Edriobittacus microcercus* (Gerstaecker) (Byers, 1974, figs 1-3). The latter differ, however, in the following: 1, the epiandrium in lateral view is arched before midlength (at c.⅔ length in *Symbittacus*), and more strongly so than in *Symbittacus*; in dorsal view it is much more deeply incised than in *Symbittacus*; 2, the aedeagus is longer; 3, there are numerous (rather than a few as in *Symbittacus*) long setae on the posterior margin of sternum 9; 4, tergum 11 is short with the apical margin truncate (elongate with apex acute in *Symbittacus*).

Symbittacus scitulus is a rainforest scorpionfly. It has only been taken at elevations of 700-800m. The specimens from Cardwell and Kirrama Ranges were collected at night while at rest on the foliage of understorey vegetation along tracks through rainforest (G.B. Monteith, pers. comm.).

Austrobittacus anomalus Riek
(Fig. 2)

Austrobittacus anomalus Riek, 1954, p.157, figs 3,4, pl.1, fig.6.

MATERIAL EXAMINED

QUEENSLAND: ANIC: holotype ♂, allotype ♀, 1 without abdomen, 4♂♂ and 10♀♀ paratypes, Rockhampton, 23.iii.1950, 1♀ paratype, Olsen's Caves, 13 miles N Rockhampton, 25.iii.1950, all I.F.B.Common; 1♂, 3♀♀, Pine Ck, 12 miles S Bundaberg, 12.iii.1976, 14.iv.1976, 1♂, Monduran Dam, 20km N Gin Gin, 2.ii.1974, all H.Frauca. KJL: 5♂♂, 6♀♀, Bruce Highway, Rosedale turnoff, 10km NW Gin Gin, 4♂♂, 6♀♀, near 'Wakelin', 20km NNW Gin Gin, all 20.iv.1985, K.J. and C.L.Lambkin.

LFW

♂♂ 14.0-15.3, ♀♀ 13.8-14.6 (Riek (1954) recorded 15.0 for the species).

REMARKS

Riek (1954) did not explicitly state which specimens were the holotype, allotype or paratypes. The holotype and allotype are labelled as such, but none of Riek's other specimens are labelled as paratypes. Riek did not, however, expressly exclude any of his specimens from the

FIG. 2. Distribution of *Symbittacus scitulus* and *Austrobittacus anomalus*.

type series (see ICZN Article 72(b)(i)), and I believe that there is sufficient evidence (see ICZN Recommendation 72B) to regard the 16 specimens listed above as paratypes (viz the collection data match those given by Riek, and the Olsen's Caves specimen matches that illustrated by Riek (1954, pl.1, fig.6) and stated to be a paratype in the figure caption).

This species is easily distinguished by the longitudinal form of the free apical portion of AA_{3+4} in the hind wing (Byers, 1991, fig.37.6C). The lateral ocelli are slightly larger than the medial one. The number of thick black setae on each side of the 4th hind tarsomere, recorded by Byers (1974) as 4-5, ranges from 2 to 7 and can vary from side to side in the same specimen.

All specimens have been taken in late summer or autumn. The Rosedale turnoff and Wakelin specimens were collected in the grass understorey of eucalypt woodland in company with *Edriobittacus microcercus* (at Wakelin only) and *Harpobittacus scheibeli* Esben-Petersen.

Material Examined

Queensland: ANIC: 1♂, 12 miles E Duaringa, 18.iii.1958, 4♂♂, 1♀, 25 miles N Gin Gin, 16(1♂) and 23.iii.1958, 2♂♂, 1♀, Hedlow Ck, nr Yeppoon, 22.iii.1958, all I.F.B.Common; 1♀, Ingham, 29.iii.1961, K.L.S.Harley; 1♂, Mackay, 17.v.1969, [G.F.] Bornemissza, 'flew to light'; 1♀, 63 miles N Marlborough, 9.v.1955, K.R.Norris; 1♂, Olsen's Caves, 13 miles N Rockhampton, 25.iii.1950, I.F.B.Common; 1♂, Palm Grove [?Cove], nr Cairns, June 1969, R.Hardie; 1 without abdomen, Pine Ck, 12 miles S Bundaberg, 12.iii.1976, 1♀, Pinock R, Hogback Range, WSW Bundaberg, via Gin Gin, 11.iii.1972, all H.Frauca; 1♀, 7 miles NNE Ravenshoe, 3300', 22.iv.1969, I.F.B.Common and M.Upton; 1 without abdomen, Rockhampton; 1♂, The Caves, 16 miles N Rockhampton, 3.iv.1967, M.S.Upton. KJL: 1♂, near 'Wakelin', 20 km NNW Gin Gin, 20.iv.1985, K.J. and C.L.Lambkin. UQ: 1♀, Walkamin, Atherton Tableland, August 1967, P.H.Twine. MV: 3♂♂, 3♀♀, 1 without abdomen, 'Queensland'.

LFW

♂♂ 16.3-19.7 (holotype recorded by Esben-Petersen (1921) as 18.0), ♀♀ 17.1-19.5

Remarks

Both sexes have the lateral ocelli much larger than the medial one (noted in the male only by Byers, 1974), and the number of thick black setae on each side of the 4th hind tarsomere, recorded by Byers (1974) as 3, ranges from 2 to 5.

The holotype was from Peak Downs. The only other previous records are those of Riek (1954): the Olsen's Caves specimen in the ANIC, and the series labelled 'Queensland' in the MV. All specimens have been taken from March to August.

Tytthobittacus macalpinei Smithers
(Figs 1E,3)

Tytthobittacus macalpinei Smithers, 1973, p.300, figs 9-11.

MATERIAL EXAMINED

NEW SOUTH WALES: KJL: 1♂, Terania Ck, 22.i.1986, L.Müller and G.Theischinger. QUEENSLAND: UQ (all in poor condition): 1♂, 1♀, Brisbane, 8.x.1959, F.Lamberth, 9.x.1966, E.Rainey; 1♀, Kenilworth State Forest, 5.xii.1966, G.B.Monteith, 'sweeping ferns in rainforest'; 1♂, Mt Coot-tha, Brisbane, 26.ix.1959, A.J.Jackson.

LFW

Terania Ck ♂13.3 (Smithers, 1973, recorded 14.0 for the species).

REMARKS

T. macalpinei is very similar in wing venation to *E. microcercus*. Further to Byers (1986), it can be distinguished by its smaller size (LFW c.13.0-14.0, vs at least 16.3 in *E. microcercus*) and two series of crossveins in the distal region of both wings (Fig. 1E) compared to three in *E. microcercus* (Fig. 1D). The latter character is particularly useful in identifying faded or teneral females, which Byers' key will not separate. The lateral ocelli are slightly larger than the medial one and there are 1-3 thick black setae on each side of the 4th hind tarsomere.

Smithers' (1973) material was all from New South Wales: Huonbrook, Mooney Mooney Creek, Mt Wilson and Wentworth Falls. The Terania Creek and Kenilworth specimens were both taken in rainforest, the former in flight along a creek bed (G. Theischinger, pers. comm.) and the latter swept from ferns. The records from Brisbane and Mt Coot-tha, not obvious rainforest localities, are based on student collections and could be doubtful. All specimens have been taken from September to March.

ACKNOWLEDGEMENTS

I appreciate the cooperation of Josephine Cardale (ANIC), Ken Walker (MV) and Margaret Schneider (UQ) in making available specimens under their care. Christine Lambkin drew Fig. 1A-C for which I am very grateful.

MIDDLE TRIASSIC ORTHOPTEROID (TITANOPTERA) INSECT FROM THE ESK FORMATION AT LAKE WIVENHOE. *Memoirs of the Queensland Museum 33(1): 258. 1993:-* This large insect wing was collected from plant fossil-rich siltstone in an old road cutting near 5 Mile Creek on the western shore of Lake Wivenhoe (GR523792 on Caboolture 1:100000 topographical sheet No.9443 (1972)), approximately halfway between the dam wall and Esk, by Leon Steinhardt in 1991. These siltstones of the Esk Formation contain a typical *Dicroidium* megaflora and an early Middle Triassic (Anisian) palynoflora (deJersey, 1972).

It is the first insect from this formation and first Queensland record of the Titanoptera; *Clatrotitan* McKeown,1937 (see Riek,1954) from the Middle Triassic of Brookvale, NSW is the only other Australian record.

The shape does not match other members of the order and this is thought to be due to preservation. A piece of fern stem, adjacent to the rear margin in the Cu and A regions, could have snagged the wing floating on a few millimetres of water. If the wind direction was from the anterior of the wing this may have swung the distal third of the wing retrally, giving the unusual shape to the anterior margin and could have crumpled the anterior marginal areas.

Order TITANOPTERA Sharov,1968

The new wing conforms in most respects with Kukalová-Peck's (1991) ground plan for this order: M with a long stem, adjacent to R; Cu not stemmed, CuA adjacent to M basally, diverging before M divides, then connected to CuP1+2 by a strut; CuP deeply forked; AA2 simple. It is, however, in the form of MA, MP, CuA, CuP1+2 and CuP3+4, very different from known species and probably represents a new family.

Because the veins are directed towards the hind rather than apical margin and RP occupies a relatively large area, it is considered a hindwing.

Steinhardtia gen.nov.

Type species. Steinhardtia maryae sp. nov.

Diagnosis. Large wing (>40mm long); primary R fork well beyond that of M; RA, RP, MA, MP, CuA, CuP1+2 and CuP3+4 all deeply dichotomously forked; RA with 4 major branches, RP with 6, MA with 8, MP with 2, CuA with 4, CuP1+2 with 3 and CuP3+4 with 5; strut from CuA to CuP1 rather than CuP1+2; first branch of AA3+4 apparently dichotomous; cellular network between veins absent or not preserved.

Remarks. In the hindwings of other genera (Sharov, 1968) the primary R fork is closer to that of M, RP is usually pectinate, and MA. MP, CuA, CuP1+2 and CuP3+4 are simple for most or all of their lengths, and when forked have few branches.

Steinhardtia maryae sp.nov. (Fig.1)

Etymology. For the collector's wife, Mary.

Material. Holotype Queensland Museum F25507a and b.

Description. Incom plete hindwing, 40 × 10mm max dimensions, basal : nd fore marginal areas not preserved. Crossveins between RA and RP, and CuP1+2 and CuP3+4 as illustrated.

Remarks. The wing has been flattened so there is no convexity to any vein and this has probably obliterated any cellular venation between the main veins.

FREQUENCY OF OBSERVATION OF BIRD SPECIES IN SUB-COASTAL FARMLAND IN SOUTHEAST QUEENSLAND

G.J. LEACH AND H.B. HINES

Leach, G.J. & Hines, H.B. 1993 06 30: Frequency of observation of bird species in sub-coastal farmland in southeast Queensland. *Memoirs of the Queensland Museum* 33(1): 259-275. Brisbane. ISSN 0079-8835.

A farming district in southeast Queensland was surveyed from June 1980 to May 1985 to determine presence of bird species. Softwood scrub was the predominant vegetation before European settlement, but now occurs only in isolated remnant patches. Standard surveys were conducted on 20 days, one per season per year, and other surveys on another 100 days. The district supports a diverse and abundant avifauna: 44 waterbird, 60 non-passerine landbird and 88 passerine species.

Nearly 40% of waterbird and passerine species observed in standard surveys were observed in over 80% of them, but only 21% of non-passerine landbird species. In contrast, 45% of the latter species were observed on 20% or fewer visits, compared with 25% of the waterbird and passerine species. Frequency of several waterbird species was minimum in the wettest year, following widespread drought in southeast Australia.

Thirty species had large differences in mean seasonal frequency; some were summer or winter visitors. Approximate dates of presence are given. Rose Robin, Grey Fantail and Yellow-faced Honeyeater were present during well-defined winter periods, while Rufous Fantail and several other species were summer visitors. Scarlet Honeyeater and Spotted Pardalote were passage migrants.

The combination of standard and other surveys generated a robust database against which changes in relative abundance can, and should, be monitored to guide management. While an effective habitat mosaic remains for passerines and waterbirds, it appears less suitable for non-passerine landbirds other than doves and parrots which can be commensal with farming. Retention and better management of native woody vegetation may be essential to forestall decline in the avifauna with more intensive settlement. ☐ *Bird, farmland, habitat, remnant vegetation, seasonal movement, management.*

G.J. Leach, PO Box 568, Kenmore, Queensland 4069, Australia; H.B. Hines, 42 Pangeza Street, Stafford Heights, Queensland 4053, Australia; *21 April, 1992.*

Since European settlement, the vegetation of Australia has been progressively cleared and modified. This has led to decreases and actual losses of fauna and flora (Saunders, 1989; Hobbs & Hopkins, 1990; Recher & Lim, 1990; Saunders & Curry, 1990). Despite these changes, agricultural landscapes may be significant wildlife habitats (Breckwoldt, 1983, 1986; Saunders et al., 1987). Remnant vegetation along roadsides, for example, is used by many species of birds (Arnold & Weeldenburg, 1990; Cale, 1990; Saunders & de Rebeira, 1991; Leach & Recher, 1993).

Various workers have reported census data from avian communities in relatively undisturbed forest, woodland and heathland (e.g. Kikkawa, 1982; Pyke, 1983, 1988; Recher et al., 1985; Ford et al., 1985; Gosper, 1992; see also Keast et al., 1985; Ford, 1989). By contrast, information from highly modified landscapes is often anecdotal (e.g. Barnard, 1925; Lord, 1956) and comparisons of historical and present day abundances based on 'reporting rates' (Blakers et al., 1984) are insufficient for the needs of management because the data are compiled at too coarse a scale (Ford, 1989).

In this paper, we report five years of census data from the Marburg district, a subcoastal farming area of southeast Queensland. The district includes a diverse mosaic of habitats and is rich in bird species (Leach & Hines, 1987). The data concern (1) the relative abundances of bird species and (2) seasonal changes in their abundances. They provide a baseline that will permit assessment of future changes in the avifauna as land management practices alter or intensify.

English names for birds follow those of R.A.O.U. (1978).

STUDY AREA AND METHODS

The survey area

The survey area was the 10′ grid square centred on 27°35′S, 152°35′E (Fig 1a). Marburg is near the centre and Rosewood, with a population of

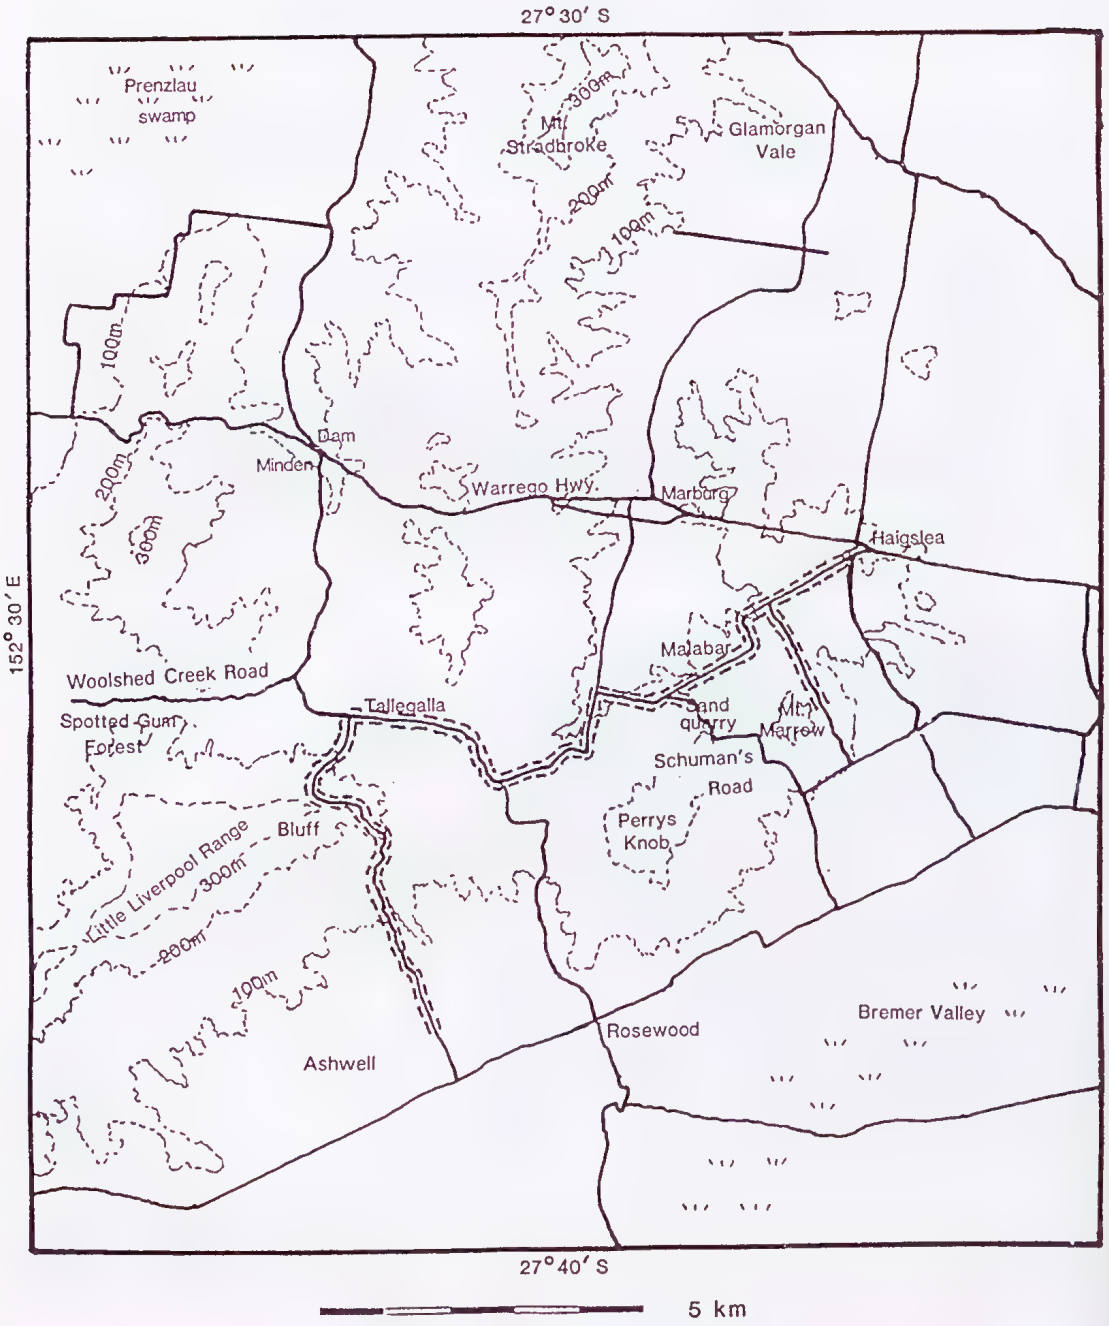

FIG. 1. The Marburg district showing (this page) the standard survey route (⁻⁻⁻), physiography and other features mentioned in the text and (next page) remnants of forest and woodland vegetation in the area of the grid square within Moreton Shire (after Young, 1985, courtesy of P.A. Young and Moreton Shire Council). An equivalent map is not available for the area beyond the shire boundary (the heavy line in the north-west) but distribution of vegetation remnants through the landscape, excluding the ephemeral swamp at Prenzlau, is not markedly dissimilar. Note that the widespread narrow galleries of vegetation along roadsides and fencelines are not shown.

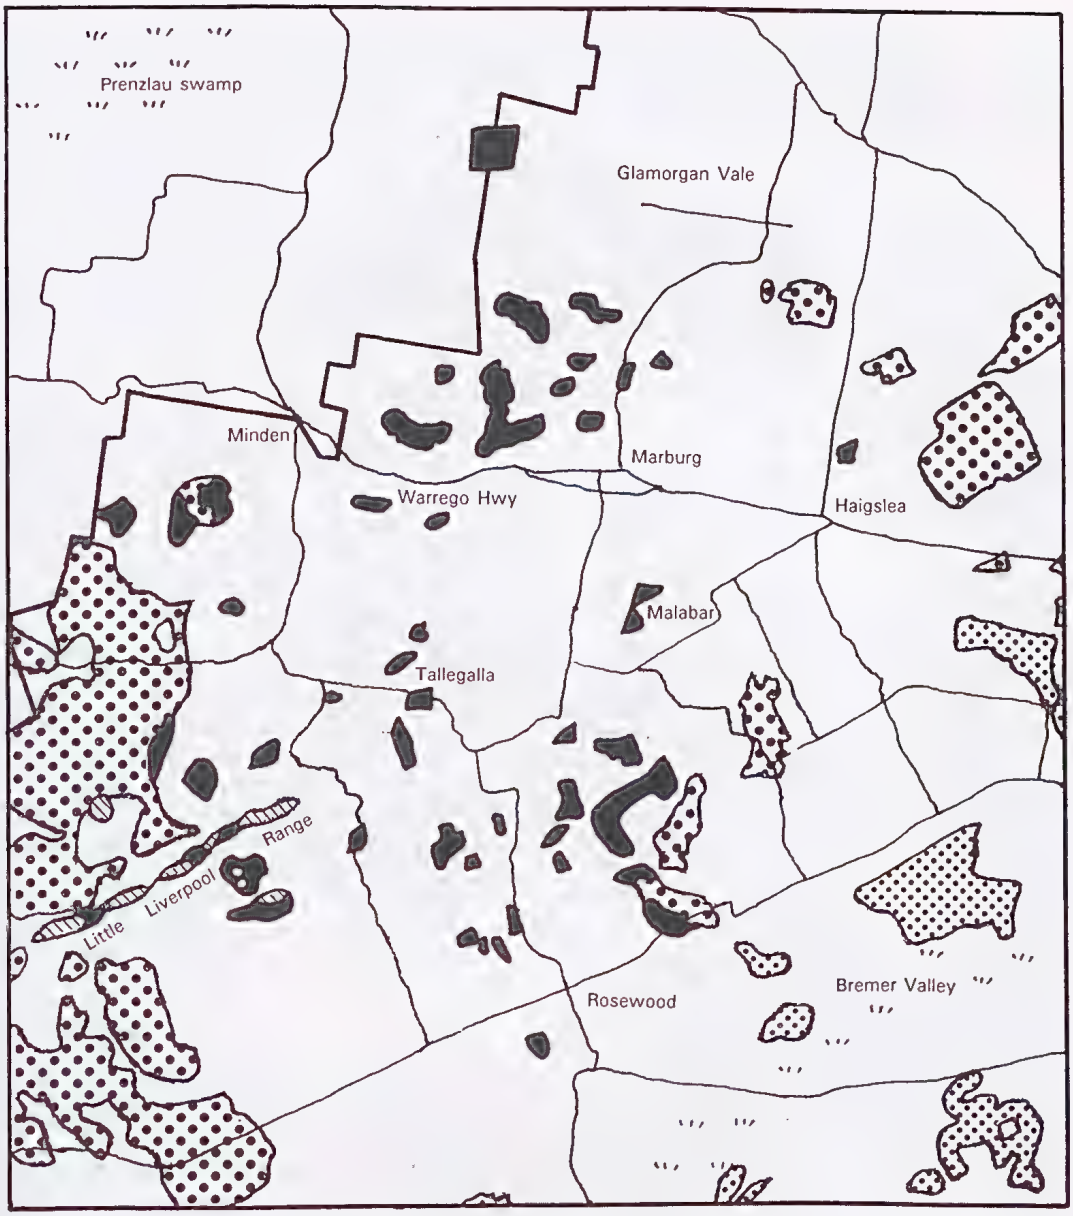

Brigalow-softwood closed-forest.

Softwood-Hoop Pine (*Araucaria cunninghamii*) closed forest.

Eucalypt open-forest (Spotted gum, ironbarks; Gum-topped Box, *E. moluccana*, northeast of Haigslea).

Eucalypt woodland (Blue Gum, *E. tereticornis*, and ironbarks).

TABLE 1. Mean seasonal frequency (MSF) in standard surveys, and mean annual frequency (MAF) in standard surveys and other surveys, for waterbird species. Species are tabulated in descending order of MAF first in the standard surveys and subsidiarily in other surveys. Seasons are: Wi, winter; Sp, spring; Su, summer; Au, autumn. Range, the difference between maximum and minimum annual frequency. Years, the number of years, in parentheses, in which species were observed.

Species	Standard surveys							Other surveys

1657, is the main town. Physiography, vegetation and land use are described by Leach & Hines (1987). The landscape, of low hills (max elevation: 396m) and broad valleys, has been substantially cleared for agriculture, other rural use and residential occupation. There are creeks that flow intermittently, small swamps and numerous farm dams.

Fertile prairie soils and grey cracking clays are common. In the past they supported low closed-forest and brigalow (*Acacia harpophylla*)-softwood closed-forest which covered about half the survey area (Anonymous, 1974; Young, 1985; Hass, 1987; Young & McDonald, 1987; Elsol, 1991). We describe these two vegetation types as softwood scrub; remnants are now patchily distributed and occupy less than 4% of the area (Fig. 1b). Many of the remnants are substantially disturbed. Thin solodic soils on some low hilly terrain support open eucalypt forest (Spotted Gum, *Eucalyptus maculata*, and the ironbarks *E. crebra* and *E. melanophloia* are common); these associations now cover about 9% of the district.

WEATHER

Weather records for Lawes, 15km west of the survey area, show a mean annual rainfall of 780±183mm (83 years) with 70% falling in October through March (Cook & Russell, 1983; Willcocks & Young, 1991). Mean monthly maximum temperatures range from 20.3°C in July to 31.0°C in December, and mean monthly minimum temperatures from 5.6°C in July to 19.1°C in February. On average, light frosts (screen minimum 0.1 to 2.2°C) occur on 12.5 days and heavy frosts (screen minimum 0.0°C or lower) on 2.3 days per year.

Between 1980 and 1985 annual rainfall (June through May) ranged from 697mm to 951mm. Seasonal variability was high with 23mm in June through August 1982 and 419mm in December through February 1981-82. In most seasons rainfall was near or below average but in March through May 1983, and June through August 1983 and 1984, rainfall exceeded the average by over 50% (Leach & Hines, 1992). Mean maximum monthly temperatures were >1°C above average from August through November 1980, in February and March 1983, in December 1984 and in January 1985 and were >1°C below average from September through November 1984. Minimum temperatures were >1°C above average from November 1981 through January 1982 and from May through October 1983 and were >1°C below average in June and July 1982. From June through August there were 17 light, and five severe, frosts in 1982, 11 light frosts in 1981, six in 1980 but only two in both 1983 and 1984.

SURVEY PROCEDURES

From June 1980 through May 1985 we surveyed birds along a standard route once each season (20 standard surveys). (Seasons are as follows: winter, June through August; spring, September through November; summer, December through February; autumn, March through May). The 20km route, from Haigslea to Ashwell (Fig 1a), was traversed between 0730 and 1200h. At eight sites foot surveys of 10 to 45 minutes were conducted (Appendix 1); additional observations were made during the 5 to 15 minute periods driving between sites. Mid-afternoon surveys of Minden Dam and its surrounds (Fig. 1a) were included in the standard survey. Surveys were conducted by two to four observers who listed all species of bird seen or heard. The main habitats sampled were open farmland (predominantly pasture with isolated acacia and other trees), degraded softwood scrub remnants, woody weeds along roadsides and fencelines, and farm dams.

In addition to the 20 standard surveys, the Marburg district was visited on another 100 days, usually between about 0700h and 1600h. Surveys conducted on these days are referred to as 'other surveys' though some wholly or partly overlapped the route of standard surveys. There were 18 visits in both winter and summer periods, 32 in both spring and autumn periods, and between 17 and 26 each year. Most observations were made while walking or driving slowly along secondary roads and bush tracks. G.J.L. was on all surveys and was usually accompanied by one or more experienced observers. Appendix 2 lists the principal areas visited, the frequency of visits and the main habitats represented. These surveys differed from the standard surveys in that eucalypt associations were often traversed.

DATA COLLATION

The likelihood that a species was present in the survey area was estimated for each species as: (number of visits on which the species was observed)/(total number of visits). Values were calculated for each season of each year (seasonal frequency) and for each year (annual frequency). Mean Seasonal Frequency (MSF) and Mean Annual Frequency (MAF) were derived from the five years of observations. Data from the standard surveys and from the other surveys are treated separately. Species with MAF>0.2 in the standard surveys are referred to as *principal* species. The difference between maximum and minimum annual frequency is used as a measure of variation across years. It is more useful than standard error, especially when means are based on observations from only one or two years.

In this report, waterbirds include all species of Podicipedidae, Pelecanidae, Anhingidae, Phalacrocoracidae, Ardeidae, Ciconidae, Plataleidae, Anatidae, Rallidae, Jacanidae, Rostratulidae, Charadriidae, Recurvirostridae, Scolopacidae and Laridae. Other non-passerines are referred to as non-passerine landbirds.

RESULTS

SPECIES OBSERVED

One hundred and thirty one species were observed in the standard surveys and 190 in other surveys (Tables 1-3). All species observed in the standard surveys, except Rose-crowned Fruit-Dove and Forest Kingfisher, were also observed in the other surveys. Thus, the total number of

species observed was 192. Tables 1, 2 & 3 separate observations for, respectively, waterbirds (44 species, 32 in standard surveys), non-passerine landbirds (60, 38) and passerines (88, 61). In each table species are ranked in descending order of MAF.

Seventy-seven species (41%, 30% and 47% of waterbirds, non-passerine landbirds and passerines, respectively) were observed every year in the standard surveys and 112 species (64%, 38% and 69%) in other surveys. Ninety-one species (55%, 35% and 52%) qualified as *principal* species.

Variation in Annual Frequency of Observation of Species

All species are classed according to variation in annual frequency in Table 4. In standard surveys, variation in frequency across years was low for 80 species (48 principal species). Variation was also low for 52 of these species (32 principal species) in the other surveys. In contrast, annual variation for Glossy Ibis, Yellow-billed Spoonbill, Hardhead, Black-winged Stilt, White-throated Gerygone, Zebra Finch and Pied Currawong was high in the other surveys. Seventeen species had high variation in annual frequency in standard surveys, but only Comb-crested Jacana and Common Myna were as variable in the other surveys. Most species that occurred only in the other surveys had low variation in annual frequency.

Variation in annual frequency among waterbirds, especially the shoreline species, was largely attributable to low frequencies in 1983-84.

In the standard surveys, annual frequencies of Pacific Heron decreased through the survey period ($P<0.05$) while those of Brown Quail increased ($P<0.05$). No consistent trends were detected across years for any other species observed in standard surveys. In other surveys, annual frequencies of eight species increased significantly through the survey period ($P<0.05$). However, the frequencies for Plumed Whistling-Duck, Grey Shrike-thrush, Weebill, White-throated Gerygone, Buff-rumped Thornbill, White-throated Honeyeater and Pied Currawong were also related to annual variation in the frequency of visits to eucalypt forest at Tallegalla, while that for Common Myna was related to frequency of visits to both Woolshed Creek Road and Prenzlau Swamp.

Because most species (131, 68%) showed little variation in frequency between years, and much of the variation for the remainder was correlated with the frequency of visits to specific habitats in different years, subsequent sections are concerned only with MAF and MSF values over the five years.

Mean Annual Frequency (MAF)

In standard surveys, 75% of waterbird and passerine species, but only 55% of non-passerine landbird species, were principal species (Tables 1-3). More of the waterbird (38%) and passerine species (39%) than of the non-passerine landbird species (21%) were among the birds observed most regularly, i.e. in over 80% of surveys.

In the other surveys, 57, 40 and 64% of waterbird, non-passerine landbird and passerine species, respectively, were observed in over 20% of surveys; 16 to 20% of the species in these three categories were observed in over 80% of surveys.

For most species, MAF was similar in standard and other surveys. All species with high MAF (>0.8) in standard surveys had an MAF of at least 0.5 in other surveys. Among species with intermediate MAF (0.21 to 0.80) in standard surveys, MAF in other surveys for Laughing Kookaburra, Grey Shrike-thrush, Speckled Warbler and Varied Triller was substantially greater (>0.2 units) and that for Royal Spoonbill, Black-fronted Plover, Fairy Martin, Richard's Pipit, Red-backed Fairy-wren, Chestnut-breasted Mannikin, Tawny Grassbird and Singing Bushlark was substantially lower. Fan-tailed Cuckoo, Leaden Flycatcher, White-throated Gerygone and Pied Currawong, with low MAF (0.1 or less) in standard surveys, had MAF substantially greater in other surveys. Little Lorikeet and seven passerines that were absent from standard surveys had intermediate MAF in other surveys.

No specific family, or guild, of waterbirds was consistently observed at either high or low MAF. Among non-passerine landbirds, ground feeding pigeons and doves, including two introduced species, had high MAF, contrasting with fruit-doves which were seldom observed. Several raptors also had low MAF, but in contrast the Australian Kestrel was always observed. Among passerines, several small species (e.g. Superb Fairy-wren, Yellow Thornbill and White-browed Scrubwren) had high MAF as did the much larger, and conspicuous, Australian Magpie and Torresian Crow.

Mean Seasonal Frequency (MSF)

Twenty-six species were observed in standard surveys in all seasons of all years and another 27

TABLE 3. Mean seasonal frequency (MSF) in standard surveys, and mean annual frequency (MAF) in standard surveys and other surveys, for passerine species. Species order and abbreviations are as in Table 1.

in all seasons of at least three years (i.e. MSF of 0.6 or higher). MSF values for another 25 species observed in standard surveys varied from lows of 0.0 or 0.2 to highs of 0.6 or 0.8, respectively, or higher; for eight of them minimum MSF on other surveys were always intermediate (>0.2) and, thus, only 17 species showed clear differences in seasonal presence. Another 11 species that were either missing from standard surveys, or observed at low MAF (0.2 or less) on those surveys, had minimum MSF<0.2 and a range >0.3 in other surveys, indicating that they also differed in seasonal presence. MSF in other surveys for Darter (range 0.0 to 0.28) and Black- faced Monarch (0.0 to 0.22) were consistent with those in standard surveys, confirming the small differences in seasonal presence. Approximate dates on which these 30 species with clear differences in MSF were present are shown in Fig. 2.

DISCUSSION

The Value of Information on Frequency of Observation

Knowledge of ways in which abundance of bird species is influenced by land use is essential to wildlife management. For a limited range of habitats, e.g. commercial forests, this can be readily obtained in structured, systematic surveys. Such surveys have not been done over farming landscapes, and management decisions depend substantially on opportunistic information.

The standard survey adequately monitored changes in abundance of individual species within seasons, but inferences on the relative abundance of different species, and of individual species between seasons, need to take account of differences in detectability (Emlen, 1971; Davies, 1984; Recher, 1988). Estimates of abundance also need to be based on several years of survey (Rice et al., 1983). The variable climate in Australia, particularly in southeast Queensland, makes this even more important. However, variation in frequency between years for most species in the Marburg district was low. The major exceptions were waterbirds that move nomadically in response to inland rainfall (Gosper et al., 1983; Woodall, 1985), and it is generally more useful to relate their frequency of occurrence to proximate causal factors than to determine unadjusted long-term mean frequencies. The wide variation in annual frequency for some land birds was associated with proportion of visits to a eucalypt association, reflecting restricted use of habitat in the district and the limitations of the other surveys.

Notwithstanding the preceding comments, the combination of seasonally balanced standard surveys with a larger number of other surveys pro-

vides adequate baseline information on seasonal and annual frequency of species for habitat management. The standard surveys are repeatable, and continue, enabling long-term changes to be monitored and compared with similar information from elsewhere (e.g. the Australian Bird Count; Ambrose, 1989). Although it would be impracticable to precisely repeat the other surveys, their number and broadly specified representation of habitats ensures a useful baseline to which changes can be related.

Frequency of Observation of Species

Waterbirds. Most of the principal waterbirds observed in the Marburg district (Table 1) are widely distributed in Australia, with 17 species occurring in over 40% of 1°grid squares (Blakers et al., 1984). Those with more restricted distribution include Cattle Egret, Intermediate Egret, Plumed Whistling-Duck, Dusky Moorhen, Purple Swamphen and Latham's Snipe. In contrast, some widespread species such as Australian Pelican, Great Cormorant and Pied Cormorant were seldom observed, even though their relative frequencies were greater than 60% in annual one-day counts for the region within 80km of Brisbane between 1972 and 1983 (Woodall, 1985). Twenty principal species were also common in northeast NSW. (Gosper, 1981; Gosper et al., 1983), with the Maned Duck the conspicuous exception.

The Marburg district, like the whole of southeast Queensland (Woodall, 1985) and northeast NSW. (Gosper, 1981; Gosper et al., 1983) is clearly rich in waterbirds. It supports many more species than regions inland of the Great Divide (Whitmore et al., 1983; Crossman & Reimer, 1986). Rural residential settlement has increased the number of dams to about 3 per km^2(see Queensland Dept Mapping and Survey, Marburg Topographic Map 9442-44). Although many dams are small and lack habitat diversity (G.J. Leach, unpublished data), they supplement older, and usually larger, dams and ephemeral shallow swamps which provide more diverse habitat (Braithwaite, 1975; Leach & Hines, 1992; Wilkinson and Schwenke, 1992). Absence of major reservoirs probably restricts deep water feeders such as Australian Pelican and the large cormorants.

The range in annual frequency was generally wider for waterbird species than for landbirds with the same MAF. Lower frequency of shoreline species in 1983-84 coincided with the end of a widespread southeast Australian drought, enabling them and birds of open water, e.g. cormorants and most ducks, to disperse inland, west of the Great Divide (Woodall, 1985; Leach & Hines, 1992). In contrast higher annual frequencies for several species occurred in the drier 1980-81 and 1982-83 years.

Non-passerine landbirds. Eleven of the principal non-passerine landbirds (Table 2) are widely distributed in Australia and the remaining 10 species occur in at least 11% of 1°grid squares (Blakers et al., 1984). Among the most frequently observed, Spotted Turtle-Dove, Peaceful Dove and Cockatiel were better represented at Marburg than in surrounding districts.

The principal species are birds of open country, the 'edge' between woody vegetation and open country, or farmlands. Few were numerous and five with a MAF of 0.5 or higher were ground-feeding pigeons and three were parrots. The Feral Pigeon, Spotted Turtle-Dove, Crested Pigeon and Galah were commensal with farming, and their abundance probably reflects the intensity of small-scale cropping, whereas the Peaceful Dove and Bar-shouldered Dove appear to depend on softwood scrub remnants. Among remaining species with MAF of 0.5 or higher, Australian Kestrel and Rainbow Bee-eater hunt over open country and contrast with Scaly-breasted Lorikeet, Pale-headed Rosella and Laughing Kookaburra utilising open-forest/woodland and the Pheasant Coucal using dense scrub and/or rank grass. Sacred Kingfisher was the only species with MAF>0.5 in other surveys that had MAF<0.5 in standard surveys, probably reflecting its preference for the open eucalypt forest with many termitaria for nest sites.

The most notable feature of the non-passerine landbirds was that half of them were observed on 5% or fewer visits, yet none are rare in southeast Queensland (Roberts, 1979). They included several raptors and parrots. The group also included the fruit-doves usually associated with closed-forest or softwood scrub, even though the district has many, isolated, *Ficus* spp. which produce heavy crops of fruit (Leach & Hines, 1987). The remnants of low closed-forest may be too small, too degraded, too isolated from extensive rainfor-

FIG. 2. Periods when species with substantial differences in MSF (see text) were present. Continuous lines/blocks join observations at closer than 4-week intervals, based on combined observations over 5 years. Number of years when species were present in each month and single observations are shown. Mean dates of arrival and departure of strongly seasonal migrants are also shown (●).

TABLE 4. The numbers of principal and non-principal species in standard surveys, and of species observed only in other surveys, classed according to low, medium and high variation in annual frequency. For standard surveys low, medium and high variation are represented by values of 0.0 or 0.25, 0.5, and 0.75 or 1.0 respectively; for other surveys the corresponding values are <=0.25, 0.26 to 0.5, and >0.5 respectively. The numbers of species with MAF <=0.20 in other surveys are shown in parentheses.

est and/or naturally floristically unsuitable for other than limited opportunistic exploitation by fruit-doves. Fruit-doves were only occasionally observed immediately following European settlement at Murphy's Creek, 50km west (Lord, 1956), but whether they were more prominent in the more extensive softwood scrub of the Marburg District (Elsol, 1991) cannot be ascertained.

Passerines. Twenty-three principal passerines (Table 3) have a wide Australian distribution, while five were reported from <11% of 1°grid squares (Blakers et al., 1984). The latter include species associated with closed-forest (Varied Triller, Eastern Whipbird and Lewin's Honeyeater) or rank grassland (Tawny Grassbird) and the Common Myna. Nine species with low MAF (0.2 or less) (Tree Martin, White-winged Triller, Jacky Winter, Restless Flycatcher, Rufous Songlark, Brown Songlark, Weebill, Varied Sittella and White-breasted Woodswallow) are widely distributed in Australia. Nine non-principal species are restricted to <11% of the Australian 1° grid squares, with Yellow-eyed Cuckoo-shrike, Black-faced Monarch, Little Cuckoo-shrike, Brown Gerygone, Satin Bowerbird and Regent Bowerbird associated with closed-forest. Species observed more frequently than in neighbouring grid squares include Grey-

crowned Babbler, Superb Fairy-wren, Yellow Thornbill, Speckled Warbler, Striped Honeyeater and Zebra Finch.

Passerines are clearly the most important component of the avifauna, both in terms of species number (Leach & Hines, 1987) and frequency of observation (Table 3). Thirty-three of the species listed in Table 3 were observed in roadside remnant vegetation in summer, including 31 principal species (Leach & Recher, 1993). The six most numerous species in roadside remnants, namely Silvereye, Superb Fairy-wren, Yellow Thornbill, Double-barred Finch, Red-backed Fairy-wren and Lewin's Honeyeater had MAF of 0.75 or more.

Cicadabird, Weebill, White-throated Gerygone, Buff-rumped Thornbill, Varied Sittella, White-throated Treecreeper, White-throated Honeyeater and Spotted Pardalote, with much higher MAF in other surveys than in standard surveys, are largely restricted to the eucalypt associations (G.J. Leach, unpublished data), corroborated by correlation of their MAF with proportion of visits to eucalypt stands at Tallegalla. Other differences in MAF between surveys also reflect the proportion of visits to eucalypt associations, e.g. Yellow-faced Honeyeater and Pied Currawong.

Among species with greater MAF in standard surveys than in other surveys, the narrow range in annual frequencies for Singing Bushlark, Tawny Grassbird and Yellow-rumped Thornbill confirms their localised distribution. This reflects preference for open country, rank grassland, and close-grazed or mown grassland around isolated trees, respectively (Leach & Hines, 1987). Larger ranges in annual frequency contribute to the difference in MAF between surveys for Fairy Martin, Richard's Pipit and Red-backed Fairy-wren, but at least part of the difference for the first two is likely to reflect preference for open habitat. The difference for the Red-backed Fairy-wren may be related to its abundance in roadside vegetation (Leach & Recher, 1993) and use of swamp grasslands (Leach & Hines, 1987).

The introduced Common Myna colonized the district from the west during this survey, reaching the eastern boundary in 1982 (Leach & Hines, 1987). Correlations with visits to Woolshed Creek Road and Prenzlau, in the west, probably reflect marginally longer colonization in these areas.

A wide range of families and feeding strategies are represented among principal passerines. Approximately half the species primarily use open, or disturbed, habitats (Schodde & Tidemann, 1986). Exceptions associated with closed-forest/softwood scrub include Varied Triller, Grey Shrike-thrush, Rufous Fantail, Eastern Whipbird, White-browed Scrubwren, Yellow Thornbill, Silvereye, Lewin's Honeyeater and Figbird (Howe, 1986; Leach & Recher, 1993).

Species using rainforest patches in northern NSW were grouped according to size of patch occupied (Howe, 1986). The first 21 species listed in Table 3 were not in the more specialised rainforest groups. The Rufous Fantail and White-throated Treecreeper were placed in a group requiring patches larger than 2.5 ha. However, the Rufous Fantail was common in narrow roadside remnants at Marburg (Leach & Recher, 1993), whereas the White-throated Treecreeper was mainly observed in open eucalypt forest on other surveys. Several species occurring in small and large rainforest patches, but predominantly the latter, were observed in roadside remnants at Marburg, indicating that habitat use differs from that in northern NSW. An explanation for the differences may be that abundant Lantana (*Lantana camara*) and other woody weeds provide a more effective linkage between small remnant patches for many bird species than in northern NSW (Lynch, 1987; Lynch & Saunders, 1991; McIntyre & Barrett, 1992; Leach & Recher, 1993). Because the diversity and abundance of passerines may be more vulnerable to intensified land use than their current status indicates (cf. Recher & Lim, 1990), it may become especially important to retain, and where possible regenerate, native woody vegetation if woody weeds are substantially controlled and cleared.

Seasonal Migrants

Surveys were sufficiently frequent to provide approximate dates of arrival and departure of migrant species (Fig 2). Some species are clearly summer (e.g. Latham's Snipe, Common Koel, Leaden Flycatcher and Rufous Fantail) or winter (e.g. Rose Robin, Grey Fantail and Yellow-faced Honeyeater) visitors, with little variation between years in dates of first or last observation. Some tended to be absent from the district for only a very short period (e.g. Black-shouldered Kite and Wedge-tailed Eagle) while White-winged Triller was present for only a short period. Others (e.g. Scarlet Honeyeater and Spotted Pardalote) were consistently observed at disjunct intervals. Several migrants consistently arrived in late September, e.g Common Koel and Dollarbird, but dates of last observation were more variable.

Information for southeast Queensland, mainly limited to honeyeaters at Wellington Point (Robertson, 1958, 1965; Robertson & Woodall, 1983), is significantly augmented. Features of special interest are the small period of overlap between the Rufous Fantail and the Grey Fantail in September and March/early April, the short winter presence of the Rose Robin, the short visit of the White-winged Triller for breeding (G.J. Leach, unpublished data), and migration patterns in the honeyeaters. Low MSF in summer and/or autumn for some otherwise relatively common raptors indicates that further study is necessary to establish if this is the result of seasonal movement, or is associated with behavioural changes that affect detectability while breeding. Latham's Snipe is the only truly seasonal migrant among the principal waterbirds because Plumed Whistling-Duck is a winter resident in the neighbouring grid square (Leach & Hines, 1987). Information for other waterbirds, e.g. Black Swan and Glossy Ibis, reflects nomadic movements.

Summer presence of the Rufous Fantail in the Marburg district agrees with observations in northeast NSW. (Cameron, 1985). However, the Grey Fantail was more numerous in summer than winter in NSW. Roberts (1979) remarks that Grey Fantails are resident in southeast Queensland with an increase in numbers in winter. Our data shows that it is not resident in all habitats, possibly because different races may occupy different habitats (Cameron, 1985). Mist netting since 1988 has shown that small numbers of both species are present outside the dates in Fig. 2 (G. R. Anderson & G.J. Leach, unpublished data), suggesting that more monitoring of their movements is necessary.

Observations for the Yellow-faced Honeyeater and Eastern Spinebill (Fig. 2) closely match those of Robertson and Woodall (1983). The continuous presence of Scarlet Honeyeaters at Wellington Point from March through September contrasts with its frequent absence through midwinter in the Marburg district where it, and also the Spotted Pardalote, appear to be seasonal migrants responding to local variation in availability of food.

CONCLUSIONS

The Marburg district supports a rich diversity of bird species, with waterbirds and passerines generally better represented than non-passerine landbirds. The diversity is sustained by the wetlands, remnants of brigalow softwood scrub, eucalypt open-forest and the woody weeds interspersed through the farmlands. The survey has established a robust database which will allow changes in mean annual and seasonal frequency of bird species to be detected. The information should be used to guide management of these diverse habitats.

While the avifauna (with the exception of most non-passerine landbirds) is well-adapted to the existing matrix of terrestrial and wetland habitats, additional human settlement and intensification of land use may lead to a breakdown of this matrix. Regular monitoring is vital. Maintenance of the present diversity and abundance of birds will require management strategies aimed at retention and better management of existing native woody vegetation, and re-vegetation with appropriate native species wherever practicable.

ACKNOWLEDGEMENTS

Landholders granted access to properties and showed much interest in the survey, especially A. Bailey, D. Bichel, N. Berg, R. Cochrane, E. Gerber, V. Millewski, W. Rea, L. Reinke and N. Tate. Several members of Queensland Ornithological Society assisted with surveys; P. Grice, K. Hughes, T. Norris, D. Watson and C. Wingate on several occasions. Rainfall data was provided by the Division of Tropical Crops and Pastures, CSIRO. G. Larkens gave advice on computer collation of data. C. Catterall, E. Date, S. Debus, K. Hulsman, C. and A. Lloyd, W. Longmore and J. Taylor provided helpful comments on earlier drafts. Referee P. Dwyer provided invaluable constructive criticism and guidance for final revision. We generously thank these individuals and organisations for their interest and assistance.

APPENDIX 1 Details of localities in the standard survey which were surveyed on foot.

Location	Grid Ref.	Duration (mins)	Habitats			
			Roadside	Paddocks	Dams	Other
Haigslea (School)	MQ631500	45	T(1,A,B), G(s-r).	T(1,A), G(s), C(1).	M1, M2 & M3 (s) + 1(s, silted with *Typha* sp. and adjacent *Schinus terebinthifolia*).	School and church grounds. T(2, native & exotic), G(s).
Haigslea	MQ618495	20	G(r).	T(1,A), G(r), C(1).	M4(m) + 1(m).	
MT Marrow	MQ627481	20	T(2,S,A), W(2,L), G(r).	T(2,S,A), W(2,L), G(s-r).	M5(s).	Road metal quarry south of road.
Malabar	MQ609483	15	T(1,A), W(1,C,L), G(r).	T(1,A,B), W(1,L,C), G(m-r).	M6(1).	
Malabar	MQ609477	30	T(2,S,A,B), W(2,L) G(r).	T(1,S,A), W(1,L), G(m-s).		Dis-used sand quarry south of road. Cliffs used by hole-nesting species (see Leach and Hines, 1987).
Tallegalla (Railway dam)	MQ577467	10	T(1,A), W(1,C,L), G(m-r).	T(1,A,B), W(1,L), G(s).	1(m, covered with Water hyacinth, *Eichhornia crassipes*).	
Tallegalla (The Bluff)	MQ550464	30	T(2,S,A), W(2,L), G(m-r).	T(2,S,A), W(2,L), G(s-m).	2(s, often empty)	Three large *Ficus* spp. at this site.
Ashwell	MQ561446	20	T(2,S,A,B), W(2,L), G(r).	T(S,B,E,A), W(2,L), G(s-r).		Small creek through site
Minden Dam	MQ548522	15	T(1,A,S), G(s-r).	T(2,E,B,S), G(s-r).	1(m - Leach & Hines, 1992).	Mid-afternoon.

1. Grid References for Marburg (9442-44) and Haigslea (9442-41) 1:25 000 Topographic Maps.
2. Vegetation:
T - trees; 2, 1 - more than 5, and 1 to 5, respectively >8m tall in vicinity. Principal trees are Brigalow (*Acacia harpophylla*) (B), other acacia spp. (A), softwood species (S, see Leach & Hines, 1987), and eucalypts (E).
W - woody weeds; 2 - extensive thickets, 1 - isolated clumps; species include lantana (*Lantana camara*) (L) and Wait-a-while (*Caesalpinia decapetala*) (C).
G - grass; s - grazed short, m - medium grazed to about 500mm tall, r - rank, often not grazed and over 1000mm tall.
C - cultivated land nearby, <20% of total area within 500m of road.
Additional details of roadside vegetation on parts of the standard route are in Leach & Recher (1993).
3. Dams - those prefixed 'M' are described in Leach (1994). Minden is described in Leach & Hines (1992).
Dams are described as large (l, >15 000m^2 maximum surface area), medium (m, 5000 to 15 000m^2) or small (s, <5000m^2).

APPENDIX 2 Principal areas visited in the 100 non-standard surveys.

Locality	Number of visits	Habitats	Remarks
Haigslea/Malabar/ MT Marrow.	92[1]	As first five sites on standard route, plus extra softwood remnants.	82 to 100% of visits each year.
Schumans Road.	71[2]	Well-conserved lengths of softwood scrub gallery, about 7m wide (Leach & Recher, 1993).	24% of visits in 1980-81; 68 to 100% thereafter.
The Bluff, Tallegalla	19	See App.1.	10 to 29% of visits each year.
Woolshed Creek Road - East.	83[2]	Lengths of softwood scrub gallery, about 8m wide plus small creek and gallery of *Melaleuca bracteata*.	65% of visits in 1980-81, progressively increasing to 100% in 1984-85.
Woolshed Creek Road - West.	78[2]	Eucalptus open-forest (especially *E. maculata*) with woody weeds and grazed grass understorey (Leach & Hines, 1987).	47% of visits in 1980-81, increasing through 69, 84, 90 and 100% in following years.
Glamorgan Vale - MT Stradbroke.	9	As Haigslea/Malabar/MT Marrow, plus more extensive areas of relatively intact Brigalow-softwood scrub.	29% of visits in 1980-81, 15% in 1981-82, none subsequently.
Prenzlau Swamp[3].	36	Shallow ephemeral swamp (Leach & Hines, 1987).	First visited in March 1981; 18% of visits in 1980-81, increasing through 23, 32, 40 and 72% in following years.

(1) Censuses of farm dams (Dams M1 to M6, see Appendix 1) were major objectives on 14 of these visits.
(2) Transect censuses carried out on 12 of these days and rolling bird surveys (Cullen, 1980) on another 40 days. Five rolling bird surveys were completed in spring and autumn of each of the last four years, substantially contributing to the discrepancy in number of visits between seasons.
(3) Prenzlau Swamp. Extensive open water (c.100ha) in March 1981, reduced by 80% by October 1981 and almost no open water by October 1982. Flooded in May 1983 and extensive open water thereafter apart from early summer 1984-85.

CRAB ISLAND REVISITED : REASSESSMENT OF THE WORLD'S LARGEST FLATBACK TURTLE ROOKERY AFTER TWELVE YEARS

COLIN J. LIMPUS, P. J. COUPER AND K. L. D. COUPER

Limpus, C.J., Couper, P.J. & Couper, K.L.D. 1993 06 30 : Crab Island revisited: reassessment of the world's largest Flatback Turtle rookery after twelve years. *Memoirs of the Queensland Museum* 33(1):277-289. Brisbane. ISSN 0079-8835.

Crab Island in northeastern Gulf of Carpentaria supports the largest nesting population of *Natator depressus*, a marine turtle endemic to the Australian continental shelf, and low density nesting by *Eretmochelys imbricata*. The reproductive status of the Flatback Turtle, *Natator depressus*, at Crab Island, is reassessed after 12 years based on a survey conducted during high density nesting in July 1991. *N. depressus* hatchling productivity from the island continues to be high. The characteristic small size of nesting females and egg diameters of *N. depressus* that breed in the Crab Island region suggests that this population is a different breeding unit from that of the southern Great Barrier Reef. The feeding areas supplying turtles to the Crab Island region rookeries extend as far north as southern Irian Jaya.
☐ *Natator depressus, Eretmochelys imbricata, Crab Island, Queensland, Australia, nesting, hatchling productivity, conservation status.*

Colin J. Limpus, Department of Environment and Heritage, PO Box 155, Brisbane, Albert Street, Queensland 4002, Australia; P.J. and K.L.D. Couper, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; 27 October, 1992

Crab Island, in the north eastern Gulf of Carpentaria, supports the largest recorded nesting aggregation of Flatback Turtles, *Natator depressus* (Limpus & Parmenter, 1986). *N. depressus* is almost totally confined to the Australian continental shelf and its breeding is restricted to Australia (Limpus et al. 1988). The biology of marine turtle populations breeding on Crab Island was reviewed by Limpus et al. (1983a) based on field surveys of the nesting turtles in 1970-1979. Because the status of this significant turtle breeding population had not been reassessed since that time, a study to redescribe the reproductive biology of the Crab Island turtles after a 12 year interval was undertaken in July 1991, during the high density nesting period identified in previous studies (Limpus et al. 1983a).

METHODS

A two person team camped on Crab Island during 6-22 July 1991 (P.J.C. and K.L.D.C.). The western (ocean) beach of the island was measured along the spring high tide level and subdivided into eleven numbered sectors (each 500m long) from south to north (Fig. 1) using a pedometer. All data recorded along the island were scored by beach sector. The beach width within sectors 1-10 was measured from the spring high tide level to the crest of the seaward dune adjacent at each sector mark. These were the sectors in which all turtle nesting activity occurred. On arrival, the team counted all existing turtle tracks by species, without attempting to age the tracks. A single track included both the emergence and return crawl of a nesting turtle. All tracks were crossed off in the sand above the high tide mark as they were counted so that previously recorded tracks could be recognised. Thereafter, a track census was conducted daily: all turtle tracks and nests from which hatchlings had emerged from the previous night were counted by species along the western beach. Because two persons could not monitor the nesting behaviour of all turtles ashore for a night along 6km of beach, a subset of the beach sectors (4 to 6) was selected for nightly measurement of nesting success of each turtle. Potential predators of the turtles, their eggs or hatchlings were identified and quantified where possible. This included counting of crocodile and bird tracks. Turtles were recorded in the waters adjacent to the nesting beach during the daily census of tracks on those days when the weather was relatively calm. As well, a male turtle was captured by 'beach jumping' (cf. Limpus & Reed, 1985).

Opportunistic tagging of nesting female turtles occurred when volunteer members of the Queensland Turtle Research Project visited Crab Island (28 December 1989 and 15-17 January, 1991) and the south beach at the mouth of the Jardine River on the mainland, 14km from Crab Island (29 December 1987). Adult turtles were tagged using

serially numbered, self piercing, self locking tags applied to the axillary flipper tagging position (Limpus & Reed, 1985). In July 1991, 3.3g monel tags (National Band and Tag Company, style 1005, size 681; SD = 0.01g, range = 3.25-3.29, n = 50), inscribed with a return address on the reverse side (Ecology, Box 26 Woden 2606 Australia), were used. On the other visits, 4.1g titanium turtle tags (Stockbrands Co. P/L., return address: Wildlife Box 155 North Quay 4002 Qld Australia; Limpus, 1992) were used. The turtles were double tagged, one tag in each front flipper. No attempt was made to tag all turtles ashore in any one night. The measurements taken followed the standard methodology of the Queensland Turtle Research Project as described by Limpus et al. (1983a): midline curved carapace length (CCL); clutch count; egg diameter, egg weight (10 eggs randomly selected per clutch); nest depth to the bottom of the egg chamber; incubation and emergence success of clutches; sand temperature at 50cm depth. Samples of eggs and recently dead hatchlings were collected and deposited in the Queensland Museum.

Air temperature, rainfall and wind data have been obtained from the Bureau of Meteorology (Brisbane) for their weather station at Thursday Island (10°35'S, 142°13'E, 60m elevation, 45km from Crab Island). This is the closest weather station to Crab Island for which there is a comprehensive data set. Tidal data for Booby Island was used (Anon, 1990). Booby Island, 47km to the north west is the closest standard port tidal bench mark across open water to Crab Island.

RESULTS

Study Site

Crab Island (10°59'S, 142°06'E. Fig. 1) is a crescentic sand island that measured 6.2km in length along the high tide level of the outer western beach on 6 July. The inner eastern margin of the island was partly mangrove lined with wide inter-tidal mud flats. The western beach was composed of mixed siliceous sand and calcium carbonate (broken mollusc) fragments and was exposed to surf. Beach rock was exposed intertidally in sectors 4 and 5. The vegetation of the foredune nesting habitat of the western beach was variable: *Melaleuca* woodland with a grass and herb understorey in sectors 5 and 6; open woodland of scattered *Casuarina equisetifolia* (sectors 4 and 7); grassland dominated by *Spinifex hirsutus*, *Ipomoea pes-caprae* and *Tribulus cistoides* (sectors 2-4, 5, 8-10); unvegetated sand dune (sector 6). There were no mangroves growing on the western beach. However, there were standing dead mangrove trunks on the northern part of the western beach that were the result of past encroachment of the island into the mangrove forest. The dead mangroves and beach rock were not an impediment to the nesting activities of the turtles.

Crab Island lies within a region with a distinct summer wet season and winter dry season. The mean monthly rainfall and the mean daily minimum and maximum temperatures for the years 1950-1991 at Thursday Island ranged from 4mm in September to 419mm in January (Fig. 2). Crab Island has no surface freshwater for most of the year. There is an ephemeral freshwater swamp system behind the dune in the northern end of sector 5 which supports at least one species of frog, *Limnodynastes ornatus* (QMJ31755-7). This swamp was dry during the July visit and in most years there would be insufficient rain to refill the swamp until January, which is the peak of the wet season (Fig. 2). Monthly mean daily maximum temperatures ranged from 31.2°C in November to 27.7°C in July, while monthly mean daily minimum temperatures ranged from 25.4°C in December to 22.5°C in July. During the middle of wet season months of January and February the wind is predominantly from the west and northwest and is mostly weaker than 20km/hr. In the middle of dry season months of May to October there are almost no westerly or northwesterly winds; the dry season winds come predominantly

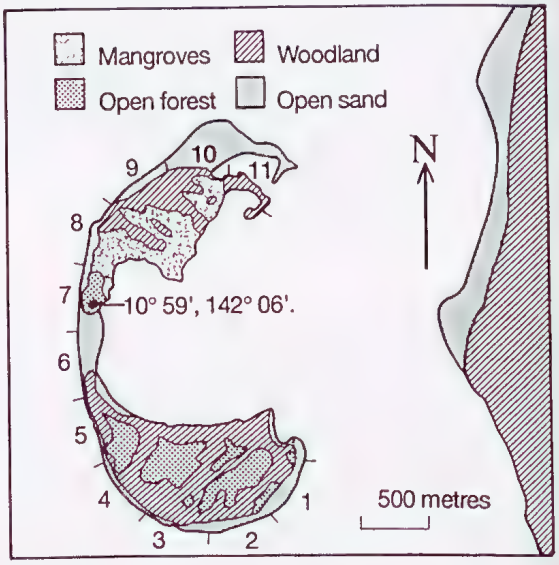

FIG. 1. Map of Crab Island showing position of numbered beach sectors and vegetation types.

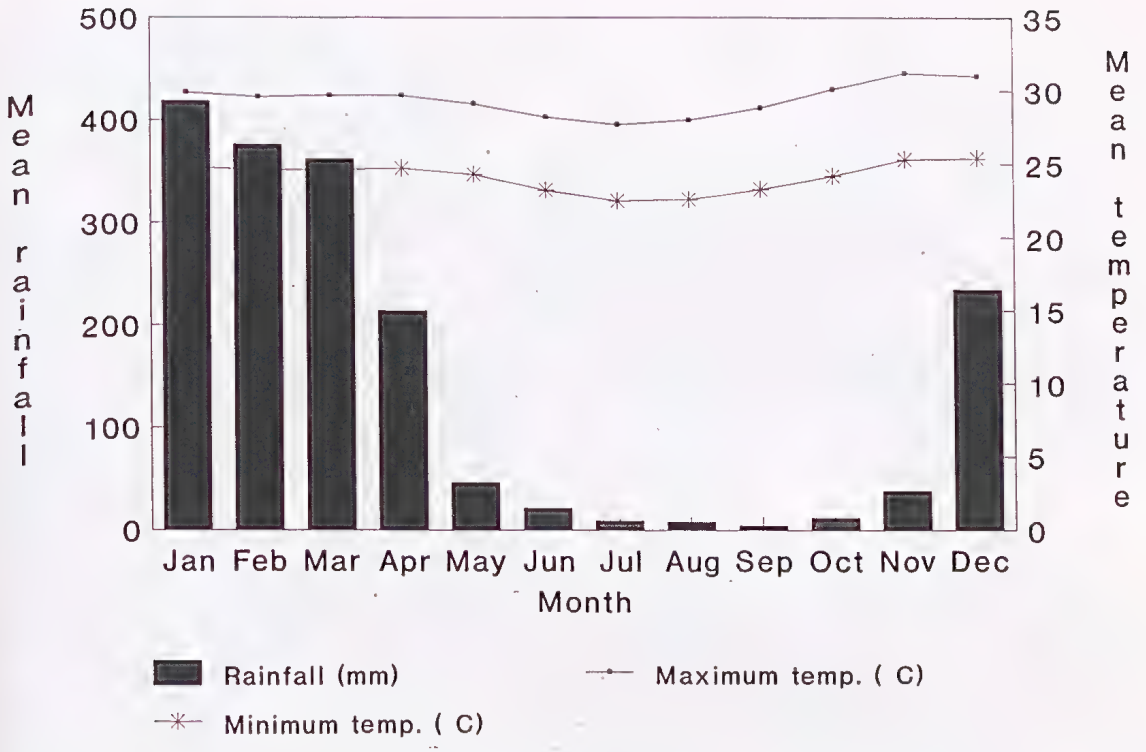

FIG. 2. Monthly mean rainfall (mm) and monthly mean daily minimum and maximum temperatures recorded at Thursday Island Meteorological Station for the years 1950-1991.

from the east and southeast and are mostly stronger than 20km/hr. Mean sand temperature at 50cm depth within the turtle nesting habitat was 27.6°C (SD = 0.49, range = 26.4 - 28.5, n = 44, 1 - 5 measurements per night).

The mean beach width above the spring high tide level was 31.3m (SD = 15.3, n = 10). The narrowest beach (8m) occurred at sector mark 3 and the widest (53m) at sector mark 10. There are two high tides per 24hr at Crab Island (Fig. 3). During 6-22 July, 1991, the daily tidal range varied from 3.46m (12th) to 2.36m (19th). The variation in night time high tide height (0.27m) was less than that of the daytime high tides and both sets of low tides (Fig. 3).

NESTING TURTLES

On the team's arrival at the island on 6 July, 1991, there were 309 turtle tracks visible (174 *N. depressus*, 135 not identifiable to species). Based on nightly track counts from the 14 nights 6-19 July (Fig. 3), there was an average of 132.7 beachings of *N. depressus* per night (SD = 52.11, n = 14, range = 68-235) from a total of 1839 recorded beachings. Similarly, there was an average of 0.6 beachings of *E. imbricata* per night (SD = 0.93, n = 14, range = 0-3) for a total of 9 beachings.

On the limited data from this visit, there is a suggestion that the maximum nightly nesting density may follow the occurrence of afternoon high tides. Only *N. depressus* was recorded coming ashore for nesting during daylight hours (19 [1.0%] of the 1839 total beachings). Most (4 and 13) of these daylight nesting emergences occurred on two days only (8th and 9th July, respectively) with the remainder being single beachings on each of the 10th and 20th July. All except one of the daylight beachings occurred on days with mid-afternoon high tides (8th-10th) while the remainder coincided with a midday high tide (20th).

Turtle nesting activity was restricted to the western (ocean) beach, except for one turtle which came ashore on the western side at the narrow middle of the island (sector 6) and returned to the sea on the eastern side. Most nesting activity occurred within the middle sectors 4-8 (Fig. 4) where the beach width ranged 26-43m. The number of turtle beachings varied nightly and among sectors. The densest activity occurred in sector 5 (nightly mean number of tracks = 43.9,

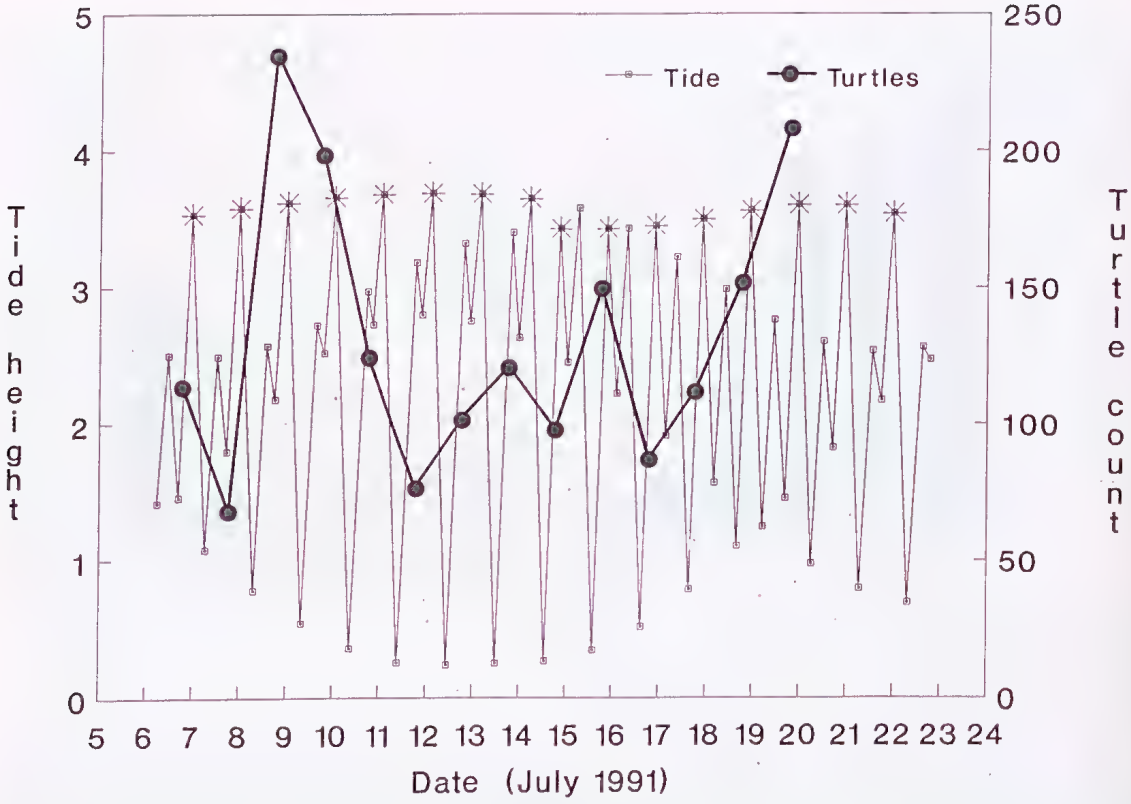

FIG. 3. Daily frequency of beachings by nesting Flatback Turtles, *Natator depressus*, at Crab Island during 6-19 July 1991. The daily variation in tide height (in metres), measured at Booby Island is also shown. *denotes a night time high tide.

SD = 25.49, n = 14, range = 21 - 102) while no tracks were recorded on any night in sector 11.

For the sample of 172 beachings by *N. depressus* examined for nesting success, 132 females (76.7%) definitely laid eggs, 14 (8.1%) could not be determined for nesting success and 26 (15.2%) returned to the sea without laying eggs. Thus there was a probability (±95% confidence limits) of between 76.7±3.2% and 84.8±2.8% that a turtle would successfully lay eggs when she came ashore. When this nesting success probability is applied to the track counts for the period 6-19 July, it is estimated that between 1352 and 1611 *N. depressus* clutches were laid on the island during the 14 nights of observation.

For the sample of 6 beachings by *E. imbricata* examined for nesting success during the same period, 4 laid and 2 did not lay. This represents a nesting success of 67% for this species with an estimated total of 7 clutches laid during the 9 beachings.

Over the 15 nights, 6-20 July, 489 nesting turtles were examined and tagged (483 *N. depressus* and 6 *E. imbricata*). There were no recaptures of any turtles that had been tagged during previous visits to the island, nor were there migrant recaptures of any turtles tagged at other locations. The size distribution of these nesting turtles are summarised in Table 1 and Fig. 5. The mean CCL of the nesting turtles was: *N. depressus* = 88.2 cm, *E. imbricata* = 83.9 cm.

Turtles Adjacent to Beach

By day when the weather was calm during 6-21 July 1991, there were numerous sightings of solitary turtles surfacing to breathe, mostly within 50m of the beach. All were adult sized *N. depressus*. Up to 15 such turtles were observed adjacent to a single sector during a track census with 0-49 isolated turtles seen during a single track census along the entire beach. The water was clear enough at high tide for adult sized *N. depressus* resting on the bottom at 2m depth to be visible from a dingy adjacent to the beach. In addition, mating turtles were observed in the surf adjacent to the beach on four days (0-2 courting pairs per

TABLE 1. Curved carapace length (cm) of nesting female turtles on Crab Island and adjacent beaches since the studies of Limpus et al. (1983a).

daily track census). All were mounted pairs of *N. depressus* and no attendant males were observed. One mounted male (B0314) was captured and measured : CCL = 83.1cm, tail length beyond the carapace = 22.0cm (Fig. 6). The adult male *N. depressus* was similar to the adult female (Fig. 7) in most external features: colour, low doming of the carapace along the midline and lateral upwards reflexing of the carapace (Limpus et al., 1988). The only observed external dimorphic characters were tail length (male very long vs female short) and claws (male elongate and strongly recurved vs female short and slightly curved). The male was mounted on the female, venter to dorsum (Fig. 8), and was gripping the female's carapace margin via the single recurved claw on each flipper. The male was mounted well forward on the female such that his head could rest on her anterior carapace and dorsal neck. His snout contacted her head when she raised her head for a breath.

Adult Mortality, Injuries and Diseases

No dead turtles were found along the beach on arrival on 6 July. The highest and narrowest dunes on the island were in sector 4. The 10m high dune front in this area was steep enough for most turtles to have difficulty in climbing it. One female *N.*

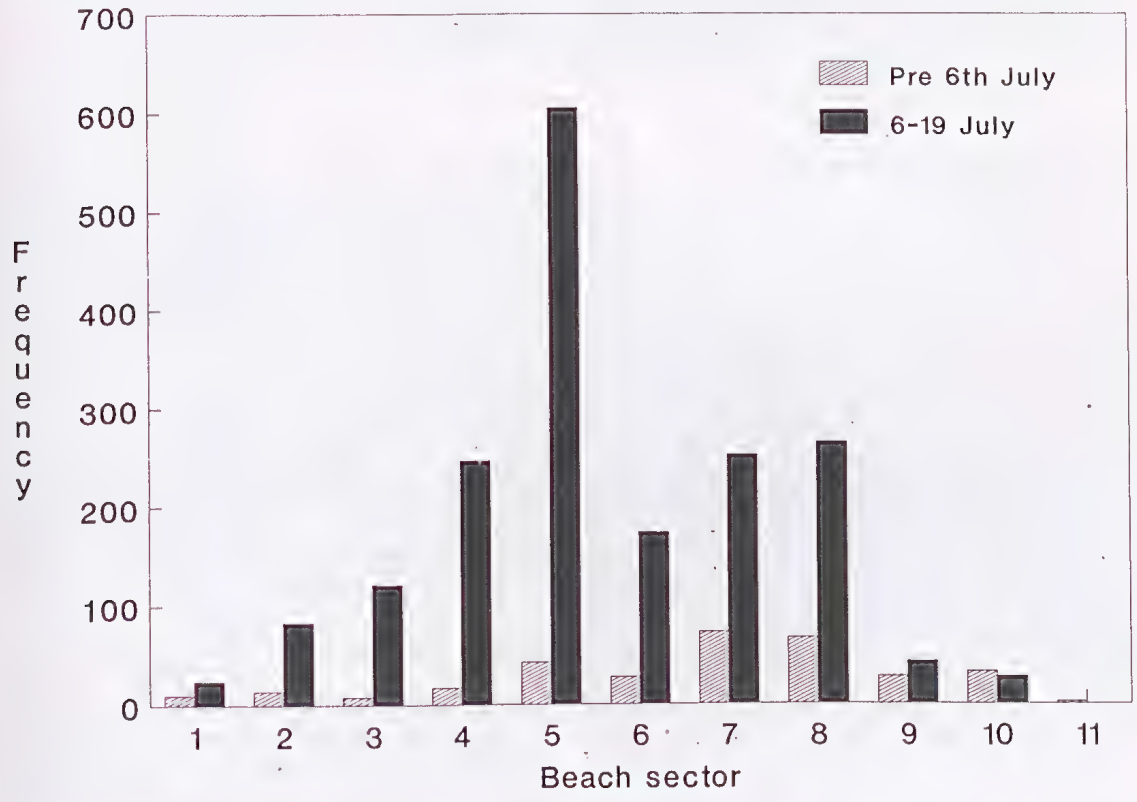

FIG. 4. Distribution of turtle tracks by beach sector on Crab Island, 6-19 July 1991.

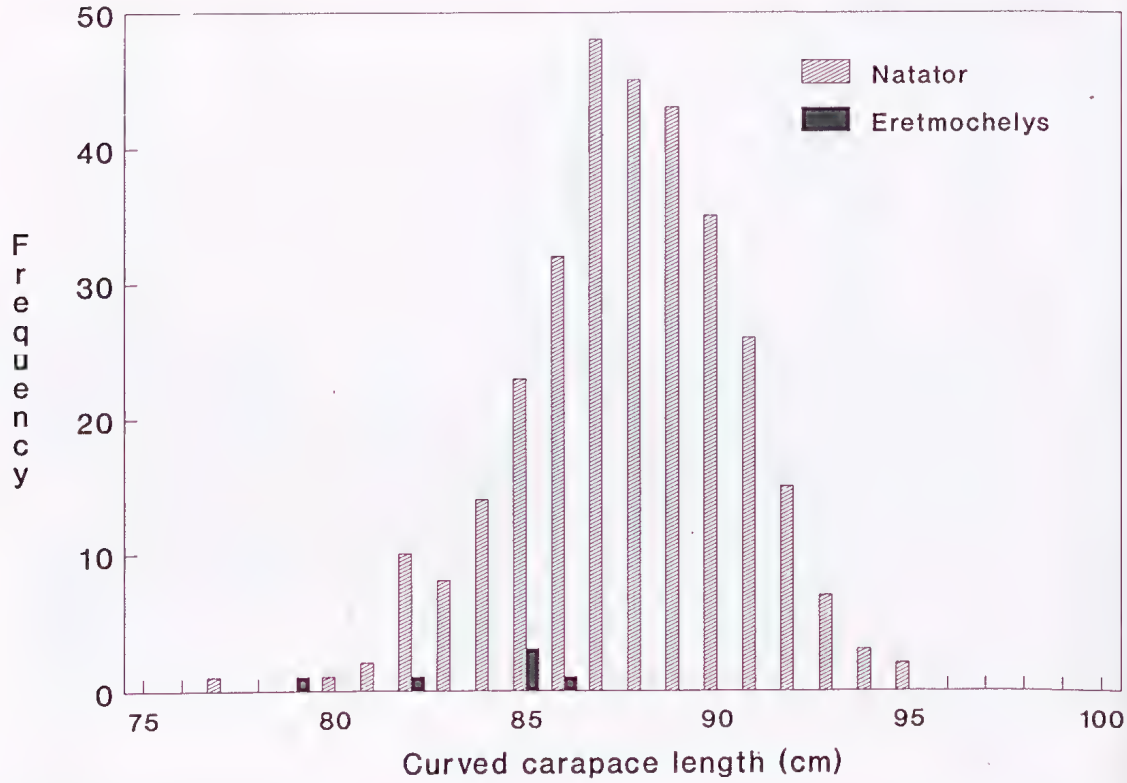

FIG. 5. Size distribution of nesting female *Natator depressus* and *Eretmochelys imbricata* at Crab Island, 6-20 July 1991.

depressus was observed to climb this dune and attempt to nest inland of the dune crest. Later, after wandering to the inland base of these dunes, she was able to find her way back to the beach and return to the sea. A search of the woodland and forest areas inland of the dune crest throughout the island revealed the old fragmented skeletal remains of two adult sized *N. depressus* lying ventral side down behind sector 4. These remains were consistent with the turtles having died after being disoriented following a nesting attempt inland of the crest of the high dunes. No nesting females died while ashore during the 6-21 July 1992 visit.

One large crocodile, *Crocodylus porosus*, (total length 3+m) was observed on most days during late mornings at the water's edge in sector 3. While this crocodile was large enough to be a predator of adult turtles, no turtles showed signs of having been mauled by a crocodile. Several nesting turtles did, however, have healed crescentic damage to the carapace that was presumed to have resulted from past shark or fish bites. For *N. depressus*, loss of large crescentic pieces from the carapace was recorded for 8 (1.7%) turtles, minor carapace damage was recorded for 17 (3.5%) turtles and loss of one third or greater of a flipper was recorded for 32 (6.6%) turtles. All of these injuries were from well before the current nesting season as indicated by their completely healed state. None of the *E. imbricata* showed signs of significant injuries.

Fibropapillomas were recorded on five of the nesting *N. depressus* only: B505, 2 fibropapillomas on neck; B535, 2 on right hind flipper; B625, 1 on right front flipper; B690, 1 on the right shoulder; B1165, 1 on neck. The largest fibropapilloma was 2.4cm in diameter. The ventral surface was not examined.

CLUTCHES

For *N. depressus*, the mean clutch count was 55.9 eggs (Table 2, Fig. 9) and the mean egg diameter was 4.93cm (Table 2). Of the 32 clutches counted at oviposition, one contained one yolkless egg and none contained multiyolked eggs. During the laying of these 32 clutches the

FIG. 6. Adult male Natator depressus, tag number B0314, returning to the sea after being brought ashore for tagging and measurement.

nesting females did not dig into any existing clutches.

For *E. imbricata*, the mean clutch count was 139.3, the mean egg diameter was 3.60cm and the mean egg weight was 26.1g (Table 2). None of the four clutches counted at oviposition contained yolkless or multiyolked eggs. During none of the five successful nestings observed did the turtle dig into an existing clutch.

Representative eggs were collected : 6 normal *N. depressus* eggs, QMJ31745; 1 yolkless *N. depressus* egg, QMJ31747; 3 normal *E. imbricata* eggs, QMJ31746.

Emerged Clutches

Eighty four freshly emerged clutches were identified to species by examination of eggs, hatchlings or hatchling tracks. All were *N. depressus* clutches. Representative hatchling *N. depressus* were collected : QMJ31748-31753. Strong winds prevented the accurate count of emerged clutches for all beach sectors on most nights. Within the relatively wind protected area of sector 5, the nightly number of emerged clutches was counted on 6-15 July. The mean number of *N. depressus* clutches emerging per night in this sector was 4.1 (SD = 2.23, range = 0-8, n = 14 nights, 57 nests). The maximum number of emerged clutches counted along the entire beach on a night with light wind was seven, with four of those in sector five. Hatchlings were often encountered crossing the beach at night but none were seen by day.

Forty nests from recently emerged clutches were dug to assess hatchling incubation and emergence success. After having been laid, two of these clutches had been each dug into by another turtle, representing a clutch disturbance rate after having been laid of 0.05. Another of these 40 emerged clutches had been laid by a turtle that had dug into an existing clutch (clutch disturbance rate at laying = 0.025). Because these latter eggs were adjacent to another previously emerged clutch they could not be counted accurately. Counts were made from the remaining 39 freshly emerged clutches (Table 3). There was no significant difference (t test, $p,<<0.05$) between mean clutch count measured at laying (Table 2) and mean clutch count measured at emergence (Table 3, Fig. 9), the latter having been laid approximately two months earlier. The mean depth to the bottom of these nests was 58.3 cm (Table 3). There were yolkless eggs (1 per clutch) in two of these clutches.

From the 2129 eggs in the 39 clutches counted, there was a mean hatching success of 81.84%, while hatchling emergence from the nest to the beach surface represented 78.56% of the eggs laid (Table 3). Egg mortality was distributed as follows: 10.4% unhatched, 7.4% undeveloped and 0.3% predation by ghost crabs, *Ocypode* sp (3 nests). Within the nests, there were dead hatchlings representing 2.4% of the eggs laid. A further 0.9% of the eggs were represented by live hatchlings that may or may not have escaped from the nests, had they not been excavated. This included 9 hatchlings that were tangled in a buried branch over one nest.

Egg and Hatchling Predation

There was no evidence of known egg predators such as varanid lizards or large mammals (pigs, dogs, cats) on the island.

Nankeen night herons (*Nycticorax caledonicus*) including adults and fledged juveniles were present in the nesting habitat each night and were observed eating hatchling *N. depressus*. These birds were most concentrated in beach sectors 4-5. At night, up to 6 birds were observed around a nest taking hatchlings as they emerged. This

TABLE 2. Clutch counts and egg measurements recorded from nesting turtles at Crab Island, 6-20 July 1991.* denotes ten eggs measured per clutch.

Species		Mean	SD	range	n
Natator depressus	clutch count	55.9	9.57	34-74	32
	egg diameter(cm)	4.93	0.173	4.52-5.17	60*
Eretmochelys imbricata	clutch count	139.3	10.30	123-151	4
	egg diameter(cm)	3.60	0.071	3.49-3.77	30*
	egg weight (g)	26.08	1.075	24.0-28.0	30*

species was observed also scavenging on turtle eggs that had been dug up by a nesting turtle. Silver gulls (*Larus novaehollandiae*, 1 pair present) flew away with two *N. depressus* hatchlings that had been released from an emerged clutch excavated during the afternoon.

Other potential predators of turtle hatchlings within the nesting habitat and beach area were: water python (*Morelia mackloti*, population estimate not attempted; 1 specimen collected, QMJ31754), estuarine crocodile (*Crocodylus porosus*, minimum of five individuals, including three whose hind foot print lengths were 27, 22.5 and 17.5cm), beach thickknee (*Burhinus neglectus*, several groups of 2-3 birds), osprey (*Pandion haliaetus*, 1 pair), whistling kite (*Haliastur sphenurus*, 1 bird), white breasted sea eagle (*Haliaeetus leucogaster*, 1 pair), frigatebird (*Fregata* sp., 1 bird). Potential predators of turtle hathlings in the adjacent surf included: Australian pelican (*Pelecanus conspicillatus*, flock of 10), numerous small black-tipped whaler sharks (*Carcharhinus* sp.).

On the team's arrival at the island, there were two recently used fire places with broken *N. depressus* egg shells and fish remains in sectors 5 and 7. During the 17 days the team was at the island, three parties of local residents from adjacent mainland communities visited to collect turtle eggs. Turtle nests were located by probing the sand in old body pits with a spear. All three parties directed their egg collecting activity in sectors 5-8, the area of highest density turtle nesting: 14 July three men collected an estimated equivalent of four clutches of *N. depressus* eggs; 17 July a party of adults and children collected multiple clutches of turtle eggs: 21 July three men collected an undetermined number of turtle eggs. On the 22 July, a fourth party from two dinghies visited the island, but the purpose of their visit was not assessed. One of the nests dug on 14 July contained eggs with dried egg shell, i.e. it was not freshly laid. The collector expressed the view that these particular eggs were of marginal quality for eating and only half of the clutch was taken and the remainder reburied.

Other Incidental Data

During a visit on the night of 29 December 1987 to the south of the Jardine River mouth, three *N. depressus* were tagged in the first 100m and several others could be seen further along the beach (E. Evans, in litt.). G. Kyriazis (pers. comm.) walked the beach along the mainland coast from 1 to 3km south of the mouth of the Jardine River during early September 1991. His impression of the track density at this time was that it was comparable to the track density on Crab Island in July 1991. There was one freshly dead *N. depressus* that had died on its return crawl to the sea after nesting. Pigs were recorded to have destroyed most of the hundreds of turtle nests seen on a 6km section of this mainland beach in the early 1980s (B. Gray, pers. comm.) and local residents continue to identify pig, dingo and varanid predation of eggs as common on this beach (G. Kyriazis, pers. comm.). The size range of female turtles tagged while nesting on other occasions during 1987-1991 at Crab Island (n = 19) and the Jardine River mouth (n = 3) are summarised in Table 1. The majority of turtles encountered on these occasions were *N. depressus*.

Recaptures

One long distance migration has been recorded from these taggings. An adult female *N. depressus* (T40505), which had been tagged while nesting at Crab Island on 15 January 1990, was captured in a fishing net off Merauke (8°30'S, 140°22'E) in southern Irian Jaya on 10 January

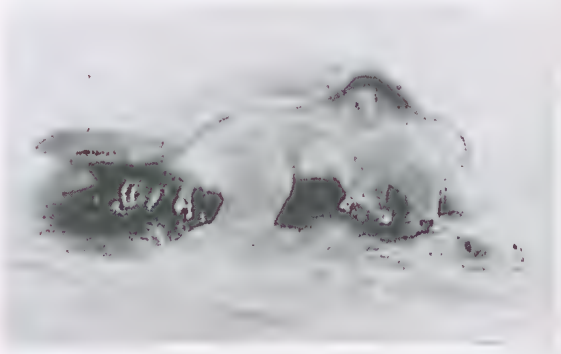

FIG. 8. Adult male *Natator depressus*, tag number B0314, mounted on female prior to capture in approximately 0.7m deep water adjacent to the beach. The female has just surfaced for a breath.

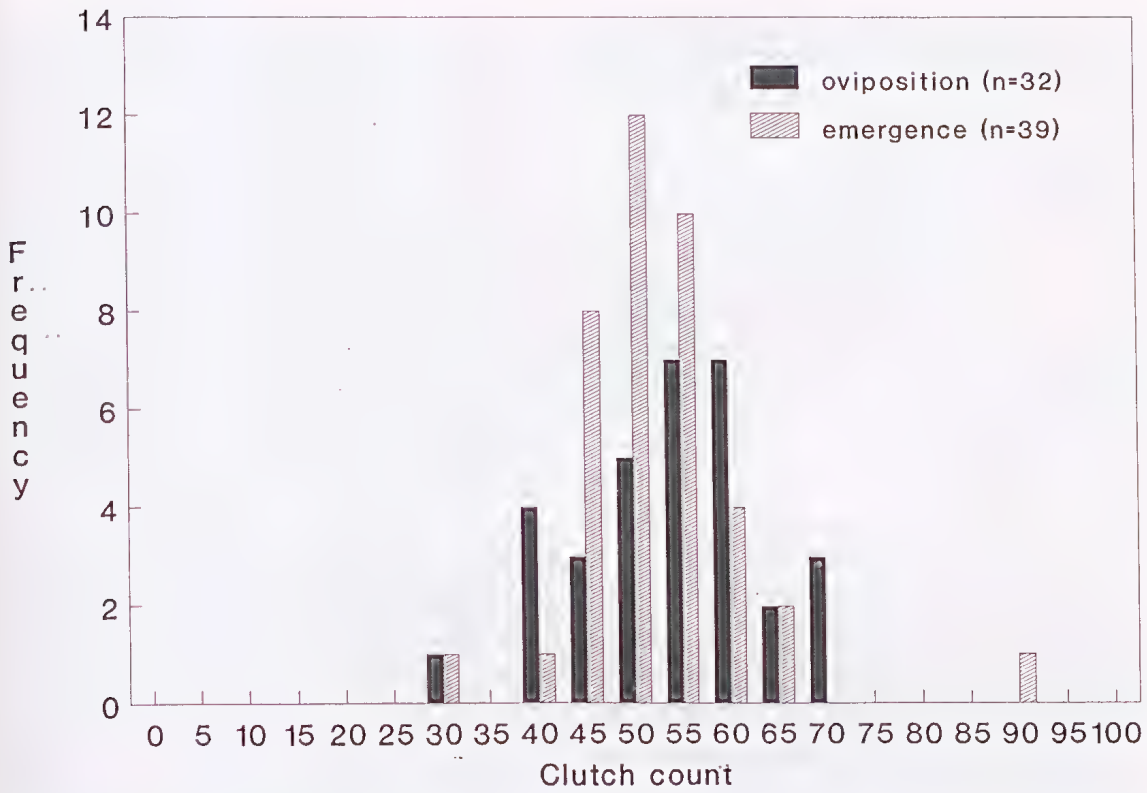

FIG. 9. Frequency distribution of *Natator depressus* clutch counts measured at oviposition and at clutch emergence, Crab Island 6-20 July 1991.

1992. This turtle was eaten. The recapture was made 310km from the nesting beach and two years after she was tagged. This is the first record of *N. depressus* from the coastal waters of Irian Jaya.

One remigration recapture has been recorded from these taggings. *N. depressus* (B1181) was recorded nesting back at Crab Island on 11 September 1992, approximately fourteen months after her initial tagging at Crab Island on 20 July 1991.

DISCUSSION

Marine turtle nesting at Crab Island was first quantified in November-December 1970 (Bustard, 1972). There were subsequent brief visits to further quantify nesting density and to tag nesting turtles during 1976-1979 (Limpus et al., 1983a). As a result of these surveys, Crab Island was found to support all year round breeding and was identified as supporting the largest recorded *N. depressus* nesting population. Low density *E. imbricata* and sporadic *Lepidochelys olivacea* nesting was also recorded for the island. Specimens of *N. depressus* were collected from Crab Island in January 1981, but the nesting population was not described (Zangerl et al., 1988). The island has remained unsurveyed for marine turtles since August 1979. Limpus et al. (1989) identified that *N. depressus* nesting occurs widely in western Torres Strait, with another large nesting concentration at Deliverance and Kerr Islands. The results of the present study allow for a re-evaluation of the status of this significant turtle rookery after 12 years.

Marine turtles typically lay multiple clutches within a single nesting season at approximately two weekly intervals, except for *Lepidochelys* spp. (Hirth, 1980; Limpus et al., 1984). Not all individuals in a particular population begin or complete nesting at the same time of the year (Limpus, 1985). At rookeries in eastern Australia where *Caretta caretta* and *Chelonia mydas* have a discrete nesting season, 60-70% of the total nesting population for the year can be expected to be recorded during a two week tagging census at

TABLE 3. Incubation and emergence success recorded from 39 freshly emerged *Natator depressus* clutches excavated for counting on Crab Island, 6-22 July 1991.

		Mean	SD	n	range
emerged hatchlings		42.9	12.99	39	17-87

Emergence success %		78.56	18.55	39	25.0-100.0

the peak of the nesting season (Limpus, 1985 and unpublished data). Therefore a two week census of the Crab Island nesting population at the peak of the nesting season also is presumed to sample a similar proportion of the total population. However, there is all year round nesting at Crab Island (Limpus et al., 1983a) and the present study may not have sampled at exactly the peak of the nesting season. Each of these factors would reduce the proportion of the total population sampled during the two week census. Therefore, the estimated 1352-1611 clutches laid during the 14 nights, 6-19 July 1991, indicate that in excess of 2200 female *N. depressus* were breeding at Crab Island during the 1991 breeding season. While there are insufficient data to identify any changes in the size of this nesting population since it was last surveyed during 1976-1979 (Limpus et al., 1983a), Crab Island continues to support the largest recorded breeding aggregation for this marine turtle. However, it should be remembered that many *N. depressus* nest on the adjacent mainland and that the species also nests on the islands extending to the north throughout western Torres Strait (Limpus et al., 1989). The total annual breeding population for *N. depressus* in the Crab Island region (northeastern Gulf of Carpentaria and western Torres Strait) remains imprecise, but must number many thousands of females. There is still no evidence that Crab Island is of anything but minor importance for nesting by other marine turtle species.

As of March 1993, there has been only one reported feeding ground recapture, a female *N. depressus* from the south eastern Irian Jaya coast, out of the many turtles tagged while nesting in the Crab Island region (1040 *N. depressus*, 11 *E. imbricata*, 1 *L. olivacea*: Bustard, 1972; Limpus et al., 1983a; present study). There have been more than 50 recaptures of *N. depressus* reported from the east coast prawn fishery from inside the Great Barrier Reef (GBR) and central Torres Strait, which had been tagged while nesting at the central Queensland rookeries (Limpus et al., 1983b; C. J. Parmenter, pers. comm.). This suggests that the *N. depressus* population nesting at Crab Island does not migrate from the feeding areas along the eastern Queensland coast. No tagged *N. depressus* from Crab Island has been reported from the northern prawn fishery of the Gulf of Carpentaria and southern Arafura Sea even though several thousand *N. depressus* are captured annually as part of the by-catch of the northern prawn fishery (Poiner & Harris, 1993). This lack of *N. depressus* tag recoveries within the northern prawn fishery contrasts with the occurrence of tag recoveries of *C. caretta* from eastern Australian rookeries in the same fishery (Limpus et al., 1992; Limpus & Reimer, 1993). This suggests that the Gulf of Carpentaria is not a significant feeding area for the *N. depressus* that nest at Crab Island. The one long distance tag recovery demonstrates that the feeding distribution of the Crab Island nesting population extends northwards at least to the southern Irian Jaya coast.

Turtle nesting and hatchling emergence have been recorded at Crab Island on all previous visits (April, May, July, August, November and December) with a seasonal variability in density (Limpus et al., 1983a). The limited data from 1991 also show seasonal variability in nesting density. The high density nesting in July (average 133 beachings per night on the whole beach and

44 beachings per night in sector 5; 77-85% nesting success) contrasts with the low number of clutches emerging at the same time (average 4 emerging clutches per night in sector 5). Because the incubation time for marine turtle eggs is approximately two months, in the absence of evidence of extensive clutch destruction or harvest at Crab Island, these data suggest that the July 1991 nesting density was approximately 10 times the magnitude of the nesting density two months earlier in May 1991. The 6-19 July 1991 nesting density appears to be considerably greater than the density recorded in 15-19 July 1978 but included nights with similar nesting density to that recorded on 13-14 August 1979 (Limpus et al., 1983a). This apparent increase in nesting population as indicated by the July nesting densities could have three different explanations: 1, this between-year vari

ability could be the result of natural annual fluctuations in the nesting population as has been recorded for *C. mydas* in eastern Queensland (Limpus & Nicholls, 1988); 2, the timing of the peak of the nesting season may vary between months in different years; 3, there may have been an increase in the size of the nesting population. Because of the high fidelity that *N. depressus* displays to particular small nesting beaches (Limpus et al., 1984) the possibility that the apparent increase in the Crab Island nesting population could have resulted from inter-rookery movements is dismissed. More extensive surveys of the rookery are needed before the stability of this population can be reliably assessed. Given the extended breeding season and the wide nesting distribution in western Torres Strait, Crab Island and northwestern Cape York Peninsula, the size and distribution of the breeding population cannot be adequately surveyed by brief visits to single localities as has been the pattern to date.

The data collected on this survey of *N. depressus* from Crab Island (Tables 1,2) provide additional support for the conclusion that the *N. depressus* nesting population from the Crab Island region consists of smaller nesting females laying comparable sized clutches of smaller eggs than those of the nesting population at the southern GBR rookeries (Limpus et al., 1989). The hatchling productivity from undisturbed clutches at Crab Island remains comparable to that recorded in previous studies (Limpus et al., 1983a).

The mid-year high density *N. depressus* nesting and associated incubation of eggs at Crab Island spans the months of lowest rainfall and daily air temperature (Fig. 2). This dry season nesting also coincides with the predominantly south easterly winds. Therefore the majority of the turtle nesting occurs on beaches with a westerly aspect; these are usually leeward to the prevailing winds and are therefore less likely to be eroded by wind driven surf when most eggs are incubating. Also, by nesting in the dry season, the turtles might be avoiding egg loss through flooding that could result from a raised water table below the dunes during the wet season.

The sand temperature (mean±SD) at 50cm depth in the nesting habitat for 6-21 July 1991 of 27.6±0.49°C was the lowest recorded in any month at Crab Island (12 Dec. 1976 = 29.6± 1.32°C, 8-10 Dec. 1978 = 31.4±0.88°C, 27 April-7 May 1978 = 29.4±1.21°C. Limpus et al., 1983a) or at Deliverance Island (2-4 October 1987 = 29.4±0.95°C. Limpus et al., 1989). However, the year round sand temperatures at nest depth in the Crab Island area remain above 24°C, the approximate lower limit for successful incubation of marine turtle eggs from all species (Miller, 1985). This facilitates the observed all year round successful nesting by marine turtles in the Crab Island region, although the mid-summer sand temperatures approach 34°C which is the approximate upper lethal incubation temperature for marine turtle eggs (Miller, 1985). In contrast, at the rookeries in central and southern Queensland, the winter sand temperatures at nest depth fall below 24°C and consequently, successful marine turtle nesting can only occur there during the warmer summer months (Limpus, 1971; Limpus et al. 1981). In northern Australia there has probably been a selective advantage for marine turtles to aggregate their nesting into the mid-year when sand temperatures are well separated from the lethal limits of incubation temperature (Guinea 1993).

The pivotal temperature, the theoretical temperature at which a 1:1 sex ratio could be expected, is not fixed for *Caretta caretta* or *Chelonia mydas* but varies between breeding units. While within each breeding unit, the species reproduces regionally on beaches that provide a range of nest temperatures spanning the pivotal temperature (Limpus et al., 1983c; C. Limpus, unpublished data). The pivotal temperature for *N. depressus* from the southern GBR region is 29.5°C, ranging from 100% male hatchling production at 28°C to 100% females at 31°C (C. Limpus, unpublished data). Based on the recorded sand temperatures at Crab Island (see above), if the Crab Island region population had

the same pivotal temperature as the southern GBR population, Crab Island would be producing mostly male hatchlings during the mid-year high density nesting, while mostly females would be produced from the low density summer nesting. However, if the Crab Island region nesting population is part of a separate breeding unit from the southern GBR population, then different pivotal temperatures could occur for the populations. This would then allow for the possibility of the Crab Island nesting population fitting the model that a turtle breeding unit chooses its nesting beaches such that its pivotal temperature occurs within the range of sand temperatures at nest depth that is available during the main nesting season. This would require that the Crab Island region and southern GBR nesting populations represent different *N. depressus* breeding units. The differences in adult and egg size between the northeastern Gulf of Carpentaria and southern GBR *N. depressus* populations also support the hypothesis that these populations are separate stocks. A precise estimate of the *N. depressus* hatchling sex ratio from Crab Island cannot be made from the available data.

The local peoples of northern Cape York Peninsula, western Torres Strait and Irian Jaya harvest small numbers of adult *N. depressus* and numerous clutches of eggs annually from this population (Johannes & MacFarlane, 1991; Limpus et al., 1983a, 1989; present study). The impact of each of these village-based harvests should not be considered in isolation. Indeed, the harvest at any one nesting beach or by any one village should be assessed within the regional context of the total breeding population. In relation to this, the significance of egg losses through harvest and predation to the regional population poses major uncertainties. If the mainland beaches have a different sand composition and hence sand colour, they would have a different temperature profile from the islands. In particular, darker sands would be warmer and result in a higher proportion of females from these mainland beaches (c.f. the situation for *Caretta caretta* in southeastern Queensland, Limpus et al., 1983c). The indicated high predation levels by pigs, dingoes and varanid lizards on the eggs laid on the mainland beaches has the potential for threatening the survival of the entire population in the long term. The observed egg harvest by local people of a few clutches each week from Crab Island could be sustainable during the mid-year high density nesting. However, if the rate of harvest is constant throughout the year and the off-peak nesting produces mostly female hatchlings, then the loss of additional female hatchling production through egg harvest must be considered in conjunction with the impact of the egg predation on mainland clutches. In addition, what impact the drowning hundreds of *N. depressus* annually in fishing gear in the northern prawn fishery (Poiner & Harris, 1993) and other Gulf of Carpentaria fisheries (P. Couper, unpublished data) has on the Crab Island nesting population needs clarification. These *N. depressus* mortalities in the dispersed feeding areas represent additional losses to this population that have commenced in recent decades. Before it can judged as to whether the current level of harvest of *N. depressus* eggs and turtles by the local peoples from these rookeries of the northeastern Gulf of Carpentaria and western Torres Strait is sustainable, the breeding unit of these turtles needs to be aligned to geographic boundaries and population size and anthropomorphic mortality for the population throughout its range quantified. In addition hatchling productivity and associated sex ratio should be quantified from the significant rookeries within the region. When these types of data are available, the long term viability of this most significant *N. depressus* population and the associated harvests can be more reliably assessed.

ACKNOWLEDGEMENTS

This research was conducted as a collaborative project between the Queensland Turtle Research Project of the Queensland Department of Environment and Heritage and the Queensland Museum. Permission to conduct the research on Crab Island was granted by the Injinoo Community Council. The Thursday Island meteorological data were supplied by the Australian Bureau of Meteorology. George, Sandyl, Nicky and Zoe Kyriazis, Nola Collins and Elizabeth Evans assisted in tagging and field data collection. George Kyriazis, in addition, provided the transport for the team between Bamaga and Crab Island and assisted in establishing the camp. Jeff Wright printed the photographs. Bronwyn Perkins prepared the map. This assistance is gratefully acknowledged.

PANDARID COPEPODS PARASITIC ON SHARKS FROM NORTH QUEENSLAND WATERS. *Memoirs of the Queensland Museum 33(1): 290. 1993:-* The Pandaridae are ectoparasitic caligoid copepods exclusive to elasmobranchs. 38 species are known worldwide (Cressey, 1967, 1970; Rangnekar & Rangnekar, 1972; Cressey & Boyle, 1978; Cressey & Simpfendorfer, 1988).

In a checklist of fish parasites from Australian waters, Beumer et al. (1983) listed 8 pandarid species based on records in two published studies of Australian copeopod parasites (Heegaard, 1962; Kabata, 1966). Beumer et al. (1983) followed Cressey (1967) in synonymising *Dinematura* Burmeister, 1833 with *Dinemoura* Latreille, 1829. However, they did not follow Cressey by regarding *Nesippus australis* Heegaard, 1962 and *N. incisus* Heegaard, 1962 as separate from *N. orientalis* Heller, 1868, or by regarding *Perissopus serratus* Heegaard, 1962 as separate from *P. dentatus* Steenstrup & Lütken, 1861. Beumer et al. (1983) thus contained 6 valid species: *Dinemoura latifolia* (Steenstrup & Lütken, 1861), *D. producta* (Müller, 1785), *Echthrogaleus coleopratus* (Guérin-Méneville, 1837), *Nesippus orientalis* Heller, 1868, *Pandarus bicolor* Leach, 1816, and *Perissopus dentatus* Steenstrup & Lütken, 1861. Cressey & Simpfendorfer (1988) added *Pseudopandarus australis* to the species known from Australian waters. This note reports the occurrence of 3 pandarid species on sharks from Cleveland Bay (19°15'S, 146°50'E), north Queensland, and provides information on their hosts. Sharks were caught between Feb. 1986 and Jan. 1988 using gillnets, longlines, otter trawls and handlines. The parasites were identified using keys in Yamaguti (1963) and Cressey (1967).

Three species were identified: *Pandarus niger* Kirtesinghe, 1950 (QMW12207, 12212); *Perissopus dentatus* Steenstrup & Lütken, 1861 (QMW12208, 12209, 12456, 12462, 12464); and *Pseudopandarus australis* Cressey & Simpfendorfer, 1988 (QMW12210, 12211). The occurrence of *P. niger* is a new record for Australian waters. It has previously been reported from Sri Lanka (Kirtesinghe, 1950) and Taiwan (Cressey, 1967) on sharks from the family Carcharhinidae. It is widespread in tropical Australian waters, regularly occurring on *C. sorrah* in the Northern Territory (J. Lyle, pers. comm.; QMW12460, 12461).

Sharks	Specimens examined	*Pandarus niger*	*Perissopus dentatus*	*Pseudopandarus australis*
Carcharhinus dussumieri	16	-	100	12.5
C. fitzroyensis	30	-	50	-
C. macloti	1	-	-	-
C. sorrah	28	21.4	21.4	-
C. tilstoni	45	-	91.4(2.2)	
Rhizoprionodon acutus	47	-	-	61.7(2.1)
R. taylori	201	-	1.0	36.8(3.0)
Hemigaleus microstoma	4	-	75	25(25)
Sphyrna lewini	91	1.1	10.6	1.1
S. mokarran	1	-	100	-

Table 1. Rates of occurrence of pandarid copepods on sharks of Carcharinidae(C), Hemigaleidae(H), and Sphyrnidae (S). Rates given are for females; where present, rate for males given in brackets.

P. dentatus is abundant and widespread in tropical and subtropical oceans, and previous workers have reported it from 29 species of shark (Yamaguti, 1963; Cressey, 1967, 1970; Hewitt, 1967; Russo, 1975; Beumer et al., 1983). Only one of the 8 host species of *P. dentatus* recorded for Cleveland Bay (*Sphyrna lewini*) has previously been reported (Hewitt, 1967).

Rates of occurrence were variable between both host and pandarid species, with female pandarids occurring more frequently, and on more host species, than males (Table 1). The three families of sharks on which the pandarids were recorded are all active, free swimming and closely related (Compagno, 1988). Two benthic shark species (*Chiloscyllium punctatum* and *Stegastoma fasciatum*) — from a different order — had no pandarids on them.

A HUMPBACK WHALE CALF AND TWO SUBADULT DENSE-BEAKED WHALES RECENTLY STRANDED IN SOUTHERN QUEENSLAND

R.A. PATERSON, C.J. QUAYLE AND S.M. VAN DYCK

Paterson, R.A., Quayle, C.J. & Van Dyck, S.M. 1993 06 30: A Humpback Whale calf and two subadult Dense-beaked Whales recently stranded in southern Queensland. *Memoirs of the Queensland Museum* **33**(1): 291-297. Brisbane. ISSN 0079-8835.

A new born Humpback Whale calf (*Megaptera novaeangliae*) and two subadult Dense-beaked Whales (*Mesoplodon densirostris*) recently stranded on the southern Queensland coast. The *M. densirostris* skeletons were recovered together with various soft tissue material. The post-cranial skeleton of the *M. novaeangliae* was not recovered. The larynges of the three specimens were examined in detail. □ *Humpback Whale, Dense-beaked Whale, stranding, Queensland.*

R.A. Paterson & S.M. Van Dyck, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; C.J. Quayle, Brisbane Clinic, 79 Wickham Terrace, Brisbane, Queensland 4000, Australia; 2 December, 1992.

Opportunities to examine stranded balaenopterid and ziphiid whales, with the exception of Minke Whales (*Balaenoptera acutorostrata*), on the Queensland coast are limited (Paterson & Van Dyck, 1990, 1991). Recently, material recovered from a new born Humpback Whale *Megaptera novaeangliae* and two subadult Dense-beaked Whales *Mesoplodon densirostris* was a valuable addition to the cetacean collection in the Queensland Museum. The *M. novaeangliae* specimen is registered JM8658 and the *M. densirostris* specimens are registered JM8807 and JM9640.

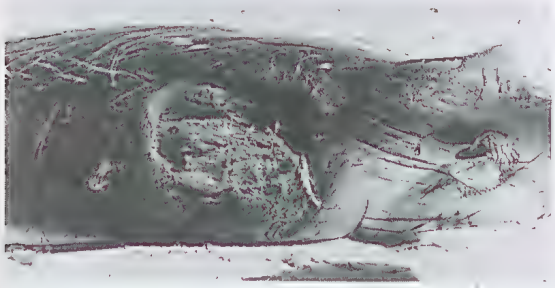

FIG. 1. Shark bites on left side of *Megaptera novaeangliae* JM8658. The anterior bite extended deeply into the thoracic muscles.

SPECIMEN DESCRIPTIONS

HUMPBACK WHALE

JM8658 was a 4.7m long new born (umbilicus unhealed) female that stranded alive during the afternoon of 19 July, 1991 at Eager's Creek (27°07'S, 153°27'E) on the oceanic shore of Moreton Island. Two large non-bleeding shark bites were noted on the left side of the body as

FIG. 2. Extensive superficial rakes on *Megaptera novaeangliae* JM8658. They are considered to be caused by sharks.

well as numerous superficial rakes (Figs 1,2). The whale was refloated and pushed into the surf but was found dead at the same location a few hours later. We examined the carcass three days later. The larger of the previously noted bites extended deeply into the thoracic muscles and its edges showed signs of early healing indicating that the shark attack was not an immediate pre-stranding event.

Material collected included the skull and mandible, blubber and skin samples (the latter for

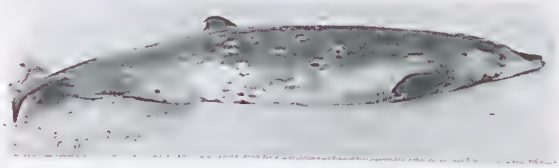

FIG. 3. Recent and healed 'cookie-cutter' lesions on *Mesoplodon densirostris* JM8807.

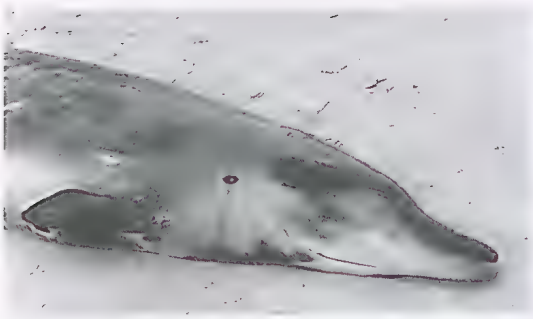

FIG. 4. Close-up view of 'cookie-cutter' lesions on *Mesoplodon densirostris* JM8807. The throat groove characteristic of ziphiids is also demonstrated.

DNA study) and the larynx. The mid-dorsal blubber thickness was 2.8cm and is consistent with recent birth. Comparative blubber thicknesses from a *M. novaeangliae* calf, approximately four weeks old, and a yearling in the Queensland Museum collection are 4.5cm and 9.7cm respectively. The right baleen row numbered 340 ± 5, consistent with the range for the species (Matthews, 1937). The largest baleen plates measured 8.5cm in length.

The stranding of a new born *M. novaeangliae* at latitude 27°S in July confirms previous sighting reports (Chittleborough, 1965; Paterson & Paterson, 1984, 1989) that occasional calving occurs during the northern migration of the species along the Australian coast at latitudes higher than those

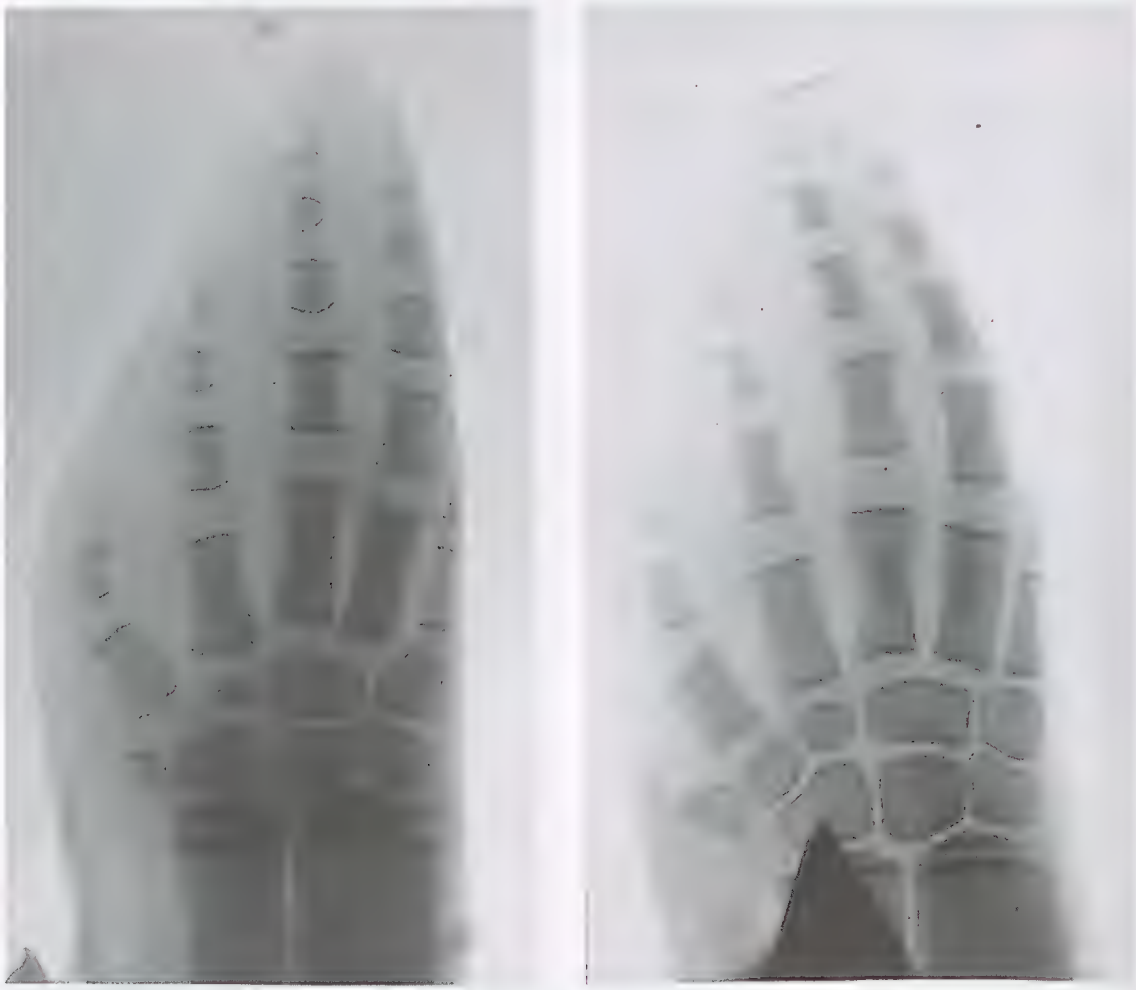

FIG. 5. Left, *Mesoplodon densirostris* JM8807. Radiograph of left pectoral flipper demonstrating distal aspects of radius and ulna, carpus, metacarpals and phalanges. Skeletal immaturity is evident. The ossification centre for the peripheral unciform has not yet appeared. Right, *Mesoplodon densirostris* JM9640. Radiograph of left pectoral flipper showing eight carpal bones compared with seven in JM8807. (The triangular structure overlying the distal ulna is frozen soft tissue from the axillary region.)

at which calving is generally considered to occur (Chittleborough, 1953; Simmons & Marsh, 1986; Townsend, 1935).

Dense-beaked Whales

JM8807 was a 3.8m long female found dead at dawn on 22 October, 1991 at Main Beach, Point Lookout (27°26'S, 153°33'E) on North Stradbroke Island. Recent and healed superficial 'cookie-cutter' lesions were noted and they coalesced ventrally (Figs 3,4). They were similar to, but not as extensive as, those noted in a mature male *M. densirostris* described by Paterson & Van Dyck (1990). The whale was dark grey dorsally and lighter grey ventrolaterally, particularly in the umbilical and genital regions and around the V-shaped throat groove characteristic of ziphiids.

We examined the carcass the day after its discovery. The entire skeleton was collected. The vertebral formula C7; T9; L10; Cdl8=44 is less than counts of 46 and 47 in two *M. densirostris* from the Atlantic coast of North America and 45 in a specimen from Lord Howe Island (Raven,

FIG. 6. *Mesoplodon densirostris* JM8807: left, dorsal aspect of skull; right, dorsal aspect of mandible.

FIG. 7. *Mesoplodon densirostris* JM8807. Left lateral mandibular radiograph demonstrating unerupted tooth characteristic of females.

1942) but is within the range described by Ross (1984). The size discrepancy between the penultimate and last caudals suggests the possibility that one caudal was lost during preparation. With the exception of the coalesced proximal three cervical vertebrae, the central epiphyses of all vertebrae were unfused. The phalangeal formula, derived from a radiograph of the left pectoral flipper (Fig. 5), is I:1, II:4, III:4, IV:3, V:2, which differs slightly from that reported by Kasuya & Nishiwaki (1971) in a Formosan specimen of *M. densirostris*. They (p.133 & fig.1) appear to have included the metacarpals in the formula. The skull and mandible are shown in Fig. 6. The characteristically shaped unerupted mandibular tooth of female *M. densirostris* is demonstrated radiographically in Fig. 7. The tooth measured 52mm in height, 30mm in length and 9mm in greatest diameter. Its pulp cavity was completely unfilled.

Moderate nematode (*Anisakis* sp.) and acanthocephalan (*Bolbosoma vasculosum*) infestation was noted in the stomach and intestine respectively. The gastro-intestinal tract was otherwise empty.

One ovary was collected. Its external features are shown in Fig. 8. Histological examination was reported as follows:

The ovary contains numerous primordial follicles, a few secondary follicles, occasional cystic atretic follicles and some small hyaline scars which may represent corpora albicans. No corpora lutea can be identified.

The presence of secondary follicles indicates sexual maturity is, at least, approached. It is uncertain whether ovulation has occurred. If the small scars are true corpora albicans this would indicate that ovulation had taken place but the evidence is insufficient to establish this with certainty.

Although the ovarian histological evidence indicates that this 3.8m long animal was approaching sexual maturity, the lack of epiphyseal fusion indicates physical immaturity. The dental, sexual and physical development of JM8807 was similar to that of the 3.56m long Formosan specimen described by Kasuya & Nishiwaki (1971).

JM9640 was a 3.65m long female found dead during the morning of 21 June, 1992 at Cathedral

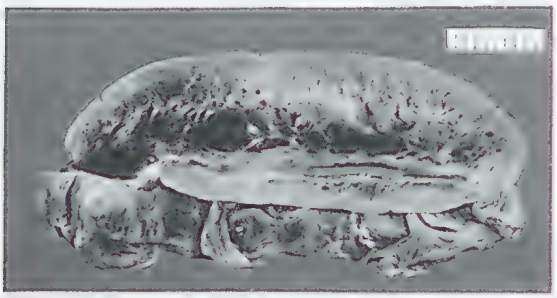

FIG. 8. *Mesoplodon densirostris* JM8807. External ovarian features. Scale in mm.

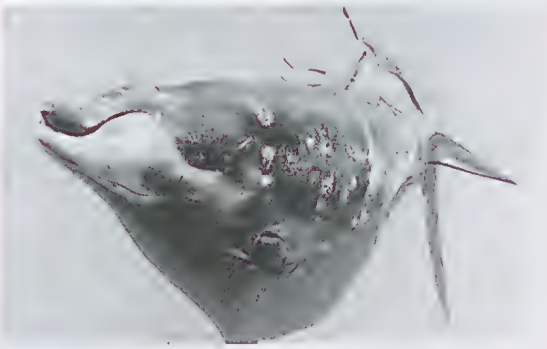

FIG. 9. 'Cookie-cutter' lesions and characteristic throat groove of ziphiids on *Mesoplodon densirostris* JM9640.

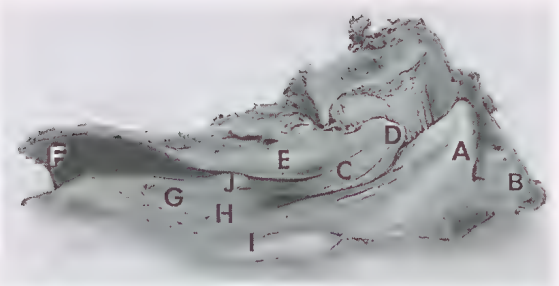

FIG. 10. Larynx *Megaptera novaeangliae* JM8658 in longitudinal section, medial aspect, with thyroid cartilage removed: (A) epiglottic cartilage; (B) fibrous attachment to thyroid cartilage; (C) arytenoid cartilage-corpus; (D) arytenoid cartilage-rostral end; (E) cricoid cartilage; (F) tracheal lumen; (G) fundus of ventral diverticulum; (H) neck of the ventral diverticulum; (I) thyroarytenoid muscle; (J) interarytenoid fibro elastic connection.

Beach (25°10'S, 153°13'E) on Fraser Island. 'Cookie-cutter' lesions of similar distribution to those on JM8807 were evident as well as the characteristic throat groove (Fig. 9).

We were unable to visit the stranding site to examine the whale but arranged for its head and a pectoral flipper to be removed and frozen so that they could be subsequently studied in a fresh state. The remainder of the carcass was buried in sand dunes behind the beach and the skeleton was retrieved two months later. The vertebral epiphyseal status and vertebral formula (C7; T9; L10: Cdl8 = 44) were identical to JM8807 but the last caudal may have been lost. Unfortunately numerous rib and vertebral fractures had occurred during transportation of the carcass to the sand dunes and those fractures detract from the specimen's quality.

The phalangeal formula I:1, II:4, III:4, IV:3, V:2 is identical to JM8807. The carpus contains eight bones (Fig. 5) compared with seven in JM8807 and the Formosan specimen. Raven (1942) demonstrated eight carpal bones in an adult male *M. densirostris*. We presume that the ossification centre of the peripheral unciform had not yet developed in either JM8807 or the Formosan specimen but are surprised at the apparent late development of this bone which is larger than its neighbours in both JM9640 and the specimen illustrated by Raven (1942).

The left tooth measured 54mm in height, 47mm in length and 10mm in greatest diameter. Its pulp cavity was extensively obliterated. On the basis of the dental and carpal development we conclude that JM9640 was more mature than JM8807.

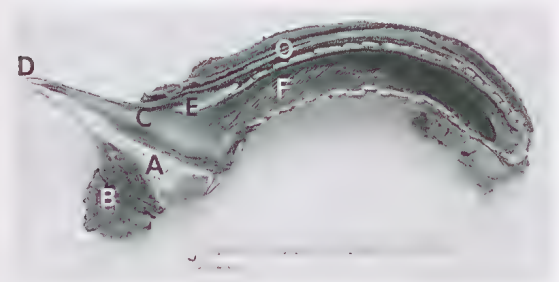

FIG. 11. Larynx *Mesoplodon densirostris* JM8807 in longitudinal section, medial aspect, with thyroid cartilage removed. (A) epiglottic cartilage; (B) fibrous attachment to thyroid cartilage; (C) arytenoid cartilage-corpus; (D) arytenoid cartilage-rostral end; (E) cricoid cartilage; (F) tracheal lumen; (O) oesophagus.

Laryngeal Structure

Various authors, including Benham (1901) and Hosokawa (1950), have compared the larynges of mysticetes and odontocetes. The former are characterised by a large ventral diverticulum surrounded by the thyro-arytenoid muscle and the latter by the aryteno-epiglottideal tube, an upward extension of the fused arytenoid and epiglottic cartilages into the choana. Those features have been demonstrated in JM8658, JM8807 and JM9640.

FIG. 12. Larynx and oesophagus *Mesoplodon densirostris* JM8807 from dorsal aspect. The bossed tip of the aryteno- epiglottideal tube is shown on the right. (C) arytenoid cartilage-corpus; (D) arytenoid cartilage-rostral end; (F) trachea; (O) oesophagus.

The larynx of JM8658 is shown in longitudinal section in Fig. 10 and the salient anatomical structures have been annotated in conformity with the description by Quayle (1991) of the larynx of a male *M. novaeangliae* of similar development to JM8658. There is no appreciable difference between those male and female specimens.

Quayle (1991) considered that phonation could occur between the apposing arytenoids in mysticetes although true vocal cords were not evident. He also proposed a functional role for the ventral diverticulum in the production of the complex sounds of *M. novaeangliae*. Mysticetes presumably generate high pressures within the oral cav-

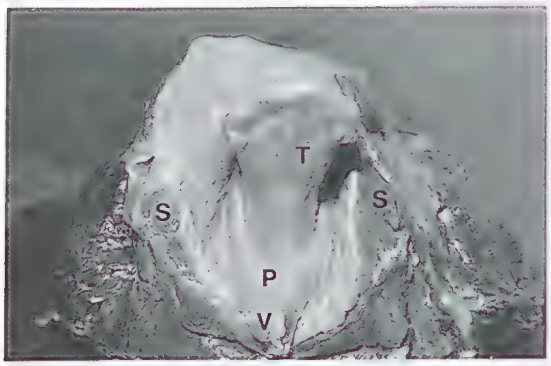

FIG. 13. Laryngo-pharynx *Mesoplodon densirostris* JM9640 from rostral aspect. (P) palato-pharyngeus; (S) superior constrictor of pharynx; (T) aryteno-epiglottideal tube; (V) vomerine attachment of palato-pharyngeus.

ity and pharynx during feeding when large volumes of water are forced through the baleen. The ventral diverticulum may have an additional function in assisting to prevent water from entering the trachea.

The larynx of JM8807 is shown in longitudinal section (Fig. 11) as well as from its dorsal aspect (Fig. 12). The aryteno- epiglottideal tube is bossed at its tip and was closely applied to the posterior narial canal. The almost complete fusion of the arytenoid and epiglottic cartilages and their relationship to the posterior nares more effectively separates the aero-digestive tracts in this odontocete compared with JM8658.

The fresh laryngo-pharynx of JM9640 is shown in Figs 13,14,15. In Fig. 13 the aryteno-epiglottideal tube is demonstrated from the rostral aspect and a large muscular cuff (the superior constrictor of the pharynx) is noted peripherally. The margin of this muscle has been dissected from the bony posterior choana. A circular muscle, whose margin was partially separated from the superior constrictor appeared to 'grip' the aryteno- epiglottideal tube. This circular muscle is the palato-pharyngeus (Hosokawa, 1950) and it had an anterior attachment to the vomer. The disposition of the superior constrictor and the palato-pharyngeus to the aryteno-epiglottideal tube in the lateral position is demonstrated in Fig. 14. We postulate that the superior constrictor in combination with the palato-pharyngeus may act inter alia to expel water from the choanal region. In Fig. 15 the laryngo-pharynx is shown in wider perspective and the palato- pharyngeus has been partially retracted. A large probe has been passed through the oro-pharynx. It traverses the pyriform fossa (which is beside the larynx) and enters the oesophagus. This further demonstrates the separation of the aero-digestive tracts in this odontocete.

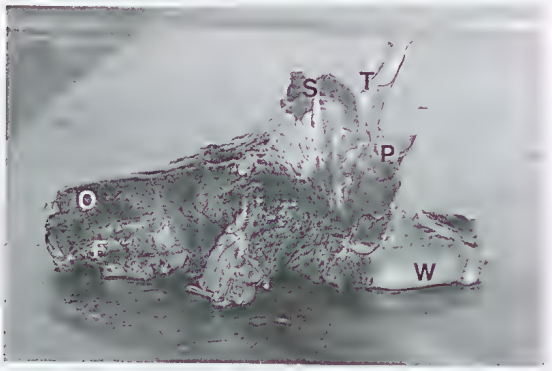

FIG. 14. Laryngo-pharynx *Mesoplodon densirostris* JM9640 from lateral aspect. (F) trachea; (O) oesophagus; (P) palato-pharyngeus; (S) superior constrictor; (T) aryteno-epiglottideal tube; (W) oro-pharynx.

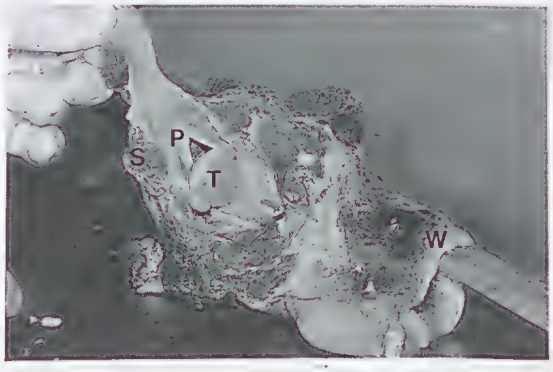

FIG. 15. Laryngo-pharynx *Mesoplodon densirostris* JM9640 from dorso-rostral aspect. The large probe is seen in the oro- pharynx. It was passed through the left pyriform fossa to enter the oesophagus which is obscured by the retracted superior constrictor and palato-pharyngeus. (P) palato-pharyngeus; (S) superior constrictor; (T) aryteno-epiglottideal tube; (W) oro-pharynx.

In this fresh specimen it was not possible to retract the aryteno-epiglottideal tube. Pilleri (1979) considered, on the basis of acoustic experiments, that the aryteno-epiglottideal tube was retracted during deglutition and disagreed with Rawitz (1900) who stated that food passed to the side of the larynx. Our opinion, based on morphological considerations, concurs with that of Rawitz.

ACKNOWLEDGEMENTS

We are indebted to many people who assisted with retrieval and preparation of the specimens. Alan Genninges of the Moreton Island Protection

Committee photographed JM8658 and Reg Lambert photographed JM8807. Brendan McLarty of QNPWS secured JM8658 and transported us to the stranding site. Lis Sedlak-Weinstein of the University of Queensland examined JM8807 for parasites and assisted with retrieval of the specimen. John Ford of QNPWS photographed JM9640 and secured the specimen. Paul Stumkat of the Queensland Museum retrieved its skeleton. John Musgrave of Sullivan, Nicolaides and Partners arranged the histological examination of JM8807 and Stephen Marmo of the X-ray Department, Royal Brisbane Hospital took the radiographs. Bruce and Carolyn Cowell patiently and skilfully photographed and prepared material at the Queensland Museum and Jeff Wright took some of the laryngeal photographs.

BRACONINE WASPS OF AUSTRALIA

DONALD L. J. QUICKE AND SIMON N. INGRAM

Quicke, D.L.J. & Ingram, S. N. 1993 06 30: Braconine wasps of Australia. *Memoirs of the Queensland Museum* 33(1): 299-336. Brisbane. ISSN 0079-8835.

An illustrated key to the 45 genera of Braconinae known from Australia is provided. *Pycnobraconoides* gen.nov. (type species: *Ichneumon mutator* Fabricius) is described and illustrated. Thirteen new species are described and illustrated: *Acrocerilia tricolor* sp.nov. (Queensland); *Africadesha tobiasi* sp.nov. (Queensland); *Atanycolus australiensis* sp.nov. (Queensland); *Calcaribracon willani* sp.nov. (Queensland); *Furcadesha walteri* sp.nov. (Queensland); *Myosoma rufescens* sp.nov. (Queensland); *Pedinopleura australiensis* sp.nov. (Queensland); *Simplicibracon nigritarsus* sp.nov. (Queensland); *Testudobracon australicolorus* sp.nov. (Queensland); *Testudobracon tatyanae* sp.nov. (Queensland); *Testudobracon unicolorus* sp.nov. (Queensland); *Trigastrotheca tricolor* sp.nov. (Queensland) and *Virgulibracon endoxylaphagus* sp.nov. (Queensland). *Poecilobracon* Cameron is treated as junior synonym of *Callibracon* Ashmead. *Bracon froggatti* Cameron is transferred to *Pycnobraconoides* gen.nov. Nine genera are recorded from Australia for the first time: *Acrocerilia* van Achterberg; *Africadesha* Quicke, *Atanycolus* Foerster, *Furcadesha* Quicke, *Gelasinibracon* Quicke, *Paranesaulax* Quicke, *Rostraulax* Quicke, *Trigastrotheca* Cameron and *Vipiomorpha* Tobias. *Calcaribracon diores* (Cameron) is recorded from Australia for the first time. Notes are provided on the distributions and biologies (when known) of all the genera. □ *Hymenoptera, Braconidae, Braconinae, wasp, parasite, Australia, key, new genera, new species, synonymy.*

Donald L.J. Quicke & Simon N. Ingram, Department of Animal and Plant Sciences, University of Sheffield, Sheffield S10 2TN, United Kingdom (address correspondence to DLJQ); 13 July, 1992.

The Braconinae is a huge, cosmopolitan subfamily of parasitic wasps with nearly 5000 described species (Shenefelt, 1978) distributed among more than 200 genera worldwide. The vast majority of species are ectoparasitoids principally on coleopterous and lepidopterous hosts though a few attack Diptera, Hymenoptera-Symphyta and possibly Homoptera and one group, the Aspidobraconina, are endoparasitic on butterfly pupae.

Only a minority of extant species have been described and there are also undoubtedly numerous new genera awaiting discovery, the Australian fauna of braconine wasps being particularly poorly known. The last generic key dealing specifically with Australia is that of Szépligeti (1906) which included 10 genera. More recently, Parrott (1953) catalogued the Australian Braconinae listing 12 genera compared with the 45 now known to occur there. More Australian species can be identified to genus with the key to the Old World genera provided by Quicke (1987b). However, since that time, several new Australian genera have been described (Quicke, 1988c, 1989d; Quicke & Tobias, 1990) and it is therefore thought that the presentation of an illustrated key to the Australian genera would be both timely and would encourage much needed investigation of Australian braconine wasp biology.

TERMINOLOGY AND COLLECTIONS

Terminology follows that of van Achterberg (1979, 1988). Wing veins are measured from the centres of their junctions (except for forewing vein r and where otherwise stated), length of head is measured perpendicular to the face (re: couplet 34), length of femur excludes trochantellus and ovipositor length refers to that part which would normally project beyond the apex of the metasoma when directed posteriorly as in most set specimens.

Abbreviations for museums are: American Entomological Institute, Gainesville (AEIG); Australian Museum, Sydney (AMSA); Australian National Insect Collection, Canberra (ANIC); Hungarian Natural History Museum, Budapest (HNHM); Natural History Museum, London (BMNH); Queensland Department of Primary Industries, Indooroopilly, Brisbane (QDPI); Queensland Museum, South Brisbane (QMBA); Quicke Collection, Sheffield (QC).

KEY TO THE GENERA AND SUBGENERA OF AUSTRALIAN BRACONINAE (♀♀ ONLY)

The following key is arranged so as to obtain reasonably quick identification of Australian genera and thus the first key character is chosen so as to divide the known genera into two, roughly equal-sized groups. By reference to Figures 27-35 the shape of the scapus of the great majority of specimens encountered should be unambiguously assignable to one category or the other. The few genera with species showing variation or intermediate conditions (notably in the Aphrastobraconina, viz *Cedilla*, *Curriea*, *Ligulibracon*, *Megalommum* and *Undabracon* and especially *Eucurriea*) are allowed for by a loop. To assist further with use of couplet 1, and to help allow for specimens in which both antennae are missing, a list of unique characters for genera and groups is provided in Table 1.

1. Scapus shorter ventrally than dorsally in lateral aspect when directed anteriorly, usually small (Figs 27, 28, 31, 47, 48, 75, 76, 81, 85), not emarginate medially (Fig. 47) and at most only weakly emarginate laterally (Figs 31, 47) (see Table 1 in case of uncertainty) 2
   - Scapus at least as long or longer ventrally than dorsally in lateral aspect when directed anteriorly, often cylindrical and large (Figs 32-35, 39, 44, 80), usually with well-developed apico-medial and apico-lateral emarginations 32
2. Forewing vein CU1a arising at the same level as 2-CU, vein CU1b much longer than 3CU-1 if the latter is distinct (Fig. 12) (Adeshini) 3
   - Forewing vein CU1a arising well below the level of 2-CU, vein 3CU-1 at least as long as and usually much longer than vein CU1b (Figs 13, 15-19, 94-100) 4
3. Posterior margin of 5th metasomal tergite strongly produced on either side of the midline (Figs 110, 111) ..... *Furcadesha*
   - Posterior margin of 5th metasomal tergite not produced sub- medially ..... *Africadesha*
4. First metasomal tergite fused to metasomal syntergite 2+3, the junction between tergites 1 and 2 being represented by a crenulate sulcus (Figs 74, 121) (Aspidobraconina) 5
   - First metasomal tergite movable joined to metasomal syntergite 2+3, there being a normal arthrodial intersegmental membrane between tergites 1 and 2 (Figs 59-71) 6
5. Median area of metanotum with a complete mid-longitudinal carina; dorsal carinae of 1st metasomal tergite running separately to posterior margin of tergite; base of hindwing with a glabrous area; median lobe of mesoscutum with a pair of submedial, longitudinal grooves anteriorly; 6th tergite with relatively shallow peri-basal, transverse groove (Fig. 121) ..... *Pedinopleura*
   - Median area of metanotum without a complete carina (Fig. 105); dorsal carinae of 1st metasomal tergite uniting mid-posteriorly well before posterior margin of tergite (Fig. 74); base of hindwing more or less evenly setose; median lobe of mesoscutum without sub-medial longitudinal grooves anteriorly; 6th tergite with deep peri-basal, transverse groove (Fig. 115) ..... *Hyboteles*
6. Propodeum with a complete, lamelliform mid-longitudinal carina (see Fig. 105) 7
   - Propodeum without a complete lamelliform mid-longitudinal carina or with only a short one posteriorly 12
7. Posterior margin of 6th metasomal tergite with a (usually) deep, narrow, semicircular, medial emargination (Figs 117, 118, 120) and (usually) tergites 3-5 distinctly roundly produced laterally (Figs 116, 119); metasomal syntergite 2+3 wider than long; ovipositor as long as or longer than the metasoma ..... *Testudobracon*
   - Posterior margin of 6th metasomal tergite not narrowly emarginate medially nor roundly produced laterally (Fig. 113); metasomal syntergite 2+3 longer than wide (Figs 71, 73); ovipositor usually shorter than half the metasoma 8
8. Posterior margin of 6th metasomal tergite with a pair of submedian emarginations leaving a sharp median prominence (Figs 112, 113) .*Trigastrotheca*

Character	State	Go to key couplet
Scapus	petiolate, strongly or angularly narrowed at base with concave basal profile (Fig 44)	40
Propodeum	with a complete, mid-longitudinal (usually lamelliform) carina (Fig 105)	2
Forewing vein 3-CU1	absent or much shorter than vein CU1b (Figs 12, 89)	3
Forewing veins CU1b	much wider than posterior part of vein 3CU1 (Figs 21, 22, 94)	32
Claws	bifurcate (Figs 57, 58)	42
Basal lobe of claw	pointed or with small accessory tooth (Figs 52-54)	2
1st metasomal tergite	fused immovably to 2nd (Fig 74)	5

TABLE 1. Characters characterizing and unique to genera or groups of genera and key couplet to proceed from to complete identification

- Posterior margin of 6th metasomal tergite without submedial emarginations nor with a median prominence 9

9. Base of hindwing with a large glabrous area distal to, and approximately the same size as, the subbasal cell; scutellum with a well-developed pit medio-anteriorly; forewing vein r-m with only a single posterior bulla; forewing 2nd submarginal cell virtually parallel-sided, veins 3-SR and 2-M not noticeably converging distally ....*Acrocerilia*

- Base of hindwing more or less evenly densely setose with at most only a small glabrous area around vein 2-1A; scutellum without a medio-anterior pit; forewing vein r-m variable but often with a distinct bulla and associated flexion line anteriorly as well as posteriorly; forewing 2nd submarginal cell narrowing distally 10

10. Hindwing vein 2-SC+R transverse (Fig. 102); ovipositor (part extending beyond apex of metasoma) longer than the median length of the 2nd metasomal tergite; transverse median clypeal carina strongly protruding (Fig. 76)..... ..... *Simplicibracon*

- Hindwing vein 2-SC+R longitudinal (Fig. 101); ovipositor (part extending beyond apex of metasoma) shorter than medial length of 2nd metasomal tergite; transverse median clypeal carina less strongly protruding 11

11. Precoxal suture represented by a deep, smooth, medial, circular pit; 2nd metasomal suture interrupted medially at least by a strong ridge, usually by a wider area (Figs 71, 73); median area of metanotum with a complete mid-longitudinal carina.....*Gelasinibracon*

- Precoxal suture represented by an elongate distinctly sculptured impression; 2nd metasomal suture not interrupted medially; median area of metanotum bulbous, without a complete mid-longitudinal carina .....*Esengoides*

12. Basal lobes of claws at least angularly narrowing before the claw (Figs 53, 54), sometimes produced into a distinct tooth-like process (Fig. 52) 13

- Basal lobe of claws smoothly curved (Figs 55-57) 20

13. Hindwing with at least a pigmented line representing vein 3- CU (Fig. 14; separated from remainder of venation); basal lobe of claws produced into a tooth-like process (Fig. 52) 14

- Hindwing without vein 3-CU (Figs 15-19); basal lobe of claws angularly narrowed, but not toothed (Figs 53, 54) 15

14. Labio-maxillary complex elongate; hindwing vein 2-SC+R strongly transverse (Fig. 14) ....*Calcaribracon* (*Calcaribracon*)

- Labio-maxillary complex normal; hindwing vein 2-SC+R interstitial or longitudinal (see Fig. 101) .....*Calcaribracon (Arostrobracon)*

15. Shortest distance between 1st discal cell and 2nd submarginal cell of forewing at least 0.85 times shortest distance between 1st submarginal and 3rd submarginal cell (Fig. 15) .....*Tropobracon*

- Shortest distance between 1st discal cell and 2nd submarginal cell not more than 0.7 times shortest distance between 1st and 3rd submarginal cells (Figs 16, 17, 87, 89) 16

16. Marginal cell of forewing short, vein SR1 reaching wing margin less than 0.65 times the distance between the apex of the pterostigma and the wing tip (Fig. 16); propodeum largely sculptured .....*Vipiomorpha*

- Marginal cell of forewing longer, vein SR1 reaching wing margin more than 0.8 times the distance between the apex of the pterostigma and the wingtip (Figs 17-19); propodeum often smooth 17

17. First metasomal tergite very slender, more than 3.0 times longer than maximally wide (Fig. 70); forewing vein 1-SR+M straight or virtually so; metasoma completely smooth and shiny .....*Myosoma*

- First metasomal tergite less than 2.5 times longer than maximally wide (see Figs 65-67); forewing vein 1-SR+M straight or curved; metasoma variably sculptured 18

18. Forewing vein 1-SR+M strongly curved posteriorly after arising from vein 1-SR (Fig. 17; see also Fig. 91); median flagellomeres shorter than wide; metasoma completely smooth and shin ....*Mollibracon*

- Forewing vein 1-SR+M straight or weakly curved (see Figs 12, 13) or if strongly curved (some *Bracon* spp.) then the median flagellomeres are distinctly longer than wide; metasoma variably sculptured 19

19. Forewing vein 3-SR more than 1.6 times longer than vein r, usually more than 1.9 times longer (see Figs 87, 88); forewing vein r more or less straight (see Fig. 88).....*Bracon* (part)

- Forewing vein 3-SR less than 1.5 times longer than vein r, usually less than 1.2 times (Fig. 86); forewing vein r usually rather sinuous (Fig. 86) .....*Habrobracon*

20. Middle of clypeus strongly produced to form a massive beak- like process (Figs 9, 10)..... .....*Psittacibracon*

- Middle of clypeus at most with a lamelliform carina (Fig. 75) 21

21. Forewing vein CU1b much wider anteriorly than posterior part of vein 3-CU1 (Figs 21, 22, 94), 1st subdiscal cell being more or less strongly ovoid

or petiolate (Figs 21, 22, 94) (Aphrastobraconina part) 33

- Forewing vein CU1b not or hardly wider than posterior part of vein 3-CU1 (Figs 95-100), 1st subdiscal cell not ovoid or petiolate 22

22. Pedicellus large, highly petiolate, medially protruding and with a large but discrete patch of specialized sensillae (Fig. 85); fore tibia with a longitudinal row of thickened, peg-like setae (Fig. 83) .....*Serratobracon*

- Pedicellus normal-sized, not petiolate and without a patch of specialised sensillae (if with sensillae then these not restricted to one side of pedicellus) (see Figs 27, 28, 31); fore tibia without a longitudinal row of thickened, peg-like setae 23

23. With a strong spur arising from forewing vein 3-CU1 (Fig. 100); transverse median clypeal carina strongly protruding (Fig. 75); forewing vein 1-SR+M moderately curved, not sharply angled (see Figs 21, 26) .....*Ploceibracon*

- Forewing vein 3-CU1 usually without a spur (see Figs 96-99) or if with a spur (e.g. some *Virgulibracon*) then transverse median clypeal carina not strongly produced (see Figs 44-48) and/or forewing vein 1-SR+M sharply angled (Figs 90, 92) 24

24. Ovipositor without a pre-apical dorsal notch or nodus (Figs 128, 130, 131) 25

- Ovipositor with a distinct pre-apical dorsal notch or nodus (see Figs 133-138) 27

25. Ovipositor very short, thick and laterally compressed (Fig. 131), the exserted part shorter than metasomal syntergite 2+3; all metasomal tergites largely smooth and shiny .....*Stigmatobracon*

- Ovipositor longer and more slender (Figs 128, 130), the exserted part longer than metasomal syntergite 2+3; at least basal 2 metasomal tergites largely coarsely sculptured (Fig. 67) 26

26. First metasomal tergite with a well-developed mid-longitudinal carina (Fig. 67); ovipositor gradually and more or less evenly narrowing from base to apex (Fig. 128); eyes virtually glabrous .....*Hybogaster*

- First metasomal tergite without a mid-longitudinal carina; ovipositor distinctly deepening pre-apically (Fig. 130); eyes usually setose..... .....*Pycnobraconoides* gen.nov.

27. Forewing vein 1-SR+M sharply and strongly angled posteriorly approximately one third of the distance from its base (Figs 19, 90, 92), often with a distinct spur arising from the angulation (Fig. 92) 28

- Forewing vein 1-SR+M straight or gently and more or less evenly curved posteriorly (see Figs 87, 91, 94, 97), without a spur 30

28. First metasomal tergite with dorsal carina joining dorso-lateral carina (Figs 66, 108); second metasomal tergite with a large well-developed mid-basal, posteriorly narrowing, triangular area (Fig. 66); 3rd metasomal tergite with well-developed antero-lateral, posteriorly diverging grooves; hindwing with a glabrous area distal to vein 1r-m .....*Vomeribracon*

- First metasomal tergite without dorsal or dorso-lateral carinae (Fig. 65); second metasomal tergite without a posteriorly narrowing, mid-basal triangular area, sometimes with a pair of posteriorly diverging grooves (Fig. 65); 3rd metasomal tergite without, or with only weak, antero-lateral grooves 29

29. Forewing vein r-m with only one bulla (posterior one); antero-lateral areas of 2nd metasomal tergite membranous, unsclerotized ... *Virgulibracon*

- Forewing vein r-m with two bullae; antero-lateral areas of 2nd metasomal tergite distinctly sclerotized .....*Virgulibraconoides*

30. Forewing cu-a interstitial or virtually so (see Figs 97-100); lower part of clypeus sharply recessed into the hypoclypeal depression (see Figs 41-43, 47); ovipositor less than 2.5 times longer than forewing; forewing veins C+SC+R and 1-SR forming an angle of more than 50°; base of hindwing usually evenly setose .....*Bracon* (part)

- Forewing vein cu-a postfurcal, removed from vein 1-M by more than the width of a vein (Figs 20, 96); lower part of clypeus hardly recessed into hypoclypeal depression, the hypoclypeal hair brushes orientated more or less anteriorly (Fig. 48); ovipositor more than 3.5 times longer than the forewing; forewing veins C+SC+R and 1-SR forming an angle of less than 50°; base of hindwing with a large glabrous area 31

31. Hindwing vein 1r-m longer than vein SC+R1 (Fig. 20) .....*Euurobracon*

- Hindwing vein 1r-m shorter than SC+R1 (see Figs 101, 102) .....*Euurobraconoides*

32. Forewing vein 3-CU1 (usually) narrowing posteriorly where it is narrower than the anteriorly thickened vein CU1b (Figs 21, 22, 94); 1st subdiscal cell with a medio-distal glabrous area (Figs 21, 22, 25); forewing vein 2-1A often markedly curved or angled (Fig. 94) (Aphrastobraconina) 33

- Forewing vein 3-CU1 not markedly narrowed posteriorly and not narrower than vein CU1b (Figs 97-99); 1st subdiscal cell usually evenly setose; forewing vein 2-1A not strongly curved or angled (see Figs 97-99) 39

33. Ovipositor formed into 3 arch-like sections poste-

riorly (Fig. 125); base of hindwing evenly setose ..... *Undabracon*

- Ovipositor at most formed into a single distal arch (Figs 123, 124, 126); base of hindwing with a large glabrous area 34

34. Ovipositor formed into a single distal arch (Figs 123, 124); fore wing vein r-m with a single posterior bulla (Figs 21, 88) 35

- Ovipositor not formed into an arch distally (Fig. 126); forewing vein r-m with two bulli (see Fig. 20) or largely unsclerotized (Fig. 22) 36

35. Ovipositor arch shallow, occupying approximately 0.3 of the exerted length of the ovipositor, base of arch indicated by angular expansion of the lower valves (Fig. 123); labio-maxillary complex somewhat elongate ..... *Ligulibracon*

- Ovipositor arch deep, occupying less than 0.2 of the exerted length of the ovipositor, without angular basal projections of the lower valves (Fig. 124); labio-maxillary complex not elongate ..... *Cedilla*

36. Width of head (across eyes)/length of head less than 1.48 ; face with coarse foveate to rugose sculpture (Fig. 41) 37

- Width of head (across eyes)/length of head more than 1.50; face shiny, smooth with scattered punctures (Fig. 43) ..... *Eucurriea*

37. Length of forewing vein 3-SR less than 1.65 times length of m-cu (Fig. 25); 1st tergite with weak dorso-lateral carinae ..... *Vipiellus* (part)

- Length of forewing vein 3-SR more than 1.7 times length of m-cu (Fig. 22); 1st tergite with or without dorso-lateral carinae 38

38. First metasomal tergite without dorso-lateral carinae (Fig. 61) ..... *Megalommum*

- First metasomal tergite with at least a trace of dorso-lateral carinae (see Figs 60, 66, 67) ..... *Curriea*

39. Scapus angularly narrowed basally (petiolate), with a broad preapical concave ledge (Figs 34-36, 39, 80); only ever with one specialized bristle at apex of hindwing vein C+SC+R (Figs 51, 103); pedicellus petiolate, strongly protruding medially with area of specialized sculpture (Figs 34, 35, 37, 38, 80) 40

- Scapus not angularly narrowed basally, without such a broad preapical ledge (Figs 29, 32); often with more than one especially thickened seta at apex of hind wing vein C+SC+R (Figs 49, 50); pedicellus more or less parallel-sided or distally narrowing, at most only slightly narrowed basally, not produced medially (Figs 29, 32, 33) 42

40. Face with a well-developed, transverse, protruding plate (Figs 39, 40, 44); apico-ventral setae of penultimate tarsal article very long, more than 0.8 times ventral length of telotarsus 41

- Face without a plate-like projection (Fig. 77); apico-ventral setae of penultimate tarsal articles much shorter, not more than 0.5 times ventral length of telotarsus (see Figs 53, 55) .. *Atanycolus*

41. Face with a horn-like, apically truncate projection medially arising from the base of the plate-like projection (Fig. 40) ..... *Chaoilta (Blastomorpha)*

- Face at most with a mid-longitudinal, lamelliform carina above the plate-like projection (Fig. 39) ..... *Chaoilta (Chaoilta)*

42. Claws bifurcate (Figs 57, 58) ..... *Macrobracon*

- Claws simple (Figs 55, 56) 43

43. Length of 1st subdiscal cell (parallel to vein 2-CU1) more than twice width of cell (perpendicular to vein 2-CU1) (Figs 23, 97); forewing vein r-m short, almost entirely unsclerotized, not tubular, without distinct bullae (Fig. 23); ovipositor with at least a weak pre-apical dorsal notch or nodus (Figs 135, 136) ..... *Eunesaulax*

- 1st subdiscal cell less than 1.9 times longer than wide (Fig. 25) or if shorter then either forewing vein r-m longer, largely sclerotized and tubular, often with 1 or 2 distinct bullae (see Figs 20-22, 24-26), or ovipositor without a pre-apical dorsal notch or nodus (Figs 127-132) 44

44. Forewing vein 1-SR+M distinctly curving towards the anterior wing margin after arising from 1-SR (Fig. 93; see also Fig. 16); angle between veins 1-SR and C+SC+R less than 50°; forewing vein r more than 0.69 times length of m-cu ..... *Stenobracon*

- Forewing vein 1-SR+M usually distinctly curved posteriorly after arising from 1-SR (see Figs 19-26, 90, 97) or if more or less straight then angle between veins 1-SR and C+SC+R more than 55°C and/or vein r less than 0.65 times length of vein m-cu 45

45. Ovipositor (part extending beyond apex of metasoma) more than twice length of forewing 46

- Ovipositor (part extending beyond apex of metasoma) less than 1.4 times length of forewing 47

46. Apex of ovipositor smoothly expanded but without a pre-apical dorsal nodus or apicoventral serrations (Fig. 127); 2nd metasomal tergite smooth (Fig. 106); 3rd metasomal tergite with a medially broken, transverse median groove or a pair of broader depressions (Fig. 106), otherwise smooth and shiny; labio-maxillary complex not elongate; posterior margin of propodeum simple, without carinae ..... *Paranesaulax*

- Apex of ovipositor with a distinct pre-apical dorsal nodus and ventral serrations; 2nd metasomal tergite coarsely sculptured (Fig. 104); 3rd metaso-

mal tergite without a transverse median groove, largely sculptured; labio-maxillary complex moderately elongate; posterior margin of propodeum with one or more pairs of short, anteriorly diverging carinae ..... *Rostraulax*

47. Ovipositor without a pre-apical dorsal notch or nodus (Fig. 129, also see Fig. 128) 48
- Ovipositor with a pre-apical dorsal notch or nodus (see Figs 133, 134) 49

48. 2nd metasomal tergite with a posteriorly narrowing, mid-basal raised triangular area (see Fig. 60); forewing vein 3-SR less than 1.9 times length of r-m (Fig. 25); posterior margins of metasomal tergites 3-5 membranous, without transverse subposterior grooves ..... *Vipiellus* (part)
- 2nd metasomal tergite without a posteriorly narrowing, mid- basal triangular area (Fig. 63); forewing vein 3-SR more than twice length of r-m; posterior margins of metasomal tergites 3-5 sclerotized and convex in lateral profile .and with transverse subposterior groove ..... *Iphiaulax*

49. Metasoma short, robust and strongly sculptured (Fig. 62); 3rd metasomal tergite more than 3.75 times wider than minimally long. *Campyloneurus*
- Metasoma moderately elongate and largely smooth and shiny (Fig. 64); 3rd metasomal tergite less than 2.25 times wider than minimally long ..... *Callibracon*

NOTES ON THE AUSTRALIAN GENERA INCLUDING DESCRIPTIONS OF A NEW GENUS AND NEW SPECIES

New records for genera occurring in Australia are indicated by an asterix. Full details of synonymy are given in Shenefelt (1978), Quicke (1987b, 1991a) and Quicke & van Achterberg (1990).

*Acrocerilia van Achterberg

Previously known only from the type species, *A. pachynervis* van Achterberg, from the Philippines where it has been reared from the gracillariid cocoa moth, *Acrocercops cramerella* Snellen. The biological details available for this species indicate that it emerges from the prepupa of its host and therefore van Achterberg (1989) cautiously suggested that it might in fact be an endoparasitoid though precise data are lacking. In terms of its relationships, *Acrocerilia* appears intermediate in structure between certain genera of the *Plesiobracon* group, in particular *Psilolobus* van Achterberg and *Simplicibracon* Quicke, and members of the Aspidobraconina (see *Hyboteles* van Achterberg and *Pedinopleura* van Achterberg). If an association with the Aspidobraconina which are endoparasitoids of butterfly pupae is proven then this would add some support to the possibility that *Acrocerilia* might also be endoparasitic.

Key to species of *Acrocerilia*

1. Top of head coriaceous; head black and white; metasoma dorsally black with a white margin; hindwing vein 1-M narrowing distally..... ..... *A. tricolor* sp.nov.
- Top of head smooth; head brownish yellow; metasoma entirely brownish yellow; hindwing vein 1-M uniformly broad along its whole length .... *A. pachynervis* van Achterberg

Acrocerilia tricolor sp.nov.

MATERIAL EXAMINED

HOLOTYPE: ♂ labelled: 'AUSTRALIA NE Queensland Conway Range Nat. Park E from Proserpine' and 'No. 226, 22.II.1981 leg. Hangay and Vojnits at light'. Deposited in QMBA.

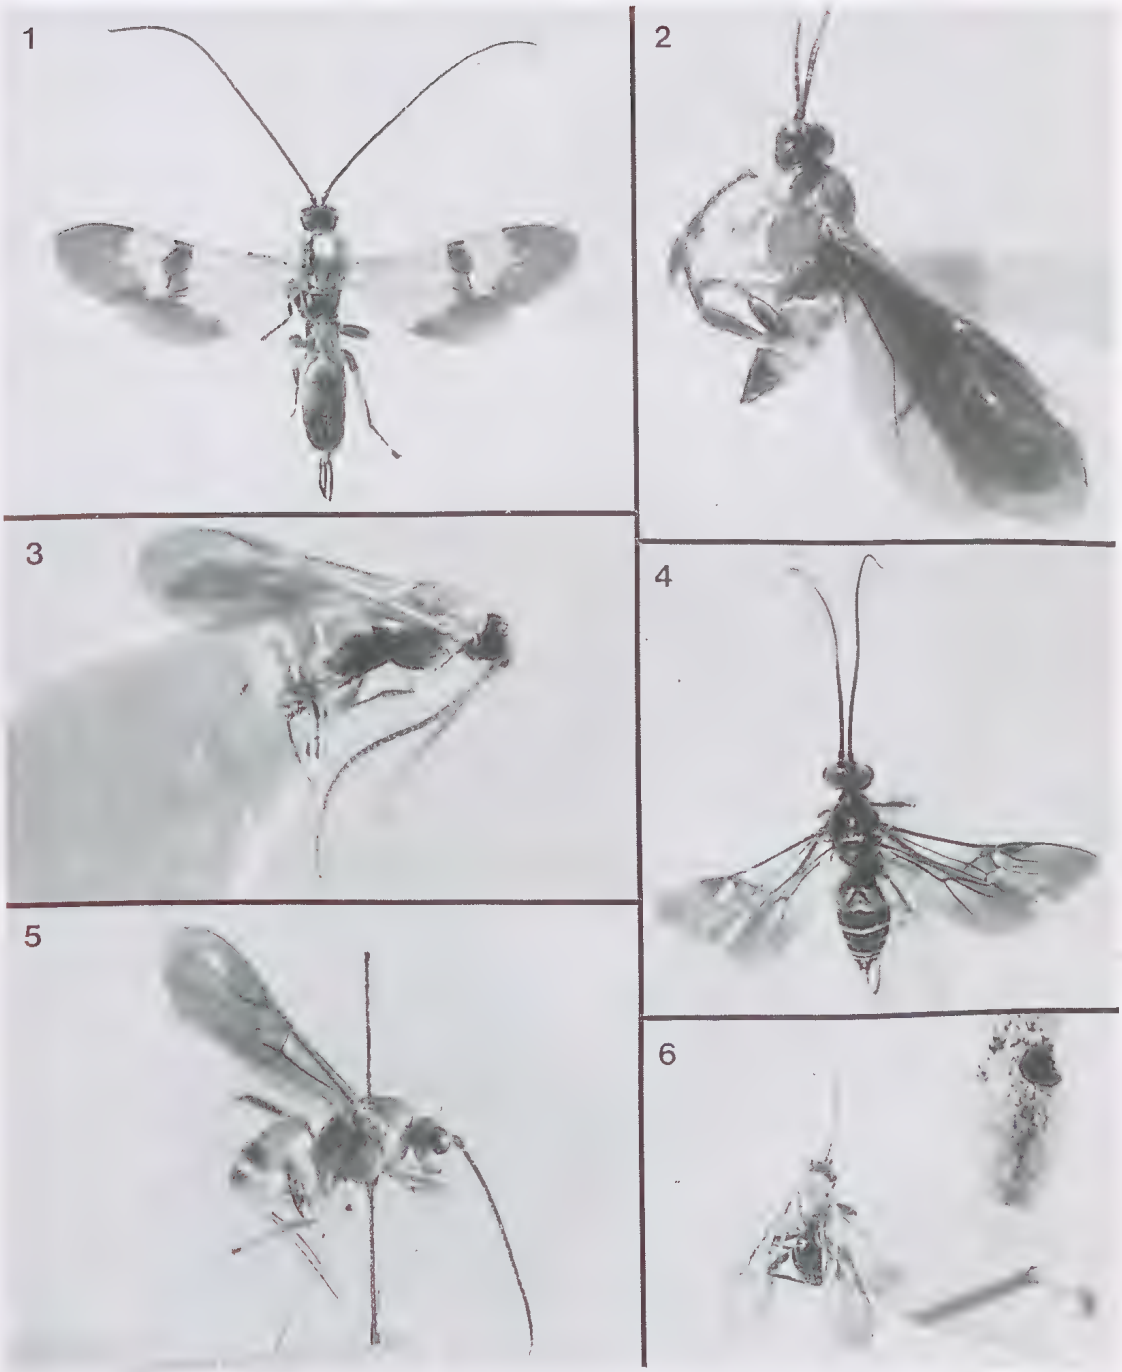
PARATYPE: ♂ labelled: 'AUSTRALIA NE Queensland Conway Range Nat. Park E from Proserpine' and '18.II.1981 No. 177 leg. Hangay and Vojnits, at light'. HNHM.

DESCRIPTION (♂♂)

Length of body 4.4-5.0mm, of forewing 4.0-4.5mm and of antenna 4.6-5.0mm.

Antennae with 43-44 flagellomeres. Terminal flagellomere acuminate. First flagellomere 1.07 and 1.15 times longer than the 2nd and 3rd respectively, the latter being 1.5 times longer than wide. Height of clypeus: inter-tentorial distance: tentorio- ocular distance = 1.0: 3.8: 2.9. Height of eye: shortest distance between eyes: width of head = 1.0:1.29:2.37. Width of face: height of face = 2.05:1.0. Face except for supra clypeal triangle densely, finely punctate, the punctures being arranged in transverse rows giving the face a striate appearance. Eyes virtually glabrous. Frons, temples and occiput coriaceous, back of head becoming finely striate. Shortest distance between posterior ocelli: transverse diameter of posterior ocellus: shortest distance between posterior ocellus and eye = 1.25:1.0:2.25. Horizontal length of eye: horizontal length of head behind eye = 2.85: 1.0.

Mesosoma 1.48 times longer than maximally high. Pronotum with crenulate groove laterally. Notauli moderately well-developed on anterior



FIGS 1-6. 1. *Stigmatobracon diversipennis* Turner, ♀. 2. *Myosoma rufescens* sp.nov., ♂ paratype. 3. *Trigastrotheca tricolor* sp.nov., ♀ paratype. 4. *Virgulibraconoides* sp., ♀. 5. *Simplicibracon nigritarsus* .sp.nov., ♀ holotype. 6. *Pycnobraconoides mutator* (Fabricius) comb. nov., ♀ and host cocoon with parasitoid's emergence hole.

half of mesoscutum, absent on posterior half. Scutellar sulcus with 5 transverse crenulae. Mesoscutum, scutellum, mesopleuron and mesosternum densely and evenly setose, punctulate. Precoxal suture indicated by a weak depression. Mesopleural suture punctate. Median area of metanotum with a short carina anteriorly; merging with a flat triangular plate posteriorly in one specimen. Propodeum with a complete mid-longitudinal carina bordered by crenulae; posterior margin with numerous strong crenulations merging into rugose sculpture on the posterior half of the propodeum.

Forewing. Pterostigma 2.8 times longer than maximally wide, Lengths of veins SR1: 3-SR:r = 5.0: 1.6: 1.0. Lengths of veins 2- SR:3-SR:r-m = 1.36:1.36:1.0. Vein 2-M curved. Vein 1-M straight. Vein 1-SR forming an angle of approximately 80°. Veins cu-a more or less interstitial.

Hindwing. Vein 1r-m 0.35 times length of SC+R1. Apex of C+SC+R with one especially thickened bristle. Vein 2-1A absent. Base of discal + subdiscal cell with a large glabrous area.

Lengths of fore femur: tibia: tarsus = 1.0: 1.13: 1.20. Lengths of hind femur: tibia: basitarsus = 2.0: 2.7: 1.0. Hind tibia slender, maximally deep at apex. Hind basitarsus 5 times long than deep.

Metasomal tergites 1-5 largely foveate-rugose. Second tergite 2.0 times wider than medially long. Second suture crenulate, moderately curved. Tergites 3-5 with well-developed, antero-lateral areas. Posterior margin of 5th tergite slightly irregular.

Head ivory-white except for tips of mandibles, a triangular mark above the clypeus and the frons, temples, occiput and back of head down to level of base of eye which are black. Mesosoma brownish orange except for propodeum which is largely piceous. Fore and middle legs brownish orange, hind legs piceous to black. Metasomal tergites black except for the following which are ivory-white: the base and lateral margins (broadly) of the 1st tergite, the lateral margins of tergites 1-5 (narrowly) and their antero-lateral triangular areas, and the posterior margin of the 5th tergite. Wings uniformly very pale brown with dark brown pterostigma and venation.

*Africadesha Quicke

Members of the Adeshini, these small wasps have wing lengths less than 3mm. *Africadesha* is previously known from a single Afrotropical species, *A. usherwoodi* Quicke, though several other undescribed Afrotropical species have been seen by the senior author. Despite the strange disjunct distribution indicated by the discovery of the new Australian species, the two species differ only in relatively small characters and there is no reason to doubt the two as being anything other than congeneric. Nothing is known of the biology of any of the Adeshini. Further, given their small size, it is quite likely that members of other genera of this tribe will be found in Australia and the reader is referred to van Achterberg (1983a) and Quicke (1986b, 1988f).

Key to species of *Africadesha*

1. First metasomal tergite more than 1.5 times longer than posteriorly wide; third metasomal tergite with well-developed longitudinally striate sculpture (Fig. 109) ..... *A. tobiasi* sp.nov.
- First metasomal tergite less than 1.4 times longer than posteriorly wide; third metasomal tergite without longitudinally striate sculpture ..... *A. usherwoodi* Quicke

Africadesha tobiasi sp.nov.
(Figs 12, 109, 134)

MATERIAL EXAMINED

HOLOTYPE: ♀ labelled: '15 km NE Kuranda, Queensland, 1.V-14.VI. 1985 MDPI FIT site 25, Storey & Halfpapp'. Deposited in QMBA.

PARATYPES: 3♀♀, same data as holotype. QMBA, QDPI and BMNH.

DESCRIPTION (♀♀)

Length of body 2.7mm, of forewing 2.6mm, of ovipositor (part exserted beyond apex of metasoma) 0.45mm and of antenna 4.2mm.

Antenna with 42 flagellomeres, considerably longer than the body. Terminal flagellomere pointed but not acuminate, 2.3 times longer than wide. Median flagellomeres 1.7 times longer than wide. First flagellomere 1.17 and 1.4 times longer than the 2nd and 3rd flagellomeres respectively, the latter being 2.25 times longer than wide. Height of clypeus: inter-tentorial distance: tentorio- ocular distance = 1.0:2.8:2.2. Face, frons and occiput coriaceous. Height of eye: shortest distance between eyes: width of head = 1.0:1.375:2.5. Shortest distance between posterior ocelli: transverse diameter of posterior ocellus: shortest distance between posterior ocellus and eye = 1.5:1.0:3.5.

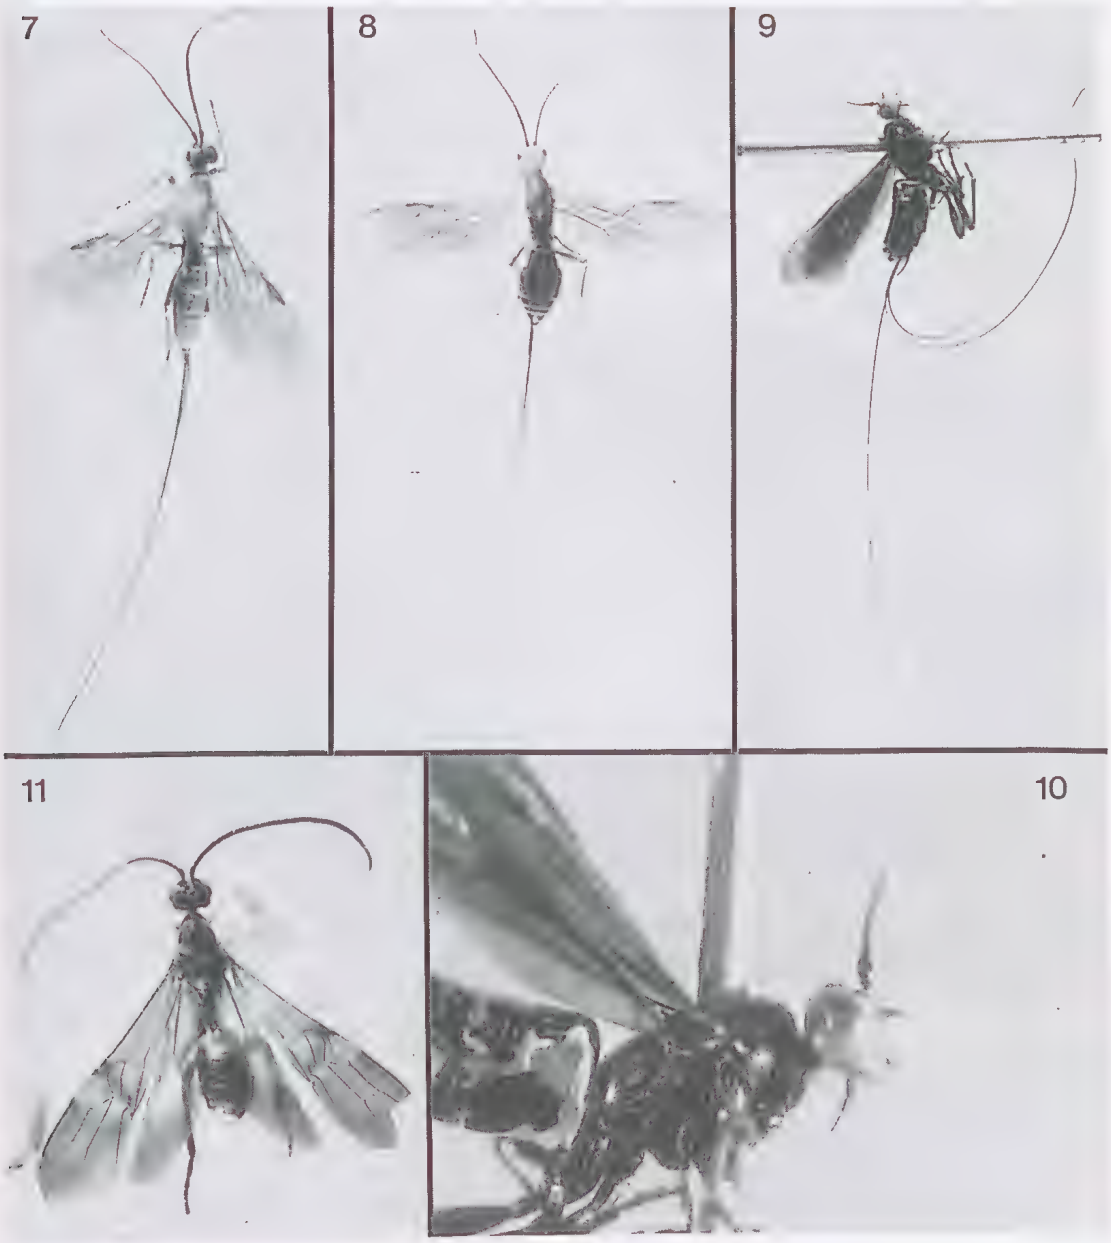
Mesosoma 1.5 times longer than high; largely coriaceous but mesosternum largely smooth and shiny. Precoxal suture very weakly, broadly im-

pressed. Mesopleural suture smooth. Propodeum with a complete mid-longitudinal carina.

Forewing. Lengths of veins SR1: 3-SR:r = 6.7:2.2:1.0. Lengths of veins 2-SR:3-SR:r-m = 1.7:2.0:1.0. Vein 2-SR+M moderately long; shortest distance between 1st subdiscal cell and 2nd submarginal cell: length of vein m-cu = 1.0: 1.25. Veins cu-a and 3-CU1 both more or less interstitial.

Lengths of fore femur: tibia: tarsus = 1.0: 1.2: 1.53. Lengths of hind femur: tibia: basitarsus = 1.47: 2.3: 1.0. Hind basitarsus 10 times long than deep.

First tergite 1.8 times longer than posteriorly wide; with rugose sculpture and with thin irregular mid-longitudinal carina. Second tergite 1.2 times wider posteriorly than medially long. Second and 3rd tergites with strong longitudinal



FIGS 7-11. 7. *Eunesaulax terebratus* Tobias, ♀. 8. *Euurobraconoides longicaudis* Quicke, ♀. 9,10. *Psittacibracon lacteolus* Quicke, ♀. 11. *Calcaribracon willani* sp.nov., ♀ holotype.

striations (Fig. 109) interspersed with punctate sculpture. Tergites 4 and 5 with fine rugulose to coriaceous sculpture. Fifth tergite without postero- lateral emarginations. Ovipositor (exserted part) about as long as the 5th tergite; with a distinct pre-apical dorsal nodus, apico-ventrally virtually smooth (Fig. 134).

Uniformly pale brownish yellow, flagellum becoming piceous beyond middle, ovipositor sheaths black. Wings weakly infuscate with brown venation.

ETYMOLOGY

Named after our esteemed colleague Vladimir Tobias of the Russian Academy of Science, St Petersburg, who drew our attention to many interesting Australian Braconinae.

*Atanycolus Foerster
(Figs 77, 80, 82, 84, 103)

Synonyms. Coelobracon Thomson; *Melanobracon* Ashmead; *Atanycolidae* Viereck.

A widespread genus of medium-sized wasps, commonest in the Nearctic and Palaearctic though with some closely related and more derived groups occurring in the neotropics (e.g. *Hemibracon* Szépligeti) and Indo-Australian region (*Nedinoschiza* Cameron). *Nedinoschiza*, which is probably only a specialized derivative of *Atanycolus*, has not yet been recorded from Australia though it may occur there; it can be distinguished from *Atanycolus* by the greatly enlarged anterior tentorial pits. (Quicke, 1987 b)

Atanycolus tomentosus Szépligeti, previously placed in the Braconinae (see Parrott, 1953), is in fact a member of the Doryctinae (Quicke, 1984).

Atanycolus australiensis sp.nov.
(Figs 77, 80, 82, 84)

MATERIAL EXAMINED

HOLOTYPE: ♀ with the following label: 'Australia 35-40 km NO Deniliquin, Tobias 12-13.iv.978'. Deposited in ANIC.

DESCRIPTION (♀)

Length of body 3.9mm, of forewing 3.8mm, of ovipositor (part exserted beyond apex of metasoma) 3.3mm and of antenna 3.0mm.

Antennae (broken) with at least 29 flagellomeres, all flagellomeres longer than wide. First flagellomere 1.25 and 1.5 times longer than 16 2nd and 3rd respectively, the latter being 1.75 times longer than apically wide. Height of eye: shortest distance between eyes: width of head = 1.1: 1.0:2.1. Face shiny, weakly at and with many deep punctures at the bases of the silvery setae. Eyes sparsely setose; emarginate opposite antennal sockets. Head very elongate (Fig. 77); length of head behind eye: horizontal length of eye = 1.0:1.0. Ocelli small; distance between posterior ocelli; transverse diameter of posterior ocellus: shortest distance between posterior ocellus and eye = 2.0: 1.0: 4.0.

Mesosoma 2.0 times longer than maximally high. Antescutal depression well-developed. Scutellar sulcus shallow with few weak punctures. Scutellum protruding in profile.

Forewing. Lengths of veins SR1: 3-SR: r = 5.3: 2.85: 1.0. Lengths of veins 2-SR: 3-SR: r-m = 1.56: 2.5: 1.0. Vein r-m largely unsclerotized. Vein 1-SR+M rather strongly curved. Veins C+SC+R and 1-SR forming an angle of approximately 80°. Vein cu-a interstitial. Vein CU1b almost as long as 3-CU1.

Hindwing. Vein C+SC+R very thick, apex with a single, very large, specialized catch bristle (Fig. 103). Base of wing evenly setose.

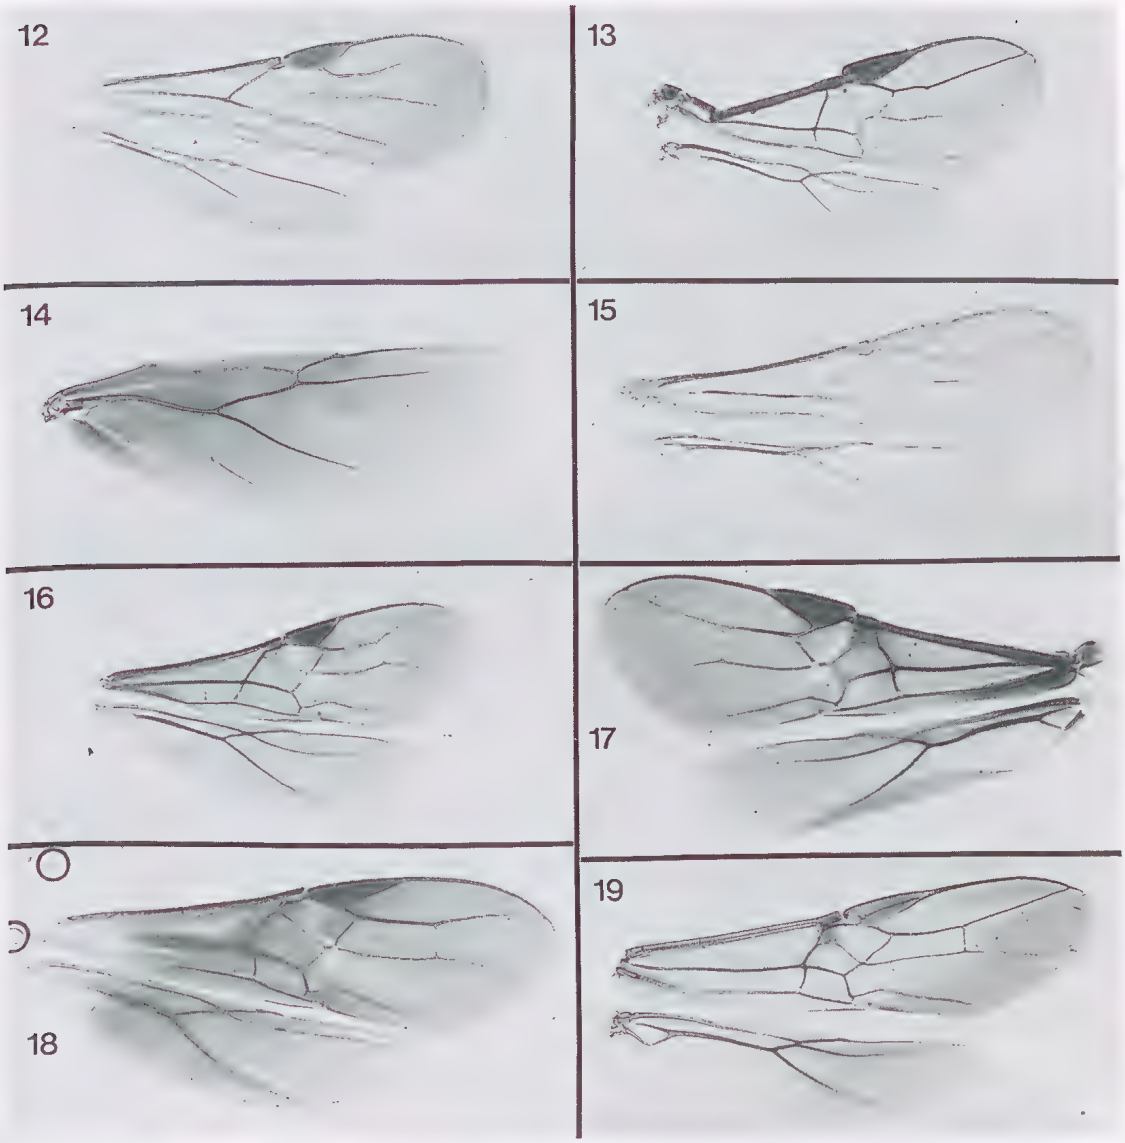
Fore tibia with a well-developed longitudinal row of pegs (Fig. 82), Length of fore femur: tibia: tarsus = 1.0: 1.16: 1.45. Length of hind femur: tibia: basitarsus = 1.95: 2.9: 1.0.

Metasoma largely smooth and shiny. First tergite more or less parallel-sided; raised median area with weak irregular, longitudinal striate sculpture. Second tergite 1.62 times wider than medially long; with a large, acute, triangular mid-basal area bordered on each side by a finely crenulate groove; with sub- lateral, curved, longitudinal, finely crenulate grooves. Second suture sinuous, crenulate. Third tergite with well developed antero-lateral areas. Tergites 3-6 smooth and shiny, without transverse sub-posterior grooves, with posterior margins membranous. Ovipositor (exserted part) approximately 0.85 times length of forewing.

Largely piceous brown except following: head orange-yellow; mesosoma and tergites 5-7, black; posterior (membranous) margins of tergites 4-6 ivory white. Wings light brown with darker brown venation.

Bracon Fabricius
(Figs 51, 53)

Synonyms. Microbracon Ashmead; *Amicoplidea* Ashmead; *Macrodyctium* Ashmead; *Tropidobracon* Ashmead; *Liobracon* (Ashmead) Nason; *Seliodus* Brethes.



FIGS 12-19. Wings: 12, *Africadesha tobiasi* sp.nov., ♀ paratype; 13, *Trigastrotheca* sp., ♀ (African species); 14, *Calcaribracon (Calcaribracon) diores* (Cameron); 15, *Tropobracon* sp., ♀ (African species); 16, *Vipiomorpha ypsilon* Tobias, ♀ (Russian specimen); 17, *Mollibracon bimaris* (Turner), ♀; 18, *Hybogaster* sp., ♀ (Papua New Guinea specimen); 19, *Virgulibracon endoxylaphagus* sp.nov., ♀.

A vast cosmopolitan genus of small wasps which parasitize a wide range of other insects (Quicke, 1988b). Concealed Lepidoptera larvae are the commonest hosts followed by Coleoptera, Diptera, and Hymenoptera-Symphyta (e.g. Austin & Faulds, 1989); in Australia, gall forming Homoptera also appear to be attacked (Chadwick & Nikitin, 1975) but this record should be checked by careful observation of larval feeding habits. To date only approximately twenty species have been recorded from Australia (Parrot, 1953; Austin & Faulds 1989). However, this is a considerable underestimate and the true number of Australian species is probably in the hundreds. The genus occurs throughout Australia and is morphologically rather diverse there with some distinctive species groups.

Calcaribracon Quicke
(Figs 11, 14, 27, 52, 91, 95)

A small genus ranging from Queensland through New Guinea, Indonesia and Malaysia to SE China and Japan. Keys to the species have been provided by Quicke (1986a, 1988d). Three species are known from Australia, all from Queensland, viz. *C.* (*Arostrobracon*) *walkeralis* (Shenefelt), *C.* (*Arostrobracon*) *diores* (Cameron) and *C.* (*Arostrobracon*) *willani* sp.nov. The Australian specimen of *C. diores* examined differs from the New Guinea specimens in the colour of the hind coxa and femur (yellow not black) and in having forewing vein cu-a less strongly curved. Thus it may in future be found to represent a further new species. We have also included the nominal subgenus in the generic key presented here though all known members of that group have a more northerly distribution (Papua New Guinea to China and Japan). Nothing is known of the biology of the Australian members of this genus but one Japanese species has been reared from larvae of members of the sesiid moth genus *Paranthrene* (Maetô, 1992), while a specimen of *C. ferax* (Smith) from Papua New Guinea in the BMNH has a label 'reared ex cerambycid larva' (Quicke, 1986a); while the former record is definitely correct and agrees better with the known hosts of the related genus *Myosoma* (Quicke, 1989c), the latter record could be erroneous.

Key to Australian species of *Calcaribracon*

1. Pterostigma, base of forewing vein r (usually), and 2nd metasomal tergite largely yellow or orange-yellow (Fig. 11); basal fifth to half of forewing yellow (Fig. 11) 2
   - Pterostigma, forewing vein r and 2nd metasomal tergite entirely piceous brown or black; forewing uniformly dark brown ..... *C. diores* (Cameron)
2. Propleuron, propodeum, mid-legs, hind femur, median area of 1st metasomal tergite, metasomal tergites 3-7 piceous or black (Fig. 11); basal half of forewing yellow ..... *C. willani* sp.nov.
   - Mesosoma and metasoma up to the 7th tergite, midlegs and hind leg except apex of tibia and tarsus, yellow or orange-yellow; forewing with only basal half of basal and sub-basal cells yellow ..... *C. walkeralis* (Shenefelt)

Calcaribracon (Arostrobracon) willani sp.nov. (Figs 11, 52, 91)

Material Examined
Holotype: ♀ with the following label: 'Zillmere Brisbane, Q. 27 August 1988 G.V. Maynard'. Deposited in QMBA.

Description (♀)
Length of body 8.3mm, of forewing 8.8mm, of ovipositor (part exserted beyond apex of metasoma) 1.1mm and of antenna 8.0mm.

Antenna with 65 flagellomeres. Terminal flagellomere acuminate, 1-8 times longer than maximally wide. Penultimate flagellomere 1.25 times longer than wide. Median part of flagellum rather flattened, median flagellomeres at their widest approximately 1.6 times wider than long. First flagellomere 1.7 times longer than both the 2nd and 3rd separately, the latter being 1.2 times wider than long. Height of eye: width of face: width of head = 1.1:1.0:2.0. Eyes sparsely setose. Lateral half of frons moderately densely with short erect setae. Horizontal length of head behind eye: horizontal length of eye = 1.0:1.37.

Mesosoma 1.7 times longer than high. Mesoscutum almost totally glabrous.

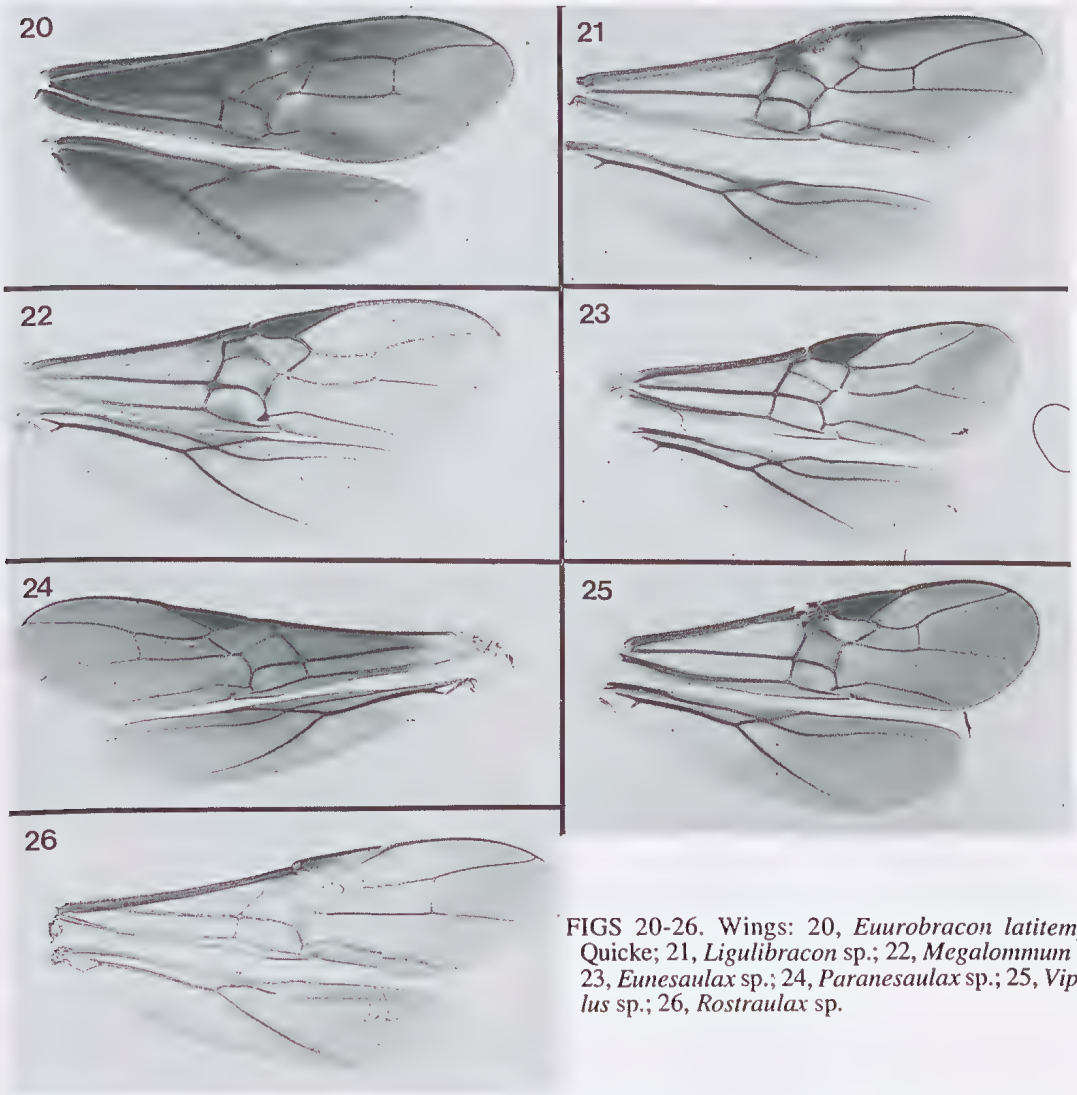
Forewing. Lengths of veins SR1:3-SR:r = 3.5:2.2:1.0. Lengths of veins 2-SR:3-SR:r-m = 1.37:2.2:1.0. Vein r-m with 2 distinct bulli. Vein cu-a antefurcal, strongly bent.

Hindwing. Lengths of veins 1r-m : SC+R1 = 1.05:1.0. Apex of vein C+SC+R with one especially thickened bristle. Vein 2-CU almost reaching wing margin.

Lengths of fore femur: tibia: tarsus = 1.0:1.13:1.33. Lengths of hind femur: tibia: basitarsus = 2.3:2.8:1.0. Hind basitarsus 3.3 times longer than deep.

First metasomal tergite approximately 2.0 times longer than maximally wide, flattened lateral areas of tergum virtually absent sub-posteriorly. Ovipositor (part exserted beyond apex of metasoma) 1.5 times longer than hind basitarsus; 0.1 times length of forewing.

Black except the following which are bright orange-red: pronotum (largely), mesoscutum, scutellum mesopleuron, mesosternum, tegulae, metanotum, posterior of propodeum, apex of fore femur, fore tibia (except spur), fore tarsus, lateral areas of 1st metasomal tergite and 2nd metasomal tergite. Forewing yellow basally, brown apically with yellow pterostigma (Fig. 11).



FIGS 20-26. Wings: 20, *Euurobracon latitempus* Quicke; 21, *Ligulibracon* sp.; 22, *Megalommum* sp.; 23, *Eunesaulax* sp.; 24, *Paranesaulax* sp.; 25, *Vipiellus* sp.; 26, *Rostraulax* sp.

ETYMOLOGY

Named after Richard Willan for his kindness and help during DLJQ's visit to Australia.

Callibracon Ashmead
(Figs 50, 64)

Synonyms. Poecilobacon Cameron syn.nov.

This is a vast, mostly Australian genus of medium-sized to large (and often common) braconines that are greatly in need of taxonomic revision. Previously species were often referred to under the genus *Ipobracon* Thomson (a junior synonym of *Cyanopterus* Haliday). Species have been reared from a variety of wood-boring, coleopterous hosts including Elateridae and Scolytidae, and three species have been collected in association with *Eucalyptus* infested with the cerambycid genus, *Phoracantha* (Quicke, 1989c; Quicke et al., 1992). Some species are gregarious parasitoids.

The genus *Poecilobracon* Cameron (type species: *Poecilobracon flaviceps* Cameron 1901: 122) is treated here as a new subjective synonym of *Callibracon* since examination of a large number of specimens has shown that the characters used by Quicke (1987b) to distinguish between these, viz. scapus length and metasomal sculpture, show great variation and cannot therefore be used as generic characters.

Campyloneurus Szépligeti
(Fig. 62)

Synonyms. Monolcia Enderlein; *Diolcia* Enderlein.

A medium-sized genus of small to medium-sized wasps which are found from India and Japan to Australia. Several species are reported from Australia (Parrott, 1953) but only two appear to be common. Several Australian species included under *Campyloneurus* in the past are referable to *Pycnobraconoides* gen.nov. Australian species of *Campyloneurus* species appear to be largely or perhaps exclusively parasitoids of cerambycid larvae, one Australian species having frequently been reared from members of the cerambycid beetle genus *Zygrita* on a variety of legumes including soya-bean. However, there is a record from grass tree (*Xanthorrhoea*) stems that were infested with both Curculionidae and Cerambycidae. Two host records from India suggest that elsewhere *Campyloneurus* spp. may also attack stem-boring pyralid moth larvae (Quicke, 1989c). The available evidence suggests that at least some species are gregarious parasitoids.

Cedilla Quicke
(Figs 94, 124)

Known from only a single Australian species of medium-sized Aphrastobraconini (Quicke & Tobias, 1990). Nothing is known of its biology though the type specimen of the type species was collected at light indicating that they may be crepuscular or nocturnal as appears to be commonly the case with Australian Aphrastobraconini (Quicke, 1992).

Chaoilta Cameron
(Figs 34, 35, 36, 37, 38, 39, 40, 44, 69)

Synonyms. Blastomorpha Szépligeti; *Platybracon* Szépligeti; *Iphioilta* Ramakrishna Ayyar.

A rather small genus of medium-sized to large braconines. Distributed from India to Australia, most species have been described from Indonesia and New Guinea. The five Australian species were treated by Quicke (1991a); *C.* (*Blastomorpha*) *decorata* Szépligeti is restricted to north Queensland the other four species belonging to the nominal subgenus are more widespread. Nothing is known of the biology of *Chaoilta*. However, the closely related genera *Atanycolus* Foerster, principally from the Holarctic, and *Odontoscapus* Kriechbaumer from the Afrotropical Region are both parasitoids of bark-boring coleopterous larvae, particularly of the families Bostrychidae and Buprestidae (Quicke, 1988b, 1989c).

Curriea Ashmead

A small genus of the tribe Aphrastobraconini originally described from the Afrotropical Region but widespread through the Old World tropics and recorded from Australia for the first time by Quicke (1992). We have seen several Australian species, all of which appear to be undescribed.

Esengoides Quicke

A small genus of the tribe Braconini known from only two species: *E. fulvus* Quicke from Australia (north Queensland) and *E. crenulatus* Quicke from the Solomon Islands (Quicke, 1989b). Small wasps with wing lengths less than 5mm. Nothing is known of their biology.

Eucurriea Quicke
(Figs 28, 31, 43)

A small genus of medium-sized wasps previously confused with *Megalommum* and *Curriea* Ashmead (see Quicke & Tobias, 1990). Frequently collected at light (Quicke, 1992); nothing else is known of their biology.

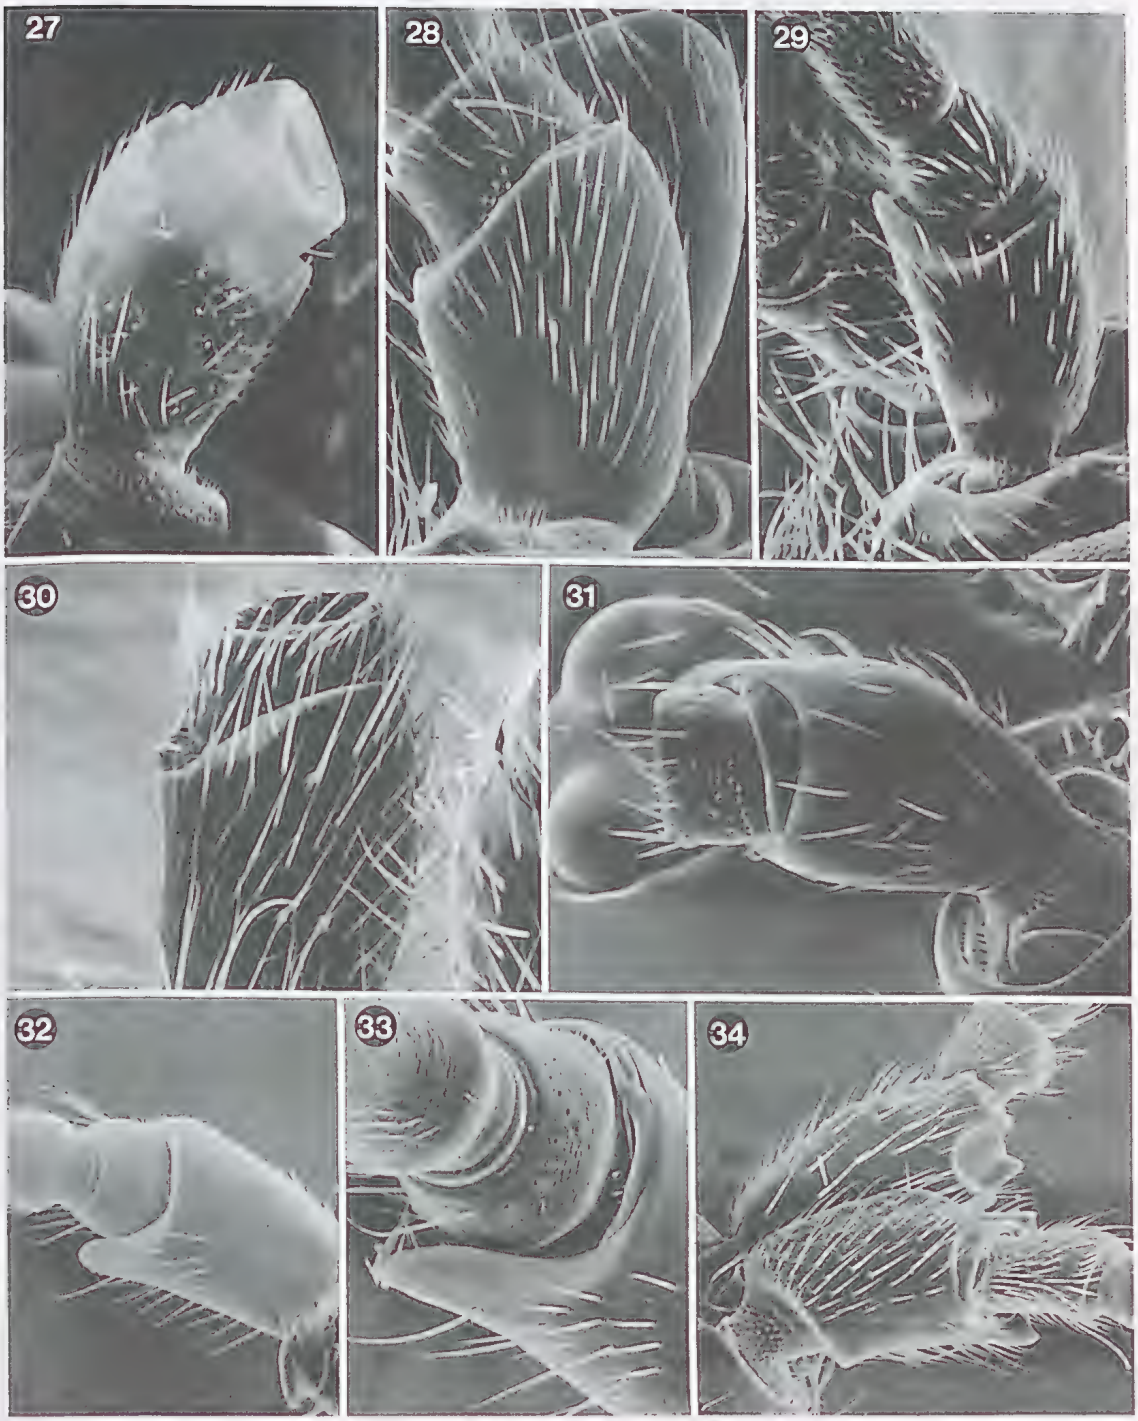
Eunesaulax Tobias
(Figs 7, 23, 60, 68, 135, 136)

A small genus of medium-sized rather slender wasps, known from three Australian species, *E. terebratus* Tobias, *E. nigriventris* Tobias and *E. radialis* Tobias (Quicke & Tobias, 1990). The wing venation is fairly distinctive but the form of the ovipositor apex shows considerable variation (Fig. 135 cf. 136). Nothing is known of their biology and their relationships are still uncertain.

Euurobracon Ashmead
(Figs 20, 48, 56, 96)

Synonyms. Delmira Cameron; *Exobracon* Szépligeti; *Lissobracon* Cameron.

It is not known for certain whether this genus occurs in Australia. A single specimen of *E. latitempus* Quicke was found in a Queensland collection but it lacked data (Quicke, 1989a). However, as *Euurobracon* occurs in Papua New Guinea it is quite likely that it also occurs at least



FIGS 27-34. Features of scapus and pedicellus: 27, *Calcaribracon* sp., medial aspect; 28, *Eucurriea* sp., lateral aspect; 29, *Ligulibracon* sp., lateral aspect; 30, *Hybogaster* sp., ventro-medial aspect; 31, *Eucurriea* sp., medial aspect; 32, *Iphiaulax* sp., lateral aspect; 33, *Iphiaulax* sp., apico-ventro-medial aspect; 34, *Chaoilta (Chaoilta)* sp., lateral and medial aspects.

in far north Queensland. *Euurobracon* species are large wasps, sometimes with extremely long ovipositors (van Achterberg, 1986; Quicke, 1987b), and they have been reared from cerambycid beetle larvae living deep within wood (Quicke, 1989c).

Euurobraconoides Quicke
(Fig. 8)

Medium-sized braconines belonging to the tribe Euurobraconini with wing-lengths between 9 and 11mm. Known from a single Australian (north Queensland) species, *E. longicaudis* Quicke (Fig. 8). Nothing is known of its biology (Quicke, 1988c) but one specimen is labelled as having been collected in rainforest.

*Furcadesha Quicke

Small wasps belonging to the Adeshini. Known only from the type species *F. huddlestoni* from India and *F. walteri* sp.nov. from south-west Queensland. Nothing is known of the biology of any of the Adeshini though both *F. walteri* and the new *Africadesha* (q.v.) species described above were collected by vacuum suction from grass and low herbs.

Key to species of *Furcadesha*

1. Forewing vein SR1 more than 2.4 times longer than vein 3-SR; lateral lobes of mesoscutum extensively setose; mesosoma and metasomal tergites extensively marked with black .... *F. huddlestoni* Quicke
- Forewing vein SR1 less than 1.8 times longer than vein 3-SR; lateral lobes of mesoscutum largely glabrous except postero- medially and along line of notaulus; mesosoma and metasoma entirely brownish yellow to brownish orange .... *F. walteri* sp.nov.

Furcadesha walteri sp.nov.

(Figs 81, 89, 110, 111)

MATERIAL EXAMINED

HOLOTYPE: ♀ with the following labels: 'MT. Nebo, S.E. Queensland. 1.IV. 1974 I.D. Galloway' and 'CAUGHT USING D- VAC SUCTION NET'. Deposited in QMBA (originally from QDPI).

DESCRIPTION (♀)

Length of body 3.1mm, of forewing 3.1mm and of ovipositor (part exserted beyond apex of metasoma) 0.3mm.

First flagellomere 1.25 times longer than the 2nd. Scapus normal, not expanded dorsally. Height of clypeus: inter-tentorial distance: tentorio-ocular distance = 1.0:1.6:1.35. Height of eye: width of face: width of head = 1.0:1.35:2.5. Face smooth. Horizontal length of eye: horizontal length of head behind eye = 2.8:1.0. Head strongly narrowed behind eye. Shortest distance between posterior ocelli: transverse diameter of posterior ocellus: shortest distance between posterior ocellus and eye = 1.6:1.0:3.3.

Mesosoma 1.65 times longer than high. Mesoscutum setose medio- posteriorly and along lines of notauli. Notauli deeply impressed, minutely crenulate. Medio-posterior part of mesoscutum rugose, otherwise mesoscutum smooth and shiny. Precoxal suture virtually absent, mesopleuron and mesosternum largely smooth and shiny.

Forewing. Lengths of veins SR1:3-SR:r = 7.25:4.5:1.0. Lengths of veins 2-SR:3-SR:r-m = 1.1:2.0:1.0. Vein 2-SR+M short; shortest distance between 1st subdiscal cell and 2nd submarginal cell: length of vein m-cu = 1.0:2.7. Vein cu-a interstitial. Vein 3-CU1 slightly postfurcal with respect to m-cu.

Base of hindwing evenly setose. Posterior margin of hindwing distinctly emarginate.

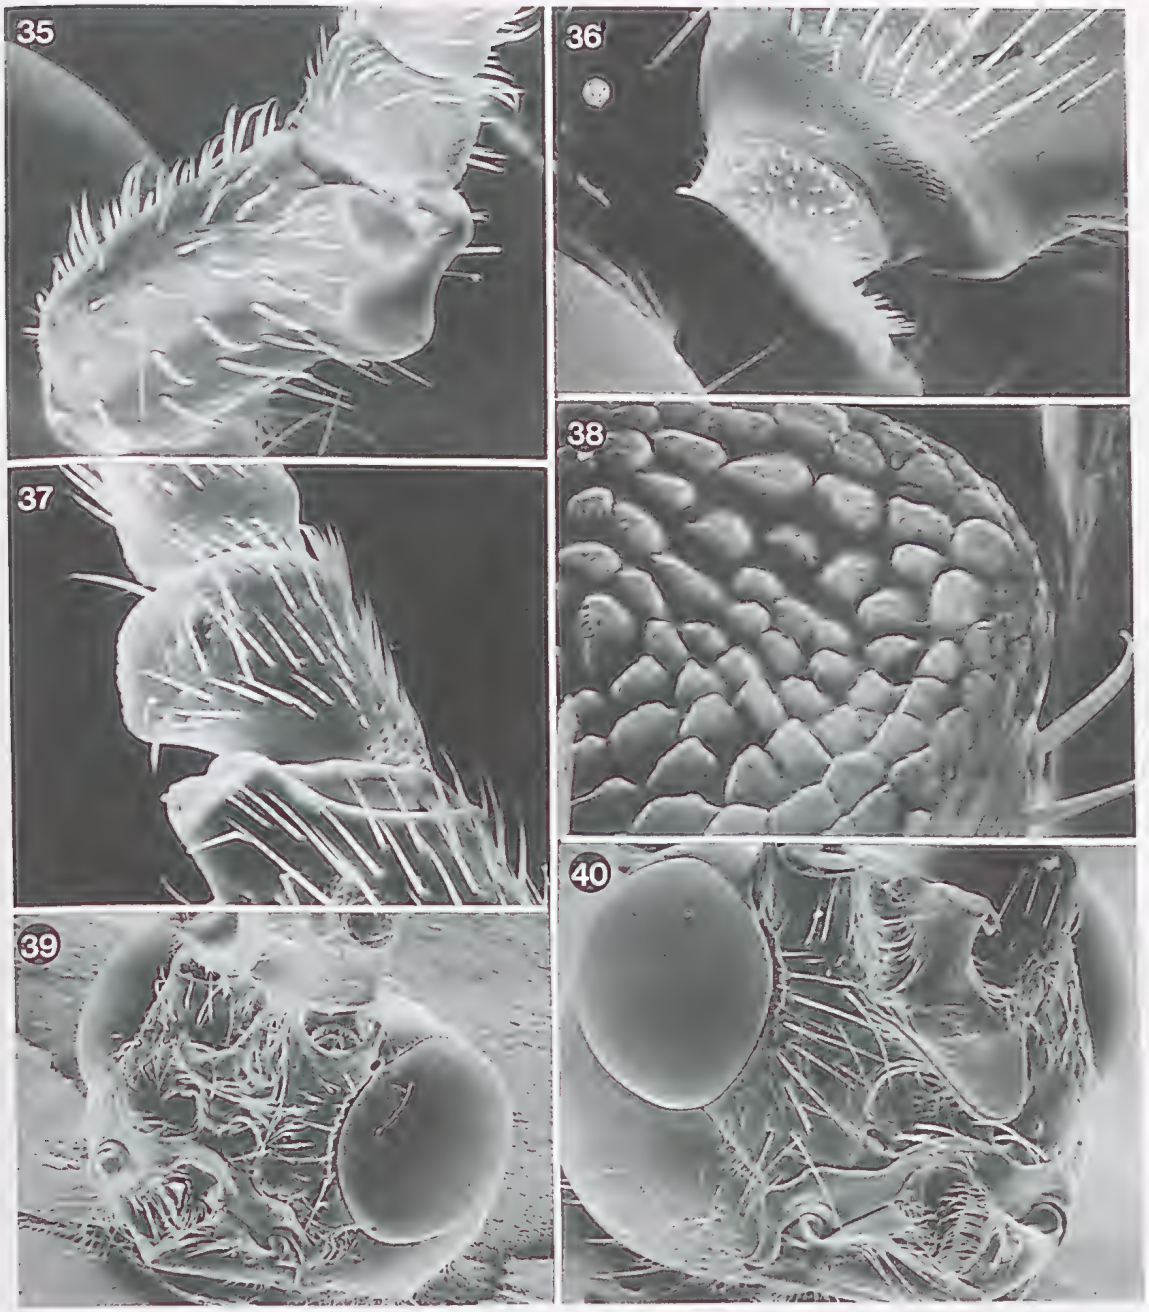
Lengths of fore femur: tibia : tarsus = 1.0:1.29:1.52. Lengths of hind femur: tibia: basitarsus = 1.3:2.4:1.0. Hind basitarsus 9 times longer than maximally deep.

Metasomal tergites largely evenly sculptured with fine, anastomosing, longitudinal ridges separated by rows of punctures (as in *huddlestoni* Quicke), but 5th tergite with longitudinal striation weaker and less regular. First tergite 1.1 times longer than posteriorly wide. Second tergite 1.5 times wider posteriorly than medially long. Posterior margin of 5th tergite with well-developed perimedial projections and with lateral emarginations.

Yellowish-brown except for antennae and apices of tarsi which are piceous and ovipositor sheaths which are black. Wings slightly hyaline with brown venation.

ETYMOLOGY

Named in honour of the senior author's father, Walter Jesse Quicke, for his years of patience.



FIGS 35-40. Features of scapus, pedicellus and face: 35, *Chaoilta (Chaoilta)* sp., scapus and pedicellus apico-medial aspect; 36, *Chaoilta (Chaoilta)* sp., base of scapus, lateral aspect; 37, *Chaoilta (Chaoilta)* sp., pedicellus, medial aspect; 38, *Chaoilta (Blastomorpha) decorata*, detail of apical part of pedicellus; 39, *Chaoilta (Chaoilta)* sp., head; 40, *Chaoilta (Blastomorpha) decorata*, head.

*Gelasinibracon Quicke
(Figs 45, 71, 73, 10)

Small braconines of the tribe Braconini with wing lengths less than 6mm. Known only from two closely related species: *G. sedlaceki* Quicke from Papua New Guinea and north Queensland and *G. simplicicaudatus* Quicke, only known

from Papua New Guinea (Quicke, 1989b). Nothing is known of their biology.

Habrobracon Ashmead
(Fig. 86)

Habrobracon is closely related to *Bracon*, which is probably paraphyletic because *Habrobracon* is classified separately. Cosmopolitan group of small wasps, with about twenty described species. Several species have been employed as biological control agents principally against stored product pests and *H. gelechiae* (Ashmead) has been introduced into Australia. *H. hebetor* (Say) is also recorded from Australia where it has been reared from *Cactoblastis cactorum.*

Hybogaster Szépligeti
(Figs 18, 30, 47, 67, 128)

Large wasps apparently related to the Euurobraconini (Quicke, 1988a). A principally Indo-Australian genus but with one species occurring in South Africa (Quicke, 1988a) and another in north Queensland. It should be noted however, that Parrott's (1953) record of *Hybogaster* from Australia is a misidentification of *Iphiaulax australiensis* Ashmead (Quicke, 1991a). Nothing is known of the biology of *Hybogaster* species but members of the related genus *Zeuzerilia* van Achterberg are parasites of Cossidae (van Achterberg, 1989).

Hyboteles van Achterberg
(Figs 72, 74, 105, 115)

Small wasps belonging to the subtribe Aspidobraconina of the Braconini. *Hyboteles* ranges from Brunei and the Philippines to north Australia and is monophyletic. Probably all Aspidobraconina are endoparasitoids of butterfly pupae; *Hyboteles toxopeusi* van Achterberg has been reared as a solitary endoparasitoid from a lycaenid pupa in Papua New Guinea (Quicke, 1987a, 1988b).

Iphiaulax Foerster
(Figs 32, 33, 63, 129)

Synonyms. Aniphiaulax Kokoujev; *Iphiaulacidea* Fahringer; *Euglyptobracon* Telenga

A large and virtually cosmopolitan genus of medium-sized braconines. Eight Australian species were treated by Quicke (1991a); several of these had previously been wrongly placed in *Cyanopterus* Haliday or *Hybogaster* Szépligeti. Subsequently, the senior author has seen specimens of two undescribed Australian species in the collection of the AEIG. Nearly all members of the genus appear to be specialized parasitoids of cerambycid beetle larvae (Quicke, 1988b) but van Achterberg (1989) reported one species as having been reared from cossid moth larvae. Some species are frequently collected amongst mangroves and females are capable of giving a painful sting (DLJQ, pers. obs.).

Ligulibracon Quicke
(Figs 21, 42, 55, 88, 123)

A small genus of medium-sized to large Aphrastobraconini entirely restricted to Australia; apparently only the type-species, *L. levor* Quicke, is described though several others have been seen in collections by the senior author. Nothing is known of the biology of *Ligulibracon*, though, in common with other Australian Aphrastobraconina, they seem to be at least partially nocturnal (Quicke, 1992).

Macrobracon Szépligeti
(Figs 57, 58)

A small genus of large braconines belonging to the *Mesobracon* Szépligeti group (see Quicke, 1987b). *Macrobracon* ranges from north Queensland to south India; only one species, *M. nobilis* Turner, occurs in Australia (Shenefelt, 1978). Nothing is known of the biology of *Macrobracon* though members of the related oriental genus *Pseudoshirakia* van Achterberg attack stem-boring pyralid moth larvae in grain crops (Achterberg, 1983).

Megalommum Szépligeti
(Figs 22, 41, 49, 61)

Medium-sized species of Aphrastobaconini primarily from Australia, where there are many undescribed species, but also occurring in Papua New Guinea. Frequently collected at light (Quicke, 1992). The ovipositors of members of this genus collectively display a great deal of variation in length and shape but typically lack apico-ventral serrations probably indicating that oviposition takes place into a soft substrate.

Mollibracon Quicke
(Figs 17, 133)

A monotypic genus of medium-sized wasps entirely restricted to Australia. *M. bimaris* (Turner) has been reared as a parasitoid of curculionid larvae, *Meriphus longirostris*, in *Banksia* cones (Quicke, 1988b). Most specimens seen by us are from Western Australia.

Myosoma Brullé
(Figs 2, 54, 70)

Synonyms. Acanthobracon Kriechbaumer; *Amyosoma* Viereck

A largely neotropical genus of small to medium-sized Braconini but with a few mostly smaller species known from the Old World tropics (Quicke & Wharton, 1989). *Myosoma rufescens* is the first true record of this genus in Australia (see Quicke, 1988b); *M. mutator* (Fabricius) belongs to *Pycnobraconoides* gen.nov. *Myosoma* spp. appear to be principally parasitoids of concealed pyralid moth larvae (Shenefelt, 1978; Quicke & Wharton, 1989) but *M. chinensis* has also been reared from the larvae of the cossid *Zeuzera* in India, and *M. yanoi* (Watanabe) has been reared from larvae of the sesiid *Paranthrene regale* in Japan (Maetô, 1992).

Key to Indo-Australian species of *Myosoma*

1. Metasomal tergites 1-5 bright orange contrasting strongly with piceous or black tergites 6-9 (Fig. 2); head largely black .....*M. rufescens* sp.nov.
- Metasomal tergites unicolorous piceous or black; head variably coloured .....
.....*M. chinensis* (Szépligeti) & other spp.

Myosoma rufescens sp.nov.
(Fig. 2)

MATERIAL EXAMINED

HOLOTYPE: ♀ with the following labels: 'AUSTRALIA: ACT Canberra, Black Mtn. Jan 25-30. 1984 L. Masner, MT' & 'Dry sclerophyl Eucalyptus for.' From AEIG but on permanent loan to ANIC by agreement with collections manager.

PARATYPE: ♂ with following labels: 'QUEENSLAND: Mirani 34km NW Mackay X-16-79' and 'HE & MA Evans & A. Hook Coll.'. ANIC.

DESCRIPTION (♀)

Length of body 5.7mm, of fore wing 5.5mm and of ovipositor (part exserted beyond apex of metasoma) 1.3mm.

First flagellomere 1.07 times longer than both the 2nd and 3rd separately. Third flagellomere 1.4 times longer than wide. Height of clypeus: intertentorial distance: tentorio-ocular distance = 1.0: 3.7: 2.3. Face smooth medially; coriaceous and densely setose laterally. Height of eye: shortest distance between eyes: width of head = 1.05:1.0:2.0. Frons densely setose except along the median line. Post-ocellar line: transverse diameter of posterior ocellus: shortest distance between posterior ocellus and eye = 1.4:1.0:3.57. Occiput largely glabrous. Horizontal length of eye 1.7 times horizontal length of head behind eye.

Mesosoma 1.5 times longer than high. Notauli weak but impressed along whole length of mesoscutum. Lateral lobes of mesoscutum glabrous.

Forewing. Lengths of veins SR1:3-SR: r = 3.9: 3.0: 1.0. Lengths of veins 2-SR:3-SR:r-m = 1.1: 2.0: 1.0. Pterostigma 3.15 times longer than maximally wide. Vein cu-a virtually interstitial. Vein 1-SR+M straight.

Hindwing. Lengths of veins 1r-m: SC+R1 = 1.0:1.7. Apex of vein C+SC+R with one especially thickened bristle. Base of wing evenly setose.

Lengths of fore femur: tibia: tarsus = 1.0: 1.1: 1.3. Lengths of hind femur:tibia:basitarsus = 1.9: 2.8 :1.0. Hind femur 3.2 times longer than maximally wide. Hind tarsus 7.0 times longer than maximally wide. Hind basitarsus 6.5 times longer than apically deep.

Metasoma smooth and shiny. First tergite approximately 2.2 times longer than maximally wide; lateral areas narrow but complete. Second tergite with antero-lateral corners with reduced sclerotization. Second suture straight, narrow, quite deep. Tergites 3 to 6 with irregular, sparse, short setosity posteriorly.

Pale orange brown to brownish yellow except for the following which are black or piceous: antennae; head except labio-maxillary complex, palps and base of mandibles; mid- and posterior legs; metasomal tergites 6 and 7; ovipositor sheaths. Wing membrane pale brown slightly paler distally; venation and pterostigma dark brown.

DESCRIPTION (♂)

As for female except slightly smaller and the middle leg is brownish yellow except for the telotarsus which is piceous.

*Paranesaulax Quicke
(Figs 24, 99, 106, 127)

Medium-sized braconines known from only one described species from Papua New Guinea, *P. nitor* Quicke. A possibly conspecific individual from north Queensland has been seen by the authors. Nothing is known of the biology of this genus.

Pedinopleura van Achterberg
(Figs 78, 114, 121, 122)

Small species belonging to the Aspidobraconina. In addition to *P. australiensis* sp.nov., two non-Australian species have been described (Achterberg, 1984) but many undescribed ones occur in South Africa, India through Malaysia to New Guinea and north Australia. There are no host records for this genus but three other genera of the Aspidobraconina (*Aspidobracon* van Achterberg, *Hyboteles* van Achterberg and *Philomacroploea* Cameron) have been reared from butterfly pupae (van Achterberg, 1984; Quicke, 1987a).

Key to the Indo-Australian species of *Pedinopleura* (♀♀ only)

1. Face, frons, temples and vertex smooth; lateral margin of syntergite 1+2+3 with an obvious notch (Fig. 122); antenna largely brownish becoming piceous apically ...*P. emarginata* van Achterberg
   - Face, frons, temples and vertex striate (Fig. 78); lateral margin of syntergite 1+2+3 without notch, evenly curved or with a single posterior lobe (Fig. 121); antenna black 2
2. Metasomal tergites 3-5 with a dark spot on either side; posterior margin of 6th metasomal tergite with a well-developed emargination; lateral margin of syntergite without a posterior lobe; frons and vertex coarsely transversely striate ....*P. koshuensis* (Watanabe)
   - Metasomal tergites 3-5 unicolorous brownish yellow; posterior margin of 6th metasomal tergite only very weakly emarginate (Fig. 114); lateral margin of syntergite with a well-developed posterior lobe (Fig. 121); frons and vertex very finely transversely striate (Fig. 78) ....*P. australiensis* sp.nov.

Pedinopleura australiensis sp.nov.
(Figs 78, 114, 121)

MATERIAL EXAMINED
HOLOTYPE: ♀ with following labels: 'Ayr Queensland 4 Sep. 1950 E.F.Riek'. Deposited in ANIC.
PARATYPE: ♂ with same data as holotype. ANIC.

DESCRIPTION (♀)
Length of body 4.5mm, and of forewing 4.3mm, of ovipositor (part exserted beyond apex of metasoma) 1.1mm and of antenna 4.1mm.

Antenna with 36 flagellomeres. Terminal flagellomere pointed but not acuminate, 2.1 times longer than basally wide. Median flagellomeres approximately as wide as long. First flagellomere 1.3 times longer than both the 2nd and 3rd separately, the latter being 1.2 time longer than wide. Height of clypeus: inter- tentorial distance: tentorio-ocular distance = 1:2:2. Height of eye: width of face: width of head = 1.0:1.5:1.77. Malar suture deep and narrow. Face with multiple, strong, parallel, transverse ridges. Eyes virtually glabrous. Frons and occiput finely subtransversely carinate. Head very transverse; horizontal length of head behind eye: horizontal length of eye = 2.35:1.0 Post- ocellar length: transverse diameter of posterior ocellus: shortest distance between posterior ocellus and eye = 1.0:1.0:2.75.

Mesosoma 1.4 times longer than high; strongly sculptured, mostly punctate. Median area of metanotum with a complete mid- longitudinal carina. Precoxal suture not impressed; indicated by a band of punctures. Propodeum with a complete mid-longitudinal carina bordered by short, rather weak crenulations.

Forewing. Lengths of veins SR1:3-SR:r = 7.3:2.8:1.0. Lengths of veins 2-SR:3-SR:r-m = 1.1:1.7:1.0 Vein 2-SR+M long, shortest distance between 1st discal cell and 2nd submarginal cell: length of vein m-cu = 1.7:1.0. Vein cu-a interstitial.

Length of fore femur: tibia: tarsus = 1.0:1.0:1.15. Length of hind femur: tibia: basitarsus = 1.94: 2.65: 1.0. Hind basitarsus 4.9 times longer than deep.

Metasoma with strong rugose sculpture. First tergite with a distinct median groove posteriorly. Posterior margin of 6th tergite very weakly emarginate. Ovipositor (part exserted beyond apex of metasoma) approximately 0.4 times length of forewing.

FIGS 41-48. Features of head: 41, *Megalommum* sp.; 42, *Ligulibracon* sp.; 43, *Eucurriea* sp.; 44, *Chaoilta (Chaoilta)* sp.; 45, *Gelasinibracon* sp.; 46, *Pycnobraconoides mutator* (Fabricius); 47, *Hybogaster* sp.; 48, *Euurobracon latitempus* Quicke.

Entirely honey-yellow except for antennae, hind tarsi, and ovipositor sheaths which are black or piceous. Wing membrane pale yellow tending to hyaline distally; vein C+SC+R and pterostigma piceous, remainder of venation yellowish.

DESCRIPTION (♂)

Very similar to female except smaller and posterior margin of 6th metasomal tergite only marginally emarginate and antenna dark rufous.

Ploceibracon Quicke
(Figs 75, 79, 100)

Known only from the type species, *P. monstrans* Quicke, from New South Wales. The holotype of *P. monstrans* has a small dark mark indicating a trace of hindwing vein 3-CU and, together with the strong spur from fore-wing vein 3-CU1, this may indicate a relationship with *Calcaribracon.* Nothing is known of its biology.

Psittacibracon Quicke
(Figs 9, 10, 132)

A rare monotypic genus of medium-sized Braconini entirely restricted to Australia. *Psittacibracon lacteolus* Quicke (Figs 9, 10) is known from a few specimens from South Australia, Western Australia and New South Wales. Nothing is known of its biology.

Pycnobraconoides gen.nov.
(Figs 6, 46, 130)

TYPE SPECIES

Ichneumon mutator Fabricius 1775: 335.

DIAGNOSIS

Pycnobraconoides can be distinguished from other members of the tribe Braconini (sensu van Achterberg, 1983) by the following combination of characters: (i) head very transverse; (ii) eyes usually moderately to very setose; (iii) precoxal suture absent; (iv) hindwing vein 1r-m much shorter than vein SC+R1(v) 2nd submarginal cell of forewing long; (vi) claws with rounded basal lobes; (vii) propodeum simple, without a mid-longitudinal carina; (viii) metasoma robust, 3rd tergite more than 2 times wider than long; (ix) ovipositor robust, without a pre-apical dorsal nodus but distinctly pre-apically expanded (Fig. 130); (x) mandibles (except for apex) white.

GENERIC DESCRIPTION

Antennae shorter than forewing, with approximately 40 flagellomeres. Terminal flagellomere acuminate. Median flagellomeres marginally longer than wide. Scapus small, shorter ventrally than dorsally in lateral aspect; not apico-medially emarginate. Labio-maxillary complex short. Mandibles ivory-white except for darker apex. Clypeus angled into hypoclypeus but without a transverse median carina: separated from face dorsally by a groove. Face smooth and shiny, setose. Eyes usually moderately to very densely setose; distinctly emarginate. Frons weakly impressed, largely setose, with a well-developed mid- longitudinal sulcus. Head very transverse; horizontal length of eye approximately 2.5 times longer than horizontal length of head behind eye.

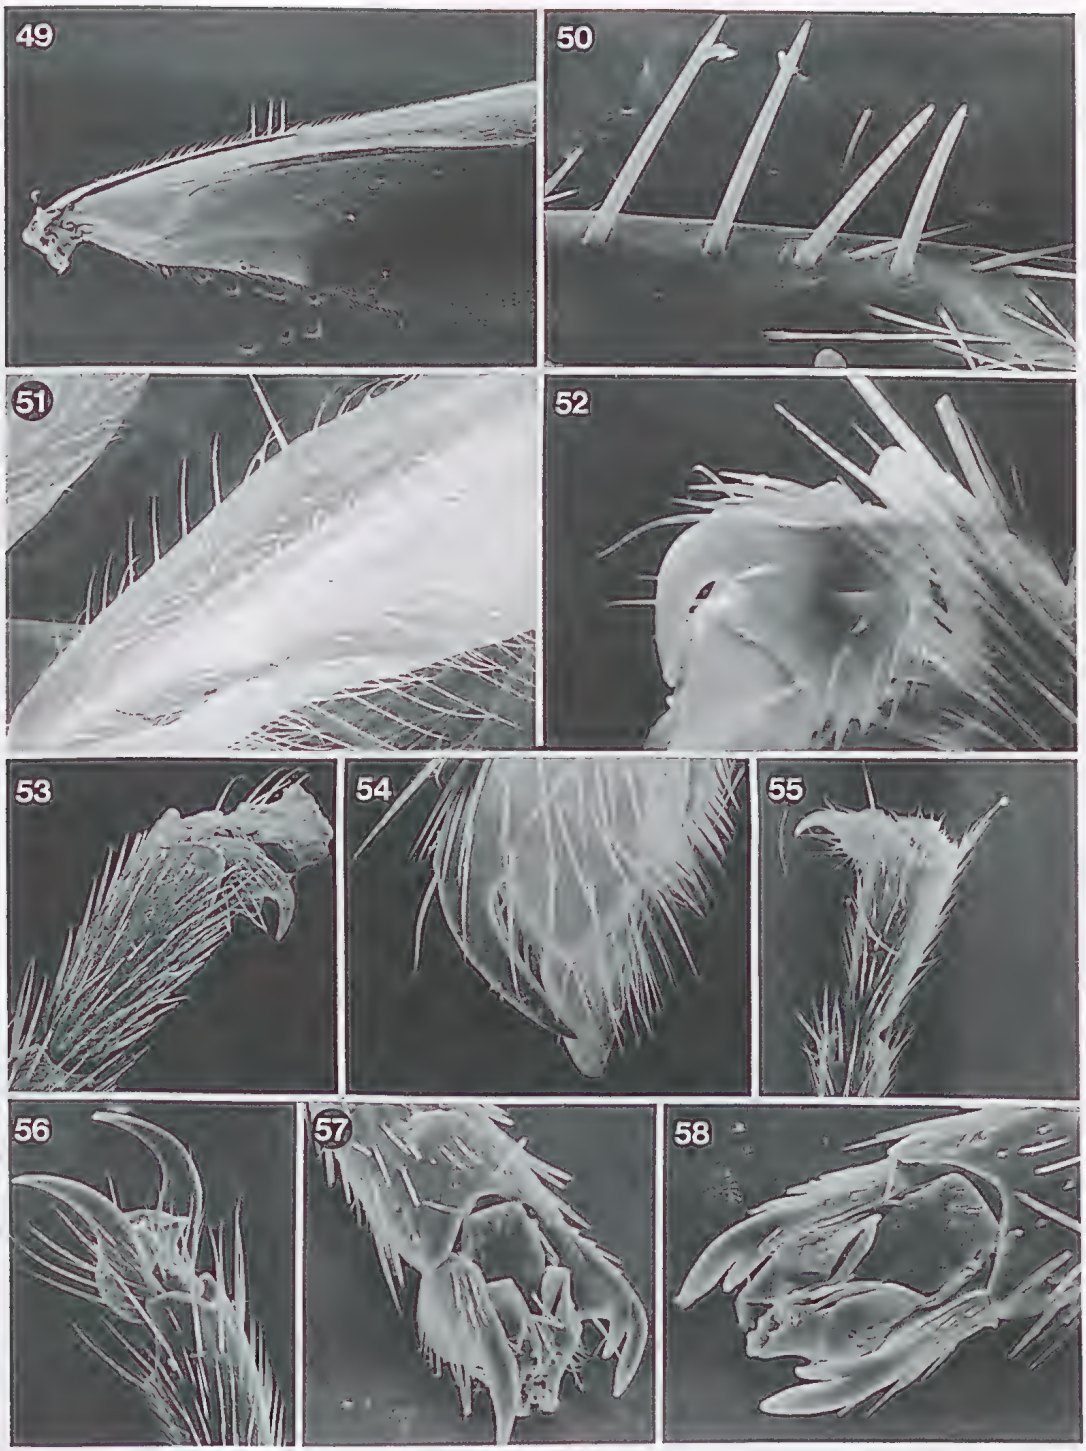
Mesosoma smooth and shiny approximately 1.3 times longer than high. Mesosotum largely glabrous except for along line of notauli. Notauli weakly impressed anteriorly, not impressed posteriorly. Scutellar sulcus narrow, crenulate. Precoxal suture absent. Mesopleural suture smooth. Median area of metanotum not carinate. Propodeum without carinae. Propodeal spiracle small, round, situated near middle of propodeum.

Forewing. Vein 1-SR+M more or less straight. Vein 2-SR+M short, more or less interstitial. Second submarginal cell long, vein 3- SR approximately 0.8 times length of vein SR1. Veins C+SC+R and 1-SR forming an angle of approximately 75°. Vein r- m unsclerotized. Vein cu-a interstitial.

Hindwing. Vein 1r-m much shorter than vein SC+R1. Apex of vein C+SC+R with only one especially thickened bristle. Base of wing evenly setose.

Claws with rounded basal lobes. Hind tibia slender, with indistinct longitudinal, lateral groove.

Metasoma short, wide, robust, largely with rugose to strong punctate sculpture but largely smooth in some species. First tergite with dorsolateral carinae; raised median area sculptured posteriorly, strongly sloping, smooth anteriorly. Second tergite wide, with or without elongate median area (defined largely by difference in sculpture); anterolaterally with a pair of longitudinal, sub-parallel grooves. Tergites 3 to 5 with posterior margins rounded in profile, rarely 5th with a weak transverse, subposterior groove. Ovipositor robust, pre-apically smoothly expanded pre-apically (Fig. 130), ventral valves without or with extremely reduced serrations; part exserted



FIGS 49-58. 49-51, apex of hindwing vein C+SC+R showing specialised bristles: 49, *Megalommum.*; 50, *Callibracon* sp.; 51, *Bracon* sp. 52-58, features of claws: 52, *Calcaribracon willani* sp.nov.; 53, *Bracon* sp.; 54, *Mysosoma* sp.; 55, *Ligulibracon* sp.; 56, *Euurobracon* sp.; 57-58, *Macrobracon* sp.

beyond apex of metasoma slightly shorter than medial length of metasomal tergite 2+3.

MALES

Very similar to females. Intertergal metasomal glands well-developed with a pair of large sac-like reservoirs (Quicke, 1990). Genitalia: digitus with a single apical tooth; parameres with only a single row of setae apically.

BIOLOGY

From many, largely unpublished, records it is clear that *Pycnobraconoides* gen.nov. is a specialised parasitoid of cryptocephaline chrysomelid beetle larvae (Quicke, 1988b). The beetle larvae (and pupae) live in a case from which single specimens of *Pycnobraconoides* commonly emerge. The following cryptocephalines have been recorded as hosts of various species of *Pycnobraconoides*:'*Cadmus*' *aurantiacus*, *Cryptocephalus speciosus*, *Lachnabothra* sp., and *Prasonotus* sp. It is presumed but not proven that *Pycnobraconoides* is ectoparasitic.

DISCUSSION

Pycnobraconoides gen.nov. appears to be most closely related to the oriental genus *Pycnobracon* Cameron which was originally described from India (Cameron, 1902), and recently members of the new genus have been dealt with under *Pycnobracon*. However, it has been recognised for some time that the Australian representatives do not fit well in *Pycnobracon*. Indeed, Quicke (1987b) considered *Pycnobracon* to comprise two sections: those keying out at couplet 108 (loc. cit.), which are referable to *Pycnobracon* sensu stricto; and those keying out at couplets 90 and 94, which are placed here under *Pycnobraconoides* gen.nov. In particular, *Pycnobraconoides* differs from *Pycnobracon* in having a robust ovipositor without a pre-apical dorsal nodus and an extremely transverse head. The biologies of the two genera also differ considerably with *Pycnobracon* sensu stricto parasitic on pyralid moth larvae while *Pycnobraconoides* attacks case-bearing Chrysomelidae (see above). Within Australia, the new genus is widely distributed and specimens representing a small number of species have been seen from Australian Capital Territory, Queensland, New South Wales, Tasmania and Western Australia.

INCLUDED SPECIES

Pycnobraconoides froggattii (Cameron) comb.nov. (= *Bracon froggattii* Cameron, 1911: 339); holotype in BMNH examined.

Pycnobraconoides mutator (Fabricius) comb. nov. (= *Iphiaulax bipartitus* Szépligeti 1905:35; junior subjective synonym, Quicke, 1991c).

*Rostraulax Quicke
(Fig. 104)

Rostraulax species are medium-sized wasps found primarily in Indonesia and New Guinea. One species, *R. xanthocephalus* (Turner), is found in Queensland and northern New South Wales rainforests as well as in Papua New Guinea. Nothing is known of the biology of *Rostraulax* but the apparently related genus *Cratobracon* has been reared from wood-boring cerambycid larvae (Quicke, unpubl. obs.). *Rostraulax* is very closely related to *Shelfordia* Cameron and may need to be synonymized with that genus (van Achterberg, pers. comm.).

Serratobracon Tobias
(Figs 83, 85, 107)

This genus is known from only a single specimen from the Northern Territory which has a highly characteristic combination of pedicellus and scapus morphology. Its affinities were discussed by Tobias in Quicke & Tobias (1990), who concluded that it may be related to either *Sylvibracon* Quicke or to the *Atanycolus* group of genera (Quicke, 1987b). However, neither of these placements is satisfactory and more material needs to be studied.

Simplicibracon Quicke
(Figs 5, 76, 102)

Previously, species of this genus were only known from Taiwan (Quicke, 1988e) and Japan (Maetô, 1991). In addition to these and the new Australian species, the senior author has seen specimens of another new species from Fiji. In *Simplicibracon*, the strongly developed transverse median clypeal carina (Fig. 76) is quite distinctive and most species (except for two seen from Japan) have hind wing vein 2-SC+R slightly transverse. The one species for which the biology is known, *S. curticaudis* Maetô, is a parasitoid of leaf-galling Cecidomyiidae on broad- leaved, evergreen trees (Maetô, 1991).

Key to the species of *Simplicibracon* (♀♀ only)

1. Hindwing vein 2-SC+R longitudinal (see Fig. 101); ovipositor (part exserted beyond apex of metasoma) less than 0.25 times length of forewing; metasomal tergites unicolorous brownish yellow to yellowish brown; 2nd metasomal tergite less than 1.8 times wider than medially long ....*S. curticaudis* Maetô
   - Hindwing vein 2-SC+R transverse (Fig. 102); ovipositor (part exserted beyond apex of metasoma) more than 0.35 times length of forewing; metasomal tergites brownish yellow to whitish yellow, marked with brown or black blotches on tergites 2 and 3 or 3 and 4; 2nd metasomal tergite more than 1.8 times wider than medially long 2
2. Notauli crenulate; metasomal tergites metasomal tergites 5-7 yellow-brown, same as tergites 1 and 2 .....*S. maculigaster* Quicke
   - Notauli smooth; metasomal tergites 5-7 cream-white, different from tergites 1 and 2 ....*S. nigritarsus* sp.nov.

Simplicibracon nigritarsus sp.nov.
(Figs 5, 76, 102)

MATERIAL EXAMINED

HOLOTYPE: ♀ with the following labels: '15.41S 145.12E Annan Riv. 3Km WbyS Black Mt. 26-27 Apr. 1981Q, I.D. Naumann ex ethanol' & 'collected at light'. Deposited in ANIC.

DESCRIPTION (♀)

Length of body 4.2mm, of fore wing 4.6mm, of ovipositor (part exserted beyond apex of metasoma) 1.9mm, and of antenna 4.1mm.

Antennae with 32 flagellomeres. First flagellomere 1.3 times longer than both the 2nd and 3rd separately, the latter being 1.5 times longer than wide. Transverse median clypeal carina strongly protruding. Height of clypeus (upper part): intertentorial distance: tentorio-ocular distance = 1.0:1.82:1.63. Face shiny with moderately well-developed punctures at the bases of the setae. Height of eye (measured parallel to face): width of face: width of head = 1.0:1.18:2.36. Face 2 times wider than high. Eyes weekly setose. Frons without a mid-longitudinal ridge; weakly impressed. Shortest distance between posterior ocelli: transverse diameter of posterior ocellus: shortest distance between posterior ocellus and eye = 1.43:1.0:3.14.

Mesosoma 1.24 times longer than high. Pronotum largely smooth and shiny with narrow crenulate groove laterally. Mesonotum moderately setose posteriorly and laterally but anterior third of middle lobe virtually glabrous. Notauli moderately impressed, not crenulate. Precoxal suture represented by only a weak rounded depression.

Forewing. Lengths of veins SR1:3-SR:r = 5.6:1.9:1.0. Lengths of veins 2-SR: 3-SR: r-m = 1.6:1.9:1.0. Vein r-m with only a single posterior bulla and associated flexion line. Length of vein m-cu: shortest distance between 1st subdiscal cell and 2nd submarginal cell = 0.8:1.0.

Hindwing. Base of wing more or less evenly, densely setose. Vein 2-SC+R distinctly transverse. Apex of vein C+SC+R with only one especially thickened bristle.

Lengths of fore femur: tibia: tarsus = 1.0:1.13:1.3. Fore tibia moderately densely with strong spine-like setae antero-laterally. Lengths of hind femur: tibia: basitarsus = 1.8:2.55:1.0. Hind tibia very robust, 6.1 times longer than maximally deep. Hind basitarsus 4.4 times longer than deep.

Metasoma with rugulose sculpture. Second tergite 2.1 times wider than medially long. Ovipositor (part exserted beyond apex of metasoma) approximately 0.4 times length of forewing.

Brownish yellow except for the following: antennae, hind tibia except extreme base, hind basitarsus, a pair of large submedial marks on the 3rd and 4th tergites, ovipositor sheaths, black. Lateral parts of 3rd and 4th tergites and all except for a mid- longitudinal yellow line on tergites 5 to 7, white. Wings pale smoky brown with brown venation.

NOTE

The holotype of *S. nigritarsus* sp.nov. is the same specimen as referred to by Quicke (1992).

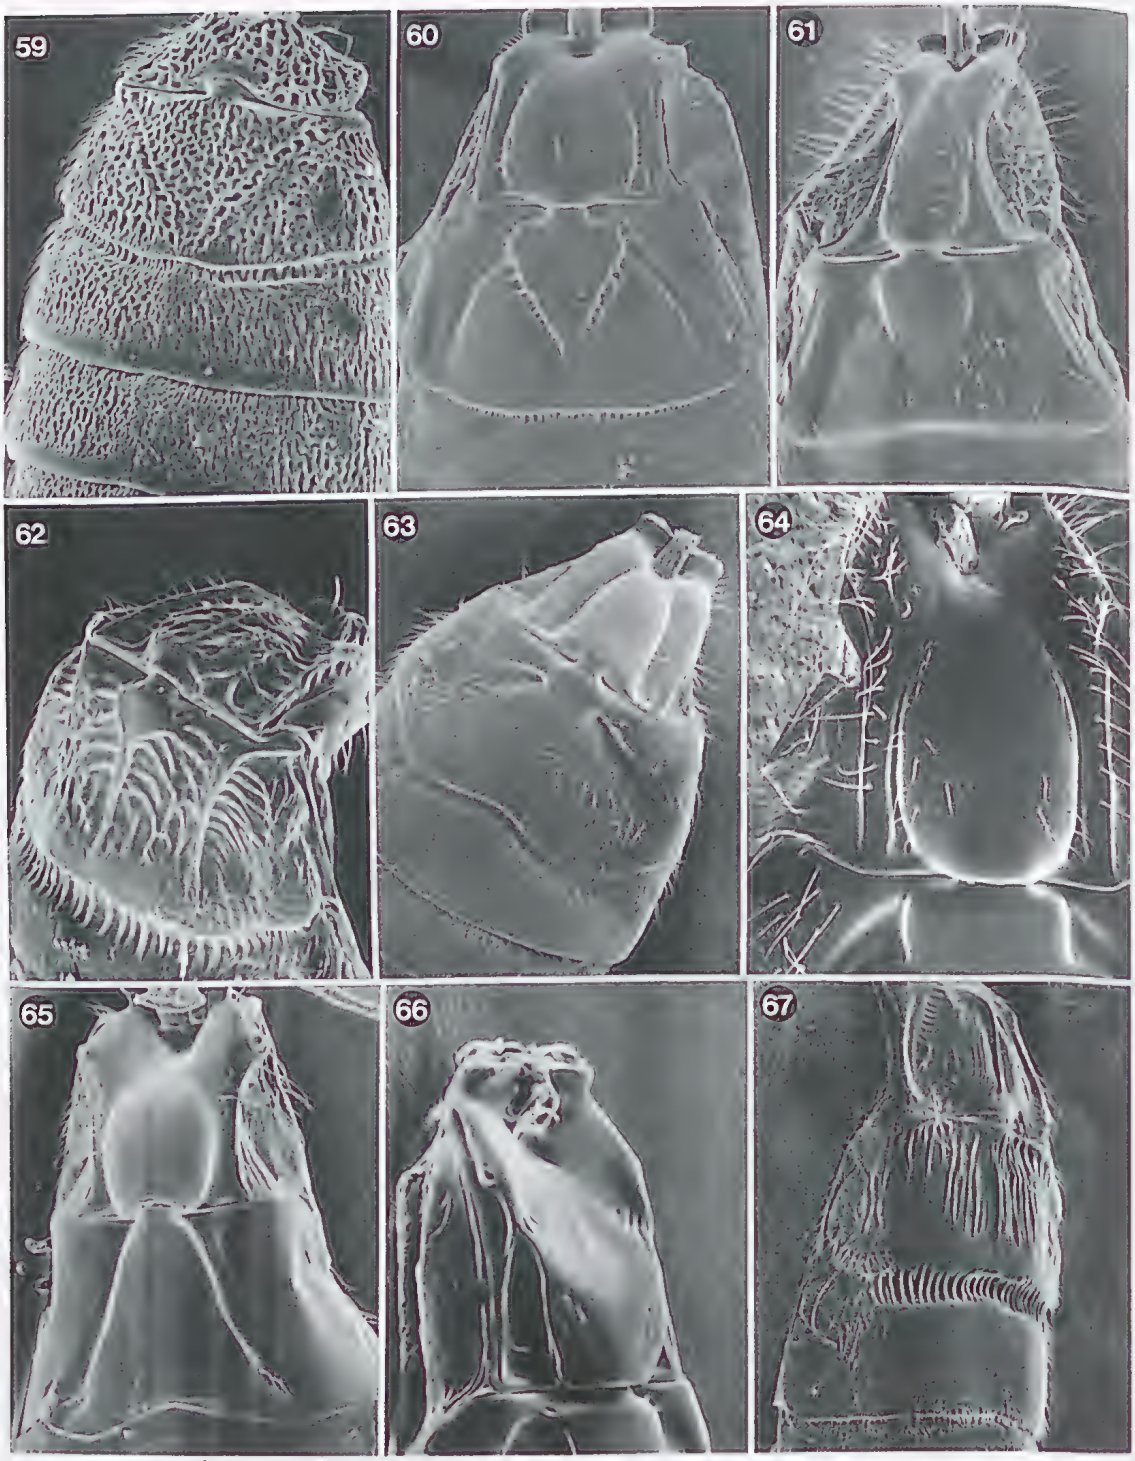
Stenobracon Szépligeti
(Fig. 93)

Synonyms. Elphea Cameron; *Phanaulax* Cameron.

A small genus of medium-sized wasps belonging to the tribe Bathyaulacini. One probably undescribed species is found in the north of Western Australia in the Kimberleys. Elsewhere, *Stenobracon* spp. are important parasitoids of Lepidoptera larvae that bore in stems of grain crops (Quicke, 1983; 1988c) but nothing is known about the biology of the Australian species.

Stigmatobracon Turner
(Figs 1, 131)

A small genus of medium-sized to large wasps.



FIGS 59-67. Features of the metasoma: 59, *Tropobracon* sp. (African) T1-T4; 60, *Eunesaulax* sp., T1-T2; 61, *Megalommum* sp., T1-T2; 62, *Campyloneurus* sp., Tj1- T2; 63, *Iphiaulax* sp., T1-T3; 64, *Callibracon* sp., T1; 65, *Virgulibracon* sp., T1-T2; 66, *Vomeribracon* sp., T1; 67, *Hybogaster* sp., T1-T4.

A key to the four described species, all from Australia, is provided by Turner (1918). However, the senior author has seen a female of *S. xanthostigma* Turner from Papua New Guinea and also males with somewhat different colouration also from Papua New Guinea These may represent a new species, though the possibility of sexual dimorphism in this group cannot be ruled out. Nothing is known of their biology though one species has been collected amongst mangroves (*Rhizophora*) in north Queensland, and other specimens have been collected in the Northern Territory, Victoria and Western Australia.

Testudobracon Quicke
(Figs 116-120)

Small wasps belonging to the Braconini. Only a few species have been described but we are aware of many undescribed ones from both Africa and the Indo-Australian region. *Testudobracon* species are apparently specialist ectoparasitoids of gall-forming, cecidomyiid Diptera, especially — and perhaps exclusively — Asphondylini (Quicke 1986a; Maetô, 1991). This is also partly confirmed by an Australian host record for the genus, based on an apparently undescribed species represented in the QDPI collection, which had been reared from a gall on '*A. polycarpa*'.

Key to the species of *Testudobracon* (♀♀ only)

1. Median emargination of 6th metasomal tergite shallow and with rounded lateral margins (Fig. 120); ovipositor (exserted part) at least 0.75 times length of forewing; precoxal suture (if distinguishable), represented by a week, complete, narrow, longitudinal groove 2
   - Median emargination of 6th metasomal tergite deep and with sharply defined (angular) lateral margins (Figs 117, 118); ovipositor (exserted part) less than 0.75 times length of forewing; precoxal suture present as a deep, smooth, rounded pit 3
2. Hind leg almost entirely pale yellow-brown; metasomal tergites 4-6 largely whitish, except for basal (anterior) third which is yellowish and postero-lateral lobes which are somewhat darker; vertex with distinct fine transverse, striate sculpture; metasomal tergites 4-6 rugulose ..... *T. longicaudis* Maetô
   - Hind leg almost entirely black; metasomal tergites 4-6 with basal (anterior) half black or piceous brown, and posterior half white; vertex totally smooth and shiny; metasomal tergites 4-6 irregularly punctate (Fig. 120) ..... *T. australicolorus* sp.nov.
3. Postero-lateral margin of 6th metasomal tergite with a pointed protuberance (Fig. 116) 4
   - Postero-lateral margin of 6th metasomal tergite with a rounded lobe-like protuberance (Fig. 119) 5
4. Middle lobe of mesoscutum largely glabrous except for line of notauli; body and legs virtually entirely brownish yellow ..... *T. unicolorus* sp.nov.
   - Middle lobe of mesoscutum largely setose (except for anterior face); body and legs commonly with black or piceous markings especially frons, vertex, part of mesopleuron, metanotum and propodeum, middle coxae and hind coxa and hind femur ..... *T. pleuralis* (Ashmead)
5. Body and legs (except telotarsi) entirely pale brownish yellow; postero-lateral margin of 6th metasomal tergite hardly produced ..... *T. tatyanae* sp.nov.
   - Body and hind legs extensively marked with black and dark reddish-brown, metasoma with obvious pattern of dark red, black and white ..... *T. niger* Quicke

Testudobracon australicolorus sp.nov.
(Fig. 120)

MATERIAL EXAMINED

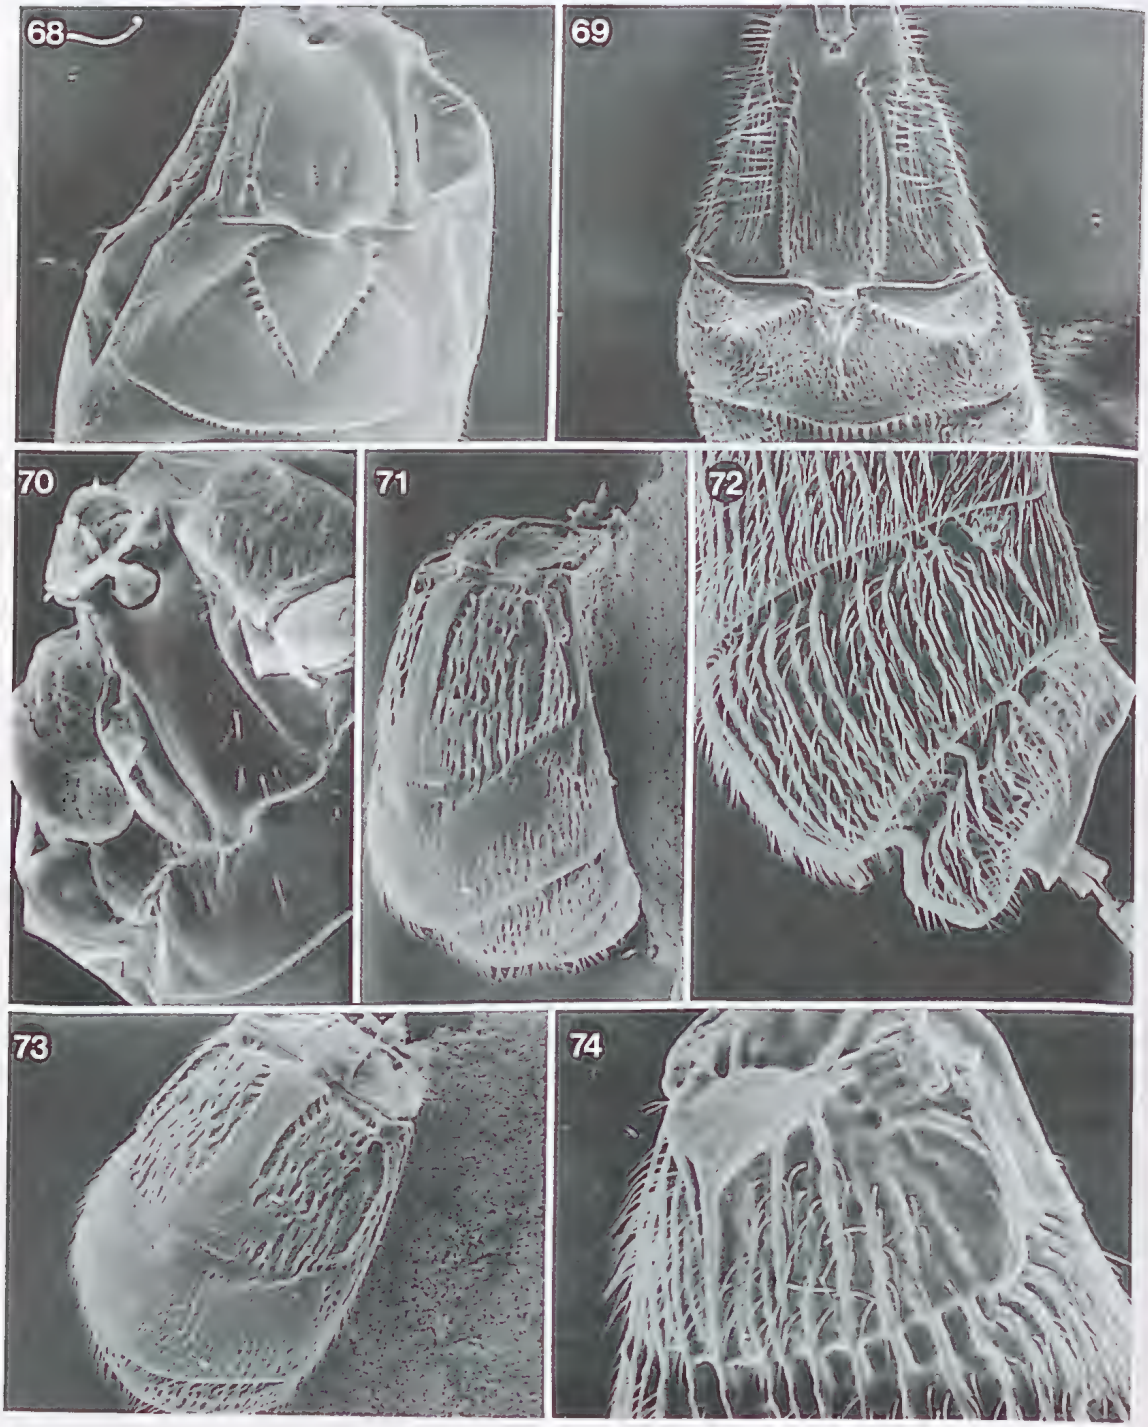
HOLOTYPE: ♀ with following labels: 'Mackay Queensland 1909-45', '834' & 'Mackay 3.92'. In collection of BMNH.

DESCRIPTION (♀)

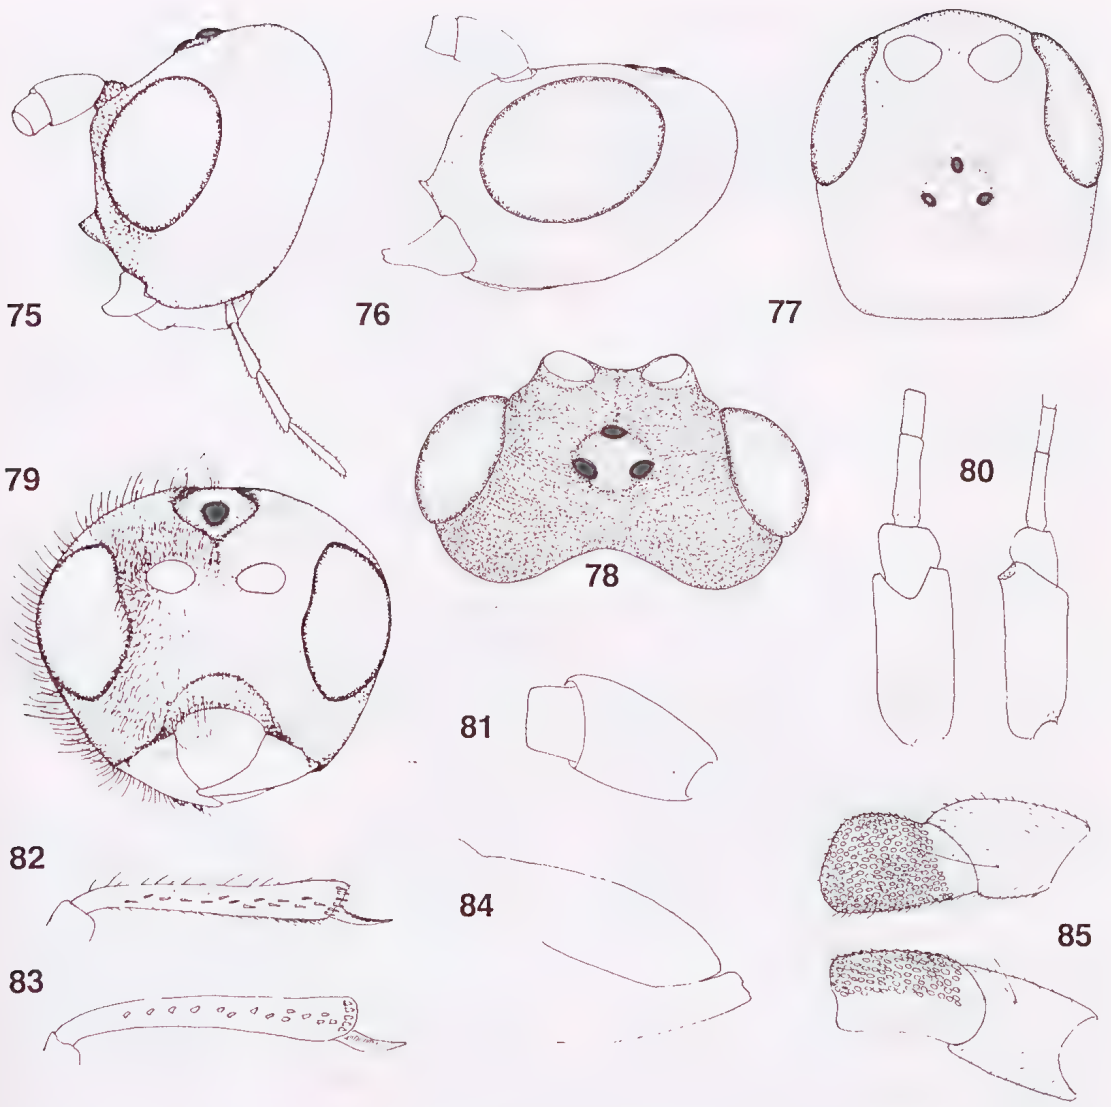
Length of body 3.7mm, of forewing 3.6mm and of ovipositor (part exserted beyond apex of metasoma) 2.9mm.

First flagellomere 1.1 times longer than both the 2nd and 3rd separately, the latter being 1.8 times longer than wide. Height of clypeus: intertentorial distance: tentorio-ocular distance = 1.0:2.2:1.58. Malar space 0.23 times height of eye. Face smooth and shiny medially, finely coriaceous laterally, without an obvious mid-longitudinal ridge. Height of eye: width of face: width of head = 1.0:1.1:2.1. Eyes sparsely short setose. Frons finely coriaceous medially, smooth and shiny laterally. Shortest distance between posterior ocelli: transverse diameter posterior ocellus: shortest distance between posterior ocellus and eye = 1.65: 1.0: 3.5. Horizontal length of eye 2.6 times horizontal length of head behind eye.

Mesoscutum smooth and shiny, setosity largely restricted to line of notauli. Precoxal suture rep-



FIGS 68-74. Features of the metasoma: 68, *Eunesaulax* sp., T1-T2; 69, *Chaoilta (Blastomorpha) decorata* Szépligeti, T1-T2; 70, *Myosoma* sp. (Indo-Australian), T1; 71, *Gelasinibracon* sp., T1-T5; 72, *Hyboteles* sp., T5- T6; 73, *Gelasinibracon* sp., T1-T3; 74, *Hyboteles* sp., T1.



FIGS 75-85. Features of head, mesosoma and legs: 75, *Ploceibracon monstrans* Quicke; 76, *Simplicibracon nigritarsus* sp.nov.; 77, *Atanycolus australiensis* sp.nov.; 78, *Pedinopleura australiensis* sp.nov.; 79, *Ploceibracon monstrans* Quicke; 80, *Atanycolus australiensis* sp.nov., base of antenna, dorso-lateral and dorsal aspects; 81, *Furcadesha walteri* sp.nov., scapus, lateral aspect; 82, *Atanycolus australiensis* sp.nov., fore tibia; 83, *Serratobracon cardaleae* Tobias, fore tibia; 84, *Atanycolus australiensis* sp.nov., profile mesoscutum and pronotum; 85, *Serratobracon cardaleae*, scapus and pedicellus, lateral and dorsal aspects.

resented by a complete but very weak, smooth, longitudinal groove.

Length of forewing veins SR1:3-SR:r = 5.2:2.8:1.0. Lengths of veins 2-SR:3-SR:r-m = 2.1:3.1:1.0.

Lengths of fore femur: tibia: tarsus = 1.05:1.0:1.2. Lengths of hind femur: tibia: basitarsus = 2.5:3.1:1.0. Hind tibia 5.7 times longer than wide.

Second metasomal tergite 2.7 times wider than medially long, with weak parallel-sided, smooth narrow median area, and with posteriorly converging, antero-lateral, longitudinal grooves nearly reaching posterior margin. Third tergite 2.9 times wider than medially long. Tergites 3 to 6 with weakly-developed, rounded postero-lateral lobes. Sixth tergite weakly emarginate me-

dially. Ovipositor approximately 0.8 times length of forewing.

Head, mesosoma fore and mid legs pale brownish orange except for piceous mark on top of head. Median parts of metasomal tergites 1-3 broadly brown to piceous, laterally whitish. Tergites 4-6 basally piceous brown, posteriorly white. Hind legs black. Wings pale brown with light to dark brown venation.

Testudobracon unicolorus sp.nov.
(Figs 116, 117)

MATERIAL EXAMINED
HOLOTYPE: ♀ with following labels: 'S.E. Queensland, Tamborine Mts. 19-26. iv. 1935' and 'AUSTRALIA: R.E.Turner B.M. 1935-240'. In BMNH collection.

DESCRIPTION (♀)
Length of body 2.6mm, of forewing 2.9mm and of ovipositor (part exserted beyond apex of metasoma) 1.7mm.

First flagellomere 1.2 and 1.4 times longer than the 2nd and 3rd respectively, the latter being 1.7 times longer than wide. Height of clypeus: intertentorial distance: tentorio-ocular distance = 1.0: 2.3: 1.7. Face largely finely coriaceous. Height of eye: width of face: width of head = 1.0:1.1:2.05. Eyes glabrous, not emarginate. Top of head shiny. Shortest distance between posterior ocelli: transverse diameter posterior ocellus: shortest distance between posterior ocellus and eye = 1.2: 1.0: 2.9. Horizontal length of eye 2.5 times horizontal length of head behind eye.

Mesosoma approximately as long as high. Notauli weak but distinct along whole length. Mesosutum setose medioposteriorly, along line of notauli and laterally. Precoxal suture represented by a deep pit.

Lengths of veins SR1:3-SR:r = 6.72: 2.5: 1.0. Lengths of veins 2- SR:3-SR:r-m = 1.25: 1.75: 1.0. Pterostigma 3.0 times longer than maximally wide.

Lengths of fore femur: tibia: tarsus = 1.0:1.0:1.27. Lengths of hind femur: hind tibia: hind basitarsus = 2.3:2.75:1.0. Hind tibia 6 times longer than maximally deep. Hind basitarsus 4.4 times longer than deep.

Second metasomal tergite 2.47 times wider than medially long; more or less uniformly foveate rugose, without mid-basal area and with only weak sub-lateral grooves anteriorly. Third tergite 2.57 times wider than medially long. Tergites 3-5 with well-developed, rounded, postero-lateral lobes. Tergite 6 postero-laterally with a pointed prominence and medially deeply semicircularly incised.

Uniformly pale brownish yellow except antennae and ovipositor sheaths which are black. Wings very pale brown with dark brown venation.

Testudobracon tatyanae sp.nov.
(Fig. 118)

MATERIAL EXAMINED
HOLOTYPE: ♀ with following labels: 'Mackay, Queensland. 1909-45.' and 'Mackay 1.01'. The type specimen is the right hand of two braconids glued to a single card square, in the BMNH collection.

DESCRIPTION (♀)
Length of body 2.25mm, of forewing 2.9mm, of ovipositor (part exserted beyond apex of metasoma) 1.6mm, and of antenna 2.6mm [face not visible, glued on to card].

Antennae with 23 flagellomeres. Terminal flagellomere 2 times longer than wide. First flagellomere 1.1 times longer than both the 2nd and 3rd separately, the latter being 1.7 times longer than wide. Head very transverse. Horizontal length of eye 2.3 times longer than horizontal length of head behind eye. Vertex and temples smooth and shiny.

Mesosoma 1.15 times longer than high. Mesoscutum setose medio- posteriorly and along lines of notauli, otherwise smooth, shiny and glabrous. Precoxal suture represented by a smooth, deep, circular pit.

Lengths of forewing veins SR1:3-SR:r =

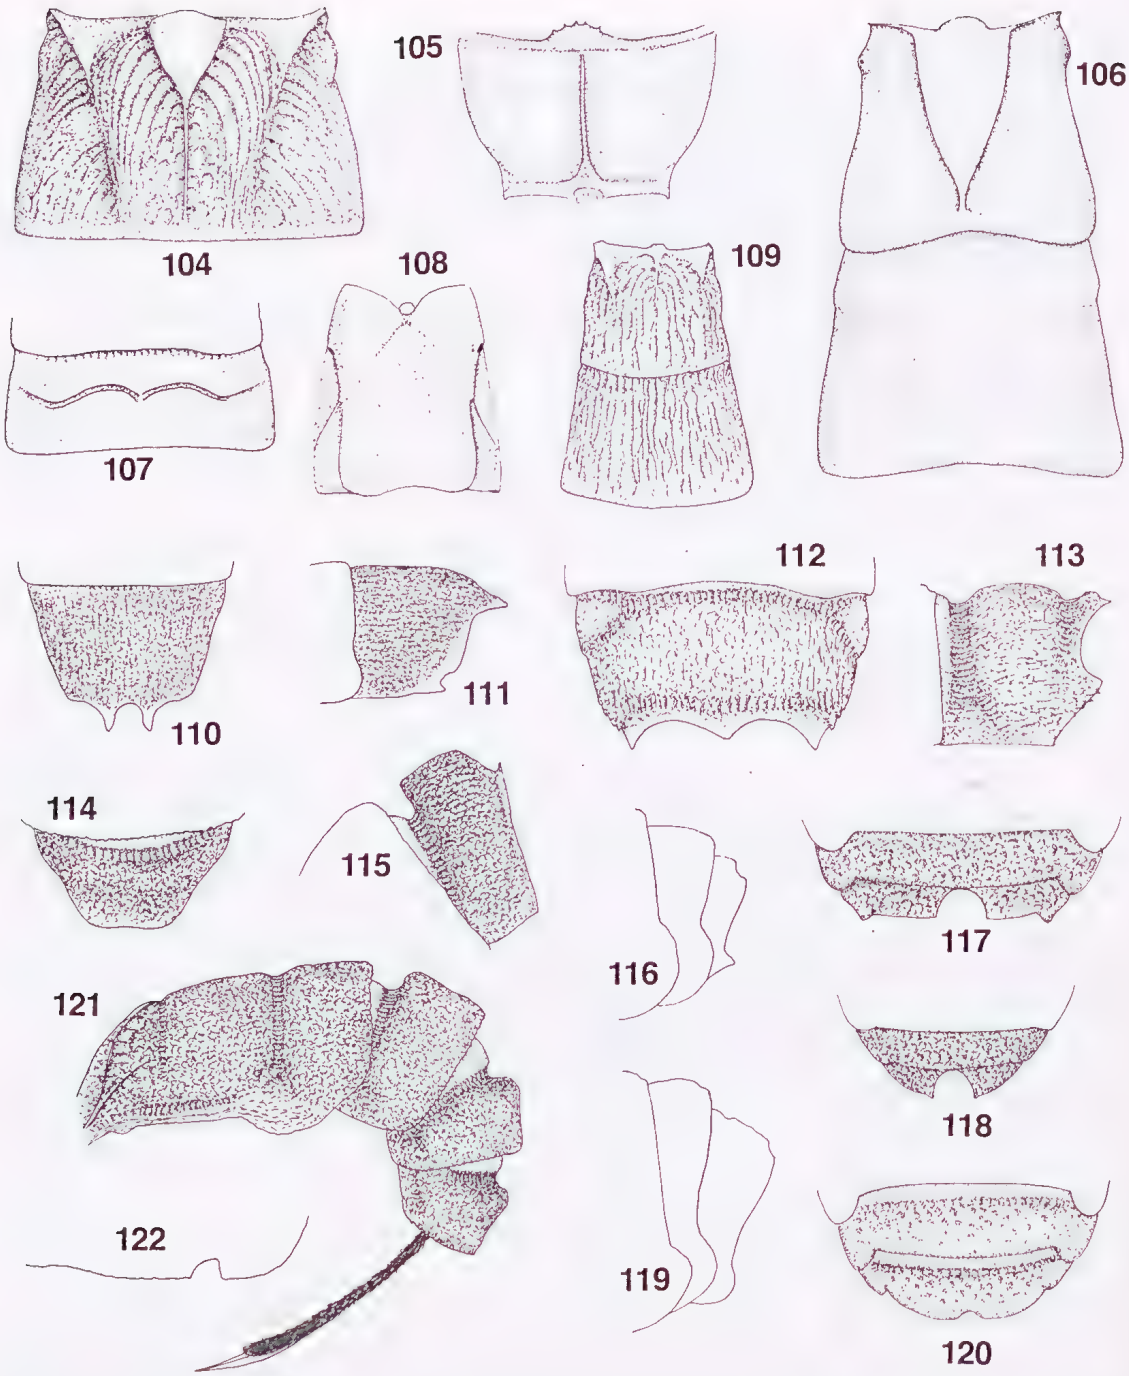

FIGS 104-122. Features of abdomen: 104, *Rostraulax xanthocephalus* (Turner), T2; 105, *Hyboteles toxopeusi* van Achterberg, propodeum; 106, *Paranesaulax* sp., T1-T2; 107, *Serratobracon cardaleae* Tobias, T3; 108 *Vomeribracon* sp., T1; 109, *Africadesha tobiasi* sp.nov., T2-T3; 110-111, *Furcadesha walteri* sp.nov., T5; 112-113, *Trigastrotheca tricolor* sp.nov., T5; 114, *Pedinopleura australiensis* sp.nov., T6; 115, *Hyboteles toxopeusi* van Achterberg, T6; 116, 117 *Testudobracon unicolorus* sp.nov., T5-T6; 118, *Testudobracon tatyanae* sp.nov., T5-T6; 119-120, *Testudobracon australicolorus* sp.nov., T5-T6; 121, *Pedinopleura australiensis* sp.nov.; 122, *Pedinopleura emarginata* van Achterberg, profile of lateral margin of syntergite T1-T3.

5.7:2.0:1.0. Lengths of veins 2-SR:3-SR:r-m = 1.47:1.53:1.0.

Lengths of fore femur: tibia: tarsus = 1.0: 1.05: 1.5. Lengths of hind femur:tibia:basitarsus = 2.8: 3.1: 1.0. Hind tibia 5.8 times longer than maximally deep. Hind basitarsus 3.8 times longer than deep.

Metasoma more elongate than typical *Testudobracon*. Second tergite 2.1 times wider than medially long; without mid-basal area but with moderately-developed sub-lateral grooves. Third tergite 2.25 times wider than medially long. Tergites 3 to 5 with very weak,, rounded postero-lateral lobes. Sixth tergite with a deep, semi-circular medial emargination.

Entirely pale brownish yellow except for antennae and ovipositor sheaths which are black and telotarsi which are slightly darkened. Wings weakly infuscate with brown venation.

ETYMOLOGY

Named after the senior author's wife Tanya for her tolerance of things hymenopterological.

*Trigastrotheca Cameron
(Figs 3, 13, 87, 112, 113)

Synonyms. *Coelodontus* Roman; *Odontopygia* Enderlein.

This is a small but widely-distributed genus originally described from Africa (*T. trilobata* Cameron) but is also known from India, the Philippines (Quicke, 1987b) and now Australia. Nothing is known of the biology of this group of Braconini though members of the closely related genus *Kenema* van Achterberg have been collected on several occasions from fields of grain crops.

Key to non-African species of *Trigastrotheca* (♀♀ only)

1. Forewing vein 3-SR more than 1.4 times longer than vein r-m; mesosoma uniformly orange; 2nd metasomal tergite unicolorous, ivory white; 3rd to 5th metasomal tergites orange .*T. tricolor* sp.nov.
- Forewing vein 3-SR less than 1.25 times longer than vein r-m; mesosoma black, marked with ivory white; 2nd metasomal tergite black medially, white laterally; 3rd to 4th metasomal tergites largely black, 5th ivory white ....*T. tridentata* (Enderlein)

Trigastrotheca tricolor sp.nov.
(Figs 3, 87, 112, 113)

MATERIAL EXAMINED

HOLOTYPE: ♀ with following labels: '7-14m. W. of Herberton, via Watsonville' and 'N. Queensland. 1 May 1967 D.H. Colless'. In ANIC collection.

PARATYPE: ♀ with same data as holotype. ANIC.

DESCRIPTION (♀♀)

Length of body 4.1mm, of forewing 4.2mm and of ovipositor (part exserted beyond apex of metasoma) 1.3mm.

Antenna with 40 flagellomeres. Terminal flagellomere acuminate, 2.1 times longer than wide. Penultimate flagellomere 1.3 times longer than wide. Median flagellomeres 1.3 times longer than wide. First flagellomere as long as the 2nd and 3rd separately, the latter 1.7 times longer than wide. Height of clypeus: inter- tentorial distance: tentorio-ocular distance = 1.0: 2.5: 2.0. Face finely punctate to coriaceous, otherwise shiny. Malar suture narrow but well-developed. Height of eye: width of face: width of head = 1.0: 1.2: 2.3. Frons flat without a mid-longitudinal ridge or lamella. Top of head finely coriaceous. shortest distance between posterior ocelli: transverse diameter of posterior ocellus: shortest distance between posterior ocellus and eye = 1.3:1.0:2.5.

Mesosoma 1.46 times longer than high, largely with punctate sculpture on background of punctulate sculpture. Pronotum with finely crenulate groove. Notauli distinctly impressed along whole length of mesoscutum. Pre-scutellar sulcus narrow, with 6-7 crenulae. Scutellum rather flat, with reduced sculpture. Precoxal suture weak. Posterior margin of propodeum crenulate.

Forewing. Lengths of veins SR1:3-SR:r = 5.5:2.05:1.0. Lengths of veins 2-SR:3-SR:r-m = 1.15:1.5:1.0. Vein r issuing approximately 0.4 distance from base pterostigma. Vein 2-SR+M long, 0.3 times length of 2-M. Vein cu-a interstitial, straight, perpendicular.

Hindwing. Apex of vein C+SC+R with one especially thickened bristle. Base of wing with a glabrous area.

Claws with rounded basal lobes. Length of fore femur: tibia: tarsus = 1.0: 1.1: 1.2. Length of hind femur: tibia: basitarsus = 2.2: 3.0: 1.0. Hind tibia moderately slender without an obvious longitudinal, lateral groove.

Metasomal tergites 1-5 foveate rugose. Tergite 1 with ill-defined dorsal carinae. Tergites 3-5 with well-developed antero-lateral areas. Ovipositor (part extending beyond apex of meta-

soma) approximately 0.3 times length of forewing.

Largely yellow-brown (ochreous) except for the following: antennae black; head piceous brown with palps, labio-maxillary complex, labrum, mandibles except apex and two large, sub- rectangular areas laterally on the frons to temple area, pinkish ivory; two lines along the notauli, the posterior half of the middle lobe of the mesoscutum and the scutellum paler ochreous than remainder of mesosoma; propleuron piceous brown; mid- and posterior legs piceous brown with the junction between femur and tibia, and the tarsi paler brown; first and second metasomal tergites, the antenno-lateral areas of the third tergite and a narrow posterior margin of the two semi-circular emarginations of the fifth tergite, ivory white; postero-lateral corners of fifth tergite piceous; ovipositor sheaths black. Wings pale brown, slightly darker apically; venation dark brown except extreme base of pterostigma which is whitish.

Tropobracon Cameron
(Figs 15, 59)

Synonym: *Shirakia* Viereck

Small species of Braconini distributed from Australia (Queensland) to India and Africa and also occurring in the Palaearctic Region (China). Elsewhere, *Tropobracon* species have frequently been reared from pyralid moth larvae boring in stems of grain crops including rice. The occurrence of the genus in Australia was noted by Quicke (1988b).

Undabracon Quicke
(Fig. 125)

A small genus of small to medium-sized Aphrastobraconini. Only two species have been described, *U. nigrithorax* Quicke from Australia and *U. sinuatus* (Baltazar) from the Philippines' though we have seen two other undescribed species from Australia. Nothing is known of the biology of *Undabracon* though they are apparently nocturnal or crepuscular in habit (Quicke, 1992). Their arched ovipositor is reminiscent of that of another braconine genus, *Zaglyptogastra* Ashmead, which includes Afrotropical species that attack twig-boring cerambycid beetle larvae, probably through frass holes (Quicke, 1991b). One Australian species has been observed flying near fallen wood.

Vipiellus Roman
(Figs 25, 98)

The species of *Vipiellus* are small to medium-sized braconines found only in Australia. *Vipiellus* is closely related to the genera of Aphrastobraconini though it typically lacks the distinctive thickening of forewing vein CU1b. Species of *Vipiellus* have been reared several times from stem- boring xyloryctid larvae (Lepidoptera) including the macadamia twig-girdler, *Neodrepta luteotactella* (Walker).

*__Vipiomorpha__ Tobias
(Fig. 16)

Although *Vipiomorpha* was originally described on the basis of a Russian species, *V. ypsilon* Tobias, apparently congeneric species occur in Africa and Australia. *Vipiomorpha* spp. are rather small members of the Glyptomorphini and are the only representatives of that tribe so far found in Australia; we know of a large number of undescribed species. Within the Glyptomorphini, *Vipiomorpha* is rather unspecialized and is probably fairly close to the basal stock of that tribe. Nothing is known of the biology of *Vipiomorpha* but other Glyptomorphini are predominantly parasitoids of concealed Coleoptera larvae.

Virgulibracon Quicke
(Figs 19, 65, 92, 137, 138)

Virgulibracon is a small genus of large, entirely Australian wasps. Nothing is known of the biology of the type- species, *Virgulibracon vulsus* Quicke. However, *V. endoxylaphagus* sp.nov., is a common and widespread species that parasitizes larvae of the cossid moth *Endoxyla* (=*Xyleutes* of Authors), which bores in *Eucalyptus* trunks and branches (see above). We have seen specimens of apparently the same species from all over Australia but, because some differences in coloration have been observed, it is possible that there may be several similar species involved. In addi-

tion, several other undescribed species vary in the number of hamuli on hindwing vein C+SC+R, wing and metasomal coloration and the development of a spur from forewing vein 3-CU1. These wasps bore through solid wood to a depth of more than 4cm to reach their hosts (see van Achterberg, 1986).

Key to species of *Virgulibracon*

1. Metasoma, fore and mid legs and pterostigma entirely black; ovipositor (part exserted beyond apex of metasoma) less than 2.25 times longer than forewing ..... *V. vulsus* Quicke
- Metasomal tergites 1-3 (at least) fore and mid legs and pterostigma orange to brownish orange; ovipositor (part exserted beyond apex of metasoma) more than 2.35 times length of forewing ..... *V. endoxylaphagus* sp.nov.

Virgulibracon endoxylaphagus sp.nov.
(Figs 19, 92, 137, 138)

MATERIAL EXAMINED

HOLOTYPE: ♀ with following data label: 'St Lucia, S.E. Queensland 8 Sep 1990. Ovipositing into *Endoxyla* (=*Xyleutes* of Authors) *cinereus* prepupa'. Deposited in QMBA.

PARATYPES: 3♀♀ with same data as holotype. 2♀ and 11♂ paratypes with following data label: 'St Lucia S.E. Queensland. 1 Sep 1990, G.B. Monteith. Emerging from Xyleutes Hole in 6' *Eucalyptus tereticornis* at 9.00 am'. All in QMBA except 1♀ and 1♂ in Quicke Collection, Sheffield.

DESCRIPTION (♀♀)

Length of body. 14.5-16.5mm, of forewing 16.0-17.0mm and of ovipositor 41-47mm.

Antenna with approximately 95 flagellomeres. Terminal flagellomere partly fused to the penultimate flagellomere. First flagellomere 1.5 and 1.8 times longer than the 2nd and 3rd flagellomeres respectively. 3rd flagellomere approximately as long as wide. Malar area shallowly depressed, finely coriaceous. Height of clypeus: inter-tentorial distance: tentorio-ocular distance = 1.0:6.0:3.8; clypeus without a transverse median carina, the lower part curved inwards to form roof of hypoclypeal depression. Face shiny with some punctuation. Height of eye: width of face: width of head = 1.0:1.36:2.5. Face 2.27 times wider than high. Frons weakly impressed with a deep mid-longitudinal sulcus. Shortest distance between posterior ocelli: transverse diameter of posterior ocellus: shortest distance between posterior ocellus and eye = 1.5:1.0:2.75. Length of head behind eye: horizontal length of eye = 1.0:1.82.

Mesosoma approximately 1.47 times longer than high. Mesopleuron largely setose. Scutellar sulcus finely crenulate.

Forewing. Lengths of veins SR1:3-SR:r = 7.7:4.6:1.0. Lengths of veins 2-SR:3-SR:r-m = 1.37:2.8:1.0. Vein 1-SR+M with well- developed spur. Vein cu-a marginally postfurcal. Vein 3-CU1 weakly expanded posteriorly. Vein CU1a with a small anteriorly directed spur near its apex.

Hindwing. Vein 2-SC+R. Apex of vein C+SC+R with one especially thickened bristle. Vein R1 with 3 or 4 proper hamules. Base of wing with a large glabrous area.

Lengths of fore femur: tibia: tarsus = 1.0:1.2:1.1. Lengths of hind femur: tibia: basitarsus = 1.52:2.65:1.0. Hind tibia slender; with a distinct longitudinal lateral groove. Hind basitarsus 9.2 times longer than deep.

Metasoma smooth and shiny. Antero-lateral parts of 2nd tergite and posterior margins of 3rd to 7th tergites membranous. Second tergite 1.3 times wider posteriorly than medially long. Ovipositor approximately 4 times longer than metasoma, 2.5 times longer than forewing.

Brown-orange except for the following which are black: antennae, mesosoma, hind legs, most of metasomal tergites 4-7, ovipositor sheaths. Membranous posterior margins of tergites 3-7 pinkish white. Basal third of wings pale yellowish, apical two thirds smoky; venation largely dark brown but C+SC+R and pterostigma orange.

DESCRIPTION (♂♂)

Males are smaller than females; body length 11-13mm.

Virgulibraconoides Quicke
(Fig. 4)

A medium-sized genus of medium-sized wasps, which has been previously confused with *Callibracon* (see e.g. Ashmead, 1900), although they are not closely related. Probably the majority of species, all of which appear to be Australian, are undescribed.

Vomeribracon Quicke
(Figs 66, 90,108)

A small genus of medium-sized to large wasps occurring in Australia (north Queensland) and Papua New Guinea. Nothing is known of the biology of the only Australian species, *V. ingres-*

sor (Turner). However, an undescribed species from Papua New Guinea is an important larval parasitoid of the curculionid, *Pantorytes szentivanyi*, which is an important pest of cocoa (G. Holloway, pers. comm.).

ACKNOWLEDGEMENTS

We would like to thank the following for allowing access to specimens in their care: Kees van Achterberg, Ted Dahms, Geoff Holloway, Terry Huston, Tom Huddleston, Ian Naumann, Gordon Nishida, Jeno Papp, Margaret Schneider, Mike Sharkey and David Wahl. Kaoru Maetô provided valuable information on the biologies of several genera, and Andy Austin prompted the examination of many specimens in connection with his reclassification of Australian Braconidae. David Hollingworth's assistance with whole insect photography is gratefully acknowledged. DLJQ also wishes to express his indebtedness to Glynn Maynard and Richard Willan for their hospitality during his stay in Brisbane.

Study of the collections of Braconinae in the Queensland University, Queensland Museum and the Department of Primary Industries, Indooroopilly was made possible by a University of Queensland Travelling Fellowship. Study of the Australian National Insect Collection was made possible by a Royal Society Australian Bicentennial Grant. This work was supported by a joint grant from the NERC to DLJQ and Dr Mike G. Fitton (Natural History Museum, London).

THE TADPOLES OF TWO QUEENSLAND FROGS (ANURA: HYLIDAE, MYOBATRACHIDAE)

STEPHEN J. RICHARDS AND ROSS A. ALFORD

Richards, S.J. & Alford, R.A. 1993 06 30: The tadpoles of two Queensland frogs (Anura: Hylidae, Myobatrachidae). *Memoirs of the Queensland Museum* **33**(1): 337-340. Brisbane. ISSN 0079-8835.

The tadpoles of two Queensland frogs, *Cyclorana brevipes* and *Uperoleia mimula*, are described and illustrated. *C. brevipes* is similar to previously described *Cyclorana*, having a rotund body and a 2(2)/3(1) tooth row formula. *U. mimula* shares with *U. lithomoda* an extremely small oral disc, a tooth row formula of 2(2)/3, and a black tail tip. □ *tadpoles, Hylidae, Myobatrachidae, Cyclorana brevipes, Uperoleia mimula, Queensland.*

Stephen J. Richards and Ross A. Alford, Zoology Department, James Cook University, Queensland 4811, Australia; 11 November, 1992.

Despite increased interest in Queensland's anuran fauna, the larvae of many species remain unknown. Given current concern about the conservation status of many species (Tyler, 1991; Wyman, 1990), accurate identification of larvae is important. The ability to identify larvae simplifies determination of the distribution and abundance of species, and is necessary for elucidation of their ecologies and life histories.

During research on frog communities in savanna woodland near Townsville, we collected amplexing pairs of two frogs whose larvae were unknown: the hylid *Cyclorana brevipes* and the myobatrachid *Uperoleia mimula*. These frogs were returned to the laboratory where oviposition occurred and larvae were reared to metamorphosis. In this paper we describe and illustrate the tadpoles of these species.

METHODS

Amplectant frogs transported to the laboratory were placed in large glass aquaria with 2-3cm of water at 25°C. Oviposition occurred within 12 hrs. When *C. brevipes* embryos reached stage 23 (Gosner, 1960) they were placed in 1000 litre plastic cattle tanks on the James Cook University campus. These tanks were assembled as described by Hearnden (1992), and supported a complex aquatic community similar to those found in temporary pools in the Townsville area, but lacking other anurans and most predators. Water temperature in the tanks ranged from 20-34°C. *U. mimula* tadpoles were reared for several weeks under artificial conditions in the laboratory prior to placement in the tanks, so no attempt was made to estimate larval period for this species.

Preserved specimens were measured using a dissecting microscope with an eyepiece micrometer. Terminology follows Altig (1970) and McDiarmid & Altig (1989). All measurements are in millimetres. Measurements involving apertures were taken from the centre of the aperture. The staging system is that of Gosner (1960). Specimens are lodged in the tadpole collection of the Zoology Department, James Cook University.

Cyclorana brevipes
(Figs 1,2)

An amplexing pair was collected in a ditch at the intersection of Black River Road and Bruce Highway, 20km north of Townsville, Qld. on the evening of 2/3/90. Oviposition occurred before 0800 on 3/3/90 (n = 930 eggs), and embryos reached stage 23 by 5/3/90. The first metamorph (stage 46), observed on 28/3/90, measured 23.0mm snout to vent length and weighed 1.26g. The minimum total duration of development (fertilization to metamorphosis) was 25 days.

A stage 37 tadpole has the following measurements (millimetres): 56.0 total length, 22.5 body length, 4.5 basal tail muscle height, 3.5 basal tail muscle width, 2.8 maximum dorsal fin height located 10.8 from body terminus, 2.5 maximum ventral fin height located 11.0 from body terminus, 11.8 maximum body width, 10.8 maximum body height, 2.5 eye diameter, 0.9 pupil diameter, 7.2 interorbital distance, 0.5 × 0.3 narial diameters, 2.9 internarial distance, 3.2 snout-naris, 6.4 snout-eye, 11.8 snout-spiracle, 3.3 naris-eye, and 5.4 transverse oral disc diameter.

The oral disc is anteroventral and non-emarginate. The marginal papillae are in a single row

ventrally, with a wide gap dorsally and additional submarginal papillae laterally and dorsolaterally. The labial tooth row formula is 2(2)/3(1). The jaw sheaths are keratinized, the lower jaw sheath broad and V-shaped, and the upper jaw sheath narrow and curved (Fig. 1). The serrations on the margin of the upper jaw sheath are much finer than those on the lower jaw sheath.

The body is rotund, the snout is rounded in dorsal view, and the eyes are dorsolateral. The nares are dorsal and oriented anterolaterally. The sinistral spiracle is short and unpigmented, is almost ventral, and is not visible in dorsal view. The vent tube is short and dextral. The dorsal fin is not arched, and tapers to a narrow point posteriorly. It originates slightly anterior to the junction of the body and the tail musculature (Fig. 2). Dark pigmentation deep in the skin layers covers the intestinal coil dorsolaterally, from a line just posterior to the eyes. Lighter, diffuse brown pigment occurs on the rest of the body, tail muscle and fins. A patch of darker pigmentation almost surrounds the nares, with a lateral gap.

Uperoleia mimula
(Figs 3,4)

An amplexing pair was captured at an overflow area of a small creek near Bentley Dam, approximately 20km south of Townsville, in March 1990. A stage 38 specimen has the following measurements: 20.2 total length, 10.0 body length, 2.3 basal tail muscle height, 1.7 basal tail muscle width, 1.9 maximum dorsal fin height located 3.8 from body terminus, 1.3 maximum ventral fin height located 4.8 from body terminus, 6.6 maximum body width, 5.4 maximum body height, 1.4 eye diameter, 0.4 pupil diameter, 2.9 interorbital distance, 0.4 narial diameter, 1.3 internarial distance, 1.1 snout-naris, 2.4 snout-eye, 8.0 snout-spiracle, 1.4 naris-eye, 1.6 transverse oral disc diameter.

The oral disc is extremely small, located anteroventrally, and is non-emarginate. The jaw sheaths are narrow and keratinized. The labial tooth row formula is 2(2)/3. The short P3 tooth row is supported on an unusual flexible flap. Large marginal papillae in a single row surround the disc, with a large anterior gap and a narrow posterior gap (Fig. 3). The snout is rounded in dorsal view and the eyes are dorsal. The nares are located dorsally and open almost verically.

The body is slightly flattened dorsoventrally, and is oval when viewed from above. The spiracle is sinistral, located laterally and near the posterior of the body. It is extremely short, lightly pigmented, and oriented posteriorly (Fig. 4). The anus is dextral. Diffuse brown pigment occurs on the dorsal and lateral surfaces of the body, and on the tail muscle. Pigmentation on the fins is concentrated at the posterior tip in tadpoles that have not reached stage 31, forming a conspicuous black 'flag' that occupies approximately the most posterior 15-20% of the tail. From about stage 31 the pigment gradually disperses, until at stage 36 the 'flag' is hardly visible.

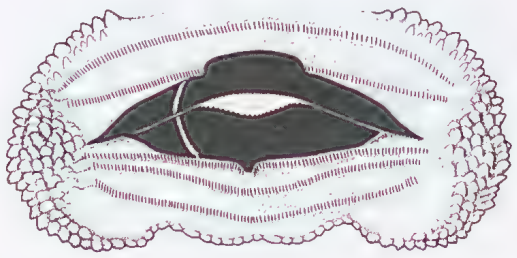

FIG. 1. Oral disc of *Cyclorana brevipes*. Scale bar = 1mm.

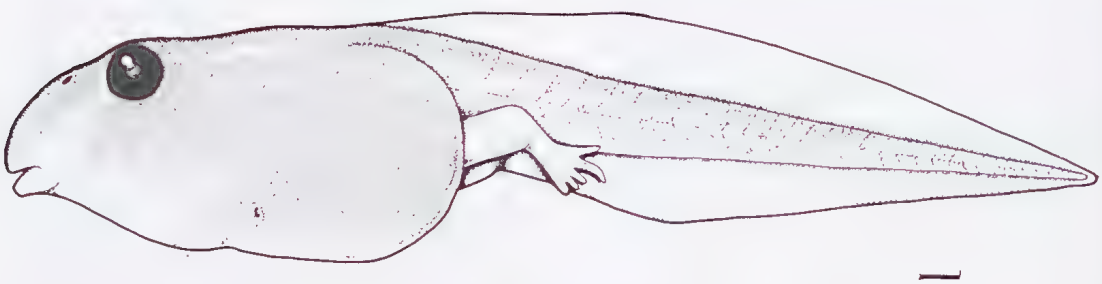

FIG. 2. Lateral view of a stage 37 *Cyclorana brevipes*. Scale bar = 2mm.

DISCUSSION

The tadpole of *Cyclorana brevipes* is difficult to distinguish from other *Cyclorana* previously described (Tyler & Martin, 1975; Tyler et al., 1982; Tyler et al., 1983; Watson & Martin, 1973). All have rotund bodies, tooth row formulae of 2(2)/3(1), and similar configurations of oral papillae. Tyler et al. (1983) were unable to distinguish tadpoles of *C. australis* from *C. longipes* when they occured together in ponds in the Northern Territory, until the distinctive dorsal pattern of *C. longipes* appeared near metamorphosis. The tadpoles of these species reached different maximum sizes, but this character is only useful if late stage tadpoles are available for comparison.

Because of the extreme morphological conservativism displayed by this genus, accurate identification of Queensland tadpoles can best be achieved by the construction of regional keys that compare only the species found in a given area. The similarities in oral morphology exhibited by *Cyclorana* tadpoles will make knowledge about colour in life (and in preservative), and about size differences during development, fundamental for accurate identification. Knowledge about Queensland *Cyclorana* is insufficient for such keys to be constructed at this stage.

Over 20 species of *Uperoleia* are now known to occur in Australia (Davies et al., 1986). However, information on the larval morphology of *Uperoleia* species is available for only four species, so meanigful comparisons are difficult. Two species, *U. inundata* (Tyler et al., 1983) and *U. lithomoda* (Davies et al., 1986) share with *U. mimula* a tooth row formula of 2(2)/3. *U. lithomoda* also shares with *U. mimula* a black tail tip. *U. laevigata* (as *U. marmorata*) is reported to lack gaps in any of the toothrows and has a formula of 1/3 (Moore, 1961). *U. tyleri* (as *U. marmorata*) differs from *mimula* in having a gap in the P1 tooth row (Watson & Martin, 1973).

None of these authors mention the unusual flap supporting the P3 tooth row. However the illustration of *U. inundata* in Tyler et al. (1983) suggests that this structure may be present in that species, and careful examination of other species may reveal its presence. The morphology and function of this structure require further study, as does the possibilty that it may be a generically diagnostic feature.

A NEW TWO-TOED SKINK FROM EASTERN AUSTRALIA

G.J. INGRAM, P.J. COUPER AND S.C. DONNELLAN

Ingram, G.J., Couper, P.J. & Donnellan, S.C. 1993 06 30: A new two-toed skink from eastern Australia. *Memoirs of the Queensland Museum* **33**(1): 341-347. Brisbane. ISSN 0079-8835.

Lerista emmotti sp.nov. has been confused with *L. punctatovittata* (Günther, 1867). However, it differs from *L. punctatovittata* in the state of the forelimb (distinctly didactyle vs monodactyle or monostylus). As well, it can be distinguished by estimates of genetic distance derived from allozyme electrophoresis. □ *Scincidae, Lerista emmotti, Lerista punctatovittata, new species, electrophoresis, Australia.*

Glen Ingram & Patrick Couper, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; Steve Donnellan, Evolutionary Biology Unit, South Australian Museum, North Terrace, Adelaide, South Australia 5000, Australia; 30 April, 1993.

When Couper & Ingram (1992) described *Lerista colliveri*, they were aware of another probable species of *Lerista* that had been confused with *L. punctatovittata*. It differed in the state of the forelimb (distinctly didactyle vs monodactyle or monostylus). However, no other morphological characteristics that differentiated them were found. As well, the different states of the limb did not appear to be a good enough reason to describe a new species. Degenerate-limbed skinks may vary in the extent of development of the toes, and the different conditions are more valuable in the study of embryology than as characters for differentiating taxa. However, subsequent work by one of us (SCD) showed that the two-toed individuals could be distinguished by estimates of genetic distance derived from allozyme electrophoresis.

Queensland Museum's specimens are prefixed by QMJ, Australian Museum's by AMR and South Australian Museum's by SAMAR.

ELECTROPHORESIS

Materials and Methods

Twenty-seven '*Lerista punctatovittata*' were collected from 11 localities in Queensland, New South Wales and South Australia. Livers were dissected from fresh specimens and stored at -80°C until use. For the genetic analysis, specimens from a single locality which showed all the expected genotypes at each locus were treated as a population of a single genetic type. On this basis, 11 populations were designated:

Noon – Noonbah Station, Qld (24°07'S, 143°11'E) (QMJ54144-6);

Ston – Waterloo Station, via Stonehenge, Qld (24°16'E, 143°17') (QMJ56312-4);

Kaka – Ka Ka Mundi, Qld (24°49'E, 147°24'S) (QMJ56090);

Nyma – Nymagee, NSW (32°01'E, 146°20S) (SAMAR33548-50/552-7);

Mtho – Mt Hope, NSW (32°51'E, 145°53'S) (SAMAR33522);

Chow – Chowilla, SA (33°56'E, 140°59'E) (SAMAR32991-2, 33003);

Poog – Pooginook CP, SA (34°04'E, 140°07'S) (SAMAR38345/352);

Waik – 2km S Waikerie, SA (34°12'E, 140°01'S) (SAMAR39731);

Broo – Brookfield CP, SA (34°19'E, 139°30'S) (SAMAR36974);

Wida – 11km S Widara HS, SA (34°20'E, 139°57'S) (SAMAR38442)

Boon – 4.5km E Boongalechie, SA (34°27;'S, 139°26'E) (SAMAR39267).

Homogenates of liver were electrophoresed on sheets of cellulose acetate (Cellogel: Chemetron) as described by Richardson et al. (1986), and were assayed for 35 enzymes which were encoded by 40 presumptive loci. The enzymes stained, E.C. numbers and abbreviations (Murphy et al., 1990) are: aspartate aminotransferase (AAT, E.C. 2.6.1.1), aconitate hydratase (ACOH, E.C. 4.2.1.3), aminoacylase (ACYC, E.C. 3.5.1.14), alcohol dehydrogenase (ADH, E.C. 1.1.1.1), adenylate kinase (AK, E.C. 2.7.4.3), alanine aminotransferase (ALAT, E.C. 2.6.1.2), carbonate dehydratase (CA, E.C. 4.2.1.1), leucine aminopeptidase (CAP, E.C. 3.4.11.1), enolase (ENO, E.C. 4.2.1.11), fructose-diphosphatase (FBP, E.C. 3.1.3.11), fumarate hydratase (FUMH, E.C.4.2.1.2), glyceraldehyde-phosphate dehydrogenase (GAPDH, E.C. 1.2.1.2), guanine deaminase (GDA, E.C. 3.5.4.3), glycerol-3-phosphate dehydrogenase (G3PDH, E.C. 1.1.1.8), glucose-6-phosphate dehydrogenase (G6PDH, E.C. 1.1.1.49), glucose-phosphate isomerase (GPI, E.C. 5.3.1.9), glutathione reductase (GR, E.C. 1.6.4.2), glutamate dehydrogenase (GTDH, E.C. 1.4.1.3), L-iditol dehydrogenase (IDDH, E.C. 1.1.1.14), isocitrate dehydrogenase (IDH, E.C.

TABLE 1. Electromorph frequencies, expressed as a percentage, in 11 populations of '*Lerista punctatovittata*' at 40 loci. Electromorphs are designated alphabetically, with 'a' being the most cathodally migrating electromorph. Where enzymes are encoded by more than one locus, the loci are designated numerically in order of increasing electrophoretic mobility. Where the electromorph frequencies are not given, the frequency is 100. See 'Material and Methods' for an explanation of the population codes. The number of individuals sampled from each population is given under each locus. The following loci were invariant: *Aat-1, Aat-2, Acoh-1, Acyc, Adh, Ak-1, Ak-2, Ca, Cap, Eno, Fumh, Gapdh, Gda, G3pdh, Gpi, Gtdh,Iddh, Ldh-1, Ldh-2, Lgl, Mdh- 1, Mdh-2, Mpi, Pgam, Pk* and *Sod*.

1.1.1.42), lactate dehydrogenase (LDH, E.C. 1.1.1.27), lactoyl-glutathione lyase (LGL, E.C. 4.4.1.5), malate dehydrogenase (MDH, E.C. 1.1.1.37), 'malic' enzyme (MDHP, E.C. 1.1.1.40), mannose-phosphate isomerase (MPI, E.C. 5.3.1.8), peptidases (PEP, E.C. 3.4.11 or 13.*), phosphoglycerate mutase (PGAM, E.C. 5.4.2.1), 6-phosphogluconate dehydrogenase (PGDH, E.C. 1.1.1.44), phosphoglucomutase (PGM, E.C. 2.7.5.1), pyruvate kinase (PK, E.C. 2.7.1.40), superoxide dismutase (SOD, E.C. 1.15.1.1), and triose-phosphate isomerase (TPI, E.C. 5.3.1.1). Electromorphs were identified by comparison with samples that were repeatedly included on each gel (internal controls) and through critical side-by-side comparisons (line-ups; see Richardson et al., 1986).

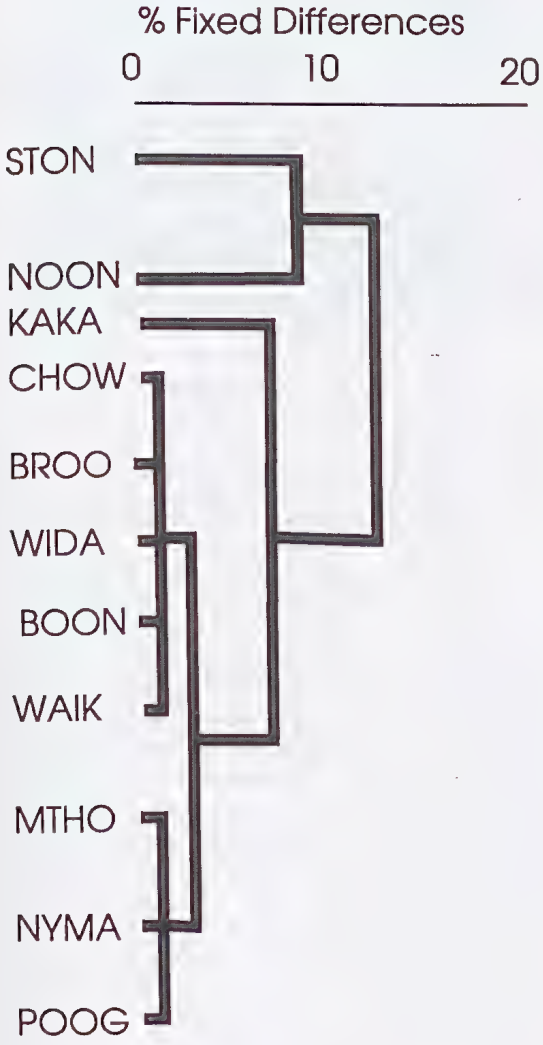

FIG. 1. Phenogram of the percentage fixed differences between populations, constructed by the unpaired group method of analysis (UPGMA).

RESULTS

Electromorph distributions at the 40 loci resolved are shown in Table 1. These data were converted into a matrix of percentages of loci showing fixed differences between populations (Table 2). A fixed difference occurs at a locus when the two populations being compared share no electromorphs (Richardson et al., 1986). Figure 1 is a phenogram of the percentage fixed differences between populations, constructed by the unpaired group method of analysis (UPGMA). The phenogram is not intended to reflect phylogenetic relationships, but rather to give a visual indication of the genetic diversity and genetic distances between the 11 populations. The specimens fell into three major genetic groups: 1, Stonehenge; 2, Noonbah; and 3, Ka Ka Mundi and the populations from NSW/SA.

The Stonehenge and Noonbah populations are regionally sympatric (separated by 15km) and have fixed differences at 3 loci (*Gpt, PepD* and *Pgdh*). The Ka Ka Mundi/NSW/SA populations have fixed differences with Stonehenge and Noonbah at a minimum of 3 (*Acoh-2*, *Alat* and *Fbp*) and 2 loci (*Acoh-2* and *Fbp*; *PepD* and *Pgdh* not scored in Brookfield population) respectively. Within the Ka Ka Mundi/NSW/SA group, Ka Ka Mundi has a single fixed difference (*Fbp*) with the NSW/SA populations.

From the preceding electrophoretic analysis, the Noonbah population is clearly distinct from the other populations. Morphologically, all the Noonbah specimens have a didactyl forelimb while the specimens from the other populations have a monodactyl or monostylar forelimb. The latter are identifiable with *L. punctatovittata* and the Noonbah specimens thus warrant recognition as members of a new species.

SYSTEMATICS

Lerista emmotti sp.nov.
(Figs 2-4)

DIAGNOSIS

A large (maximum snout-vent length 103mm) *Lerista* with a movable eyelid and didactyl fore- and hindlimbs. A member of the *L. macropisthopus* species group (cf. Wilson & Knowles, 1988), of which the following members may also be didactyle on both fore- and hindlimbs: *L. gerrardii*, *L. neander* and *L. picturata*. *L. emmotti* is readily distinguished from *L. gerrardii* by pattern (broad black upper lateral stripe absent vs broad black upper lateral stripe present); from *L. nean-*

der by the number of supraciliaries (5 vs 3); from *L. picturata* by the number of supraciliaries (5 vs 1-3). *L. emmotti* most closely resembles *L. punctatovittata* but it can be separated from this species by the state of the forelimb (distinctly didactyle vs monodactyle or monostylus). *L. emmotti* is further distinguished from *L. punctatovittata* by the biochemical data in Table 1.

DESCRIPTION

Snout-vent length: 39-103mm (N 24, mean 72.6). Length of appendages etc. (% snout-vent length): forelimb 3-7 (N 24, mean 4.5), hindlimb 11-16 (N 24, mean 13.0), tail 87-122 (N 13, mean 105.2), head length 8-13 (N 24, mean 9.9), head width 6-9 (N 24, mean 6.9).

Nasal contact narrow (N 1) to moderate (N 20) to broad (N 5). Nostril positioned anteriorly to centrally on nasal scale. Rostral shield rounded in profile. Prefrontals small to moderate, widely spaced. Interparietal large and free. Frontoparietals narrowly (N 4) to moderately (N 22) spaced, smaller than interparietal. Parietals in narrow contact (N 1), moderate contact (N 3), broad contact (N 22). Enlarged nuchal scales 5-9 (N 14, mean 7.8), of which only two contact the parietals. Lower eyelid movable. Opaque disc occupying more than half the lower eyelid. Supraoculars 3, first two in contact with the frontal. Supraciliaries 5 (N 26). Loreals 2, second usually smaller. Presuboculars 2. Supralabials 6, fourth below eye. Infralabials 5-6 (N 26, mean 5.9). Primary temporals 1. Secondary temporals 2, lower smallest and overlapping upper. Ear aperture minute, overlapped by scales. Midbody scale rows 18, rarely 20 (N 26, mean 18.3). Paravertebral scales 78-90 (N 24, mean 85.5). Two enlarged preanal scales (N 25); right overlapping left (N 14), left overlapping right (N 11). Forelimb with two digits; both digits clawed (N 19), only one digit clawed (N 6), neither digit clawed (N 1). Hindlimb with two clawed digits, 2nd digit markedly longer than 1st. Lamellae under longest toe 9-12 (N 26, mean 10.6).

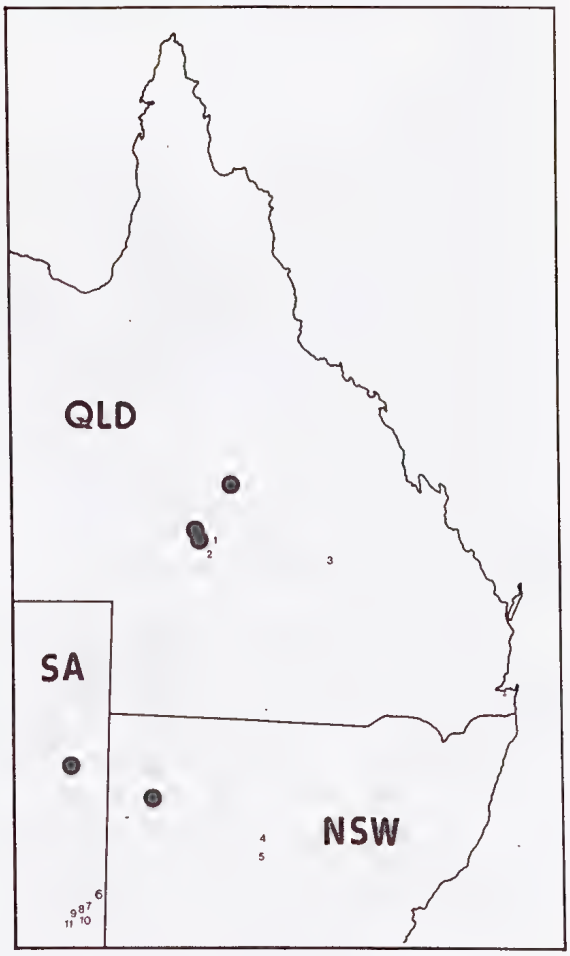

FIG. 4. Distribution of *Lerista emmotti* sp.nov. Numbers refer to populations of '*L. punctatovittata*' electrophoresed: 1, Noon; 2, Ston; 3, Kaka; 4, Nyma; 5, Mtho; 6, Chow; 7, Poog; 8, Waik; 9, Broo; 10, Wida; 11, Boon.

Dorsal and upper lateral ground colour tan to mid-brown with the each scale bearing a dark streak, which in turn form longitudinal lines of dark spots. Mid to lower lateral zone cream, marked by dark flecks. Venter either immaculate cream, or sometimes obscurely marked by dark-edged scales. Under surface of tail faintly to strongly patterned with dark flecks. Head shields dark-edged; lips barred; loreals and temporals marked by a dark streak which breaks up posteriorly.

DISTRIBUTION

From Muttaburra (22°36'E, 144°33'S), central Queensland, southwest to old Arumpo homestead, (33°48'E, 142°53'S), New South Wales. Also extending into South Australia (30°25'E, 139°25'S).

ETYMOLOGY

Named for Angus Emmott, naturalist and friend of the Queensland Museum.

REMARKS

Our examination of the holdings of the Queensland and Australian Museums showed '*L. punctatovittata*-like' *Lerista* with didactyl forelimbs to be confined to the western edge of the known distribution of *L. punctatovittata*. These specimens, described here as *L. emmotti*, are both morphologically and biochemically distinct from *L. punctatovittata*. However, monostylar individuals from central Queensland, which appear to be morphologically indistinguishable from *L. punctatovittata*, are biochemically distinct from the more easterly and southerly populations of this species.

Clearly, *L. punctatovittata* as currently recognised is a composite species. Unfortunately the locality given for the holotype is simply 'Queensland'. Although it is tempting to assume that this specimen was most likely collected from more coastal populations, such an assumption would be unsound because considerable settlement of western Queensland had taken place by the time *L. punctatovittata* (Günther, 1867) was described. The distribution of *L. punctatovittata* and the description of cryptic forms within this species complex warrant further investigation.

As well, even though we have assigned didactyl specimens from NSW/SA to *L. emmotti*, nevertheless the possibility remains that some populations of *L. punctatovittita* are polymorphic for the didacty-monodactyl condition. This possibility should be tested by further allozyme analysis.

The holotype of *L. punctatovittata* (Natural History Museum, London BMNH 1946.8.18.80; Cogger et al, 1983) has a monostylar forelimb (Boulenger, 1887) and is not a specimen of *L. emmotti*. Cogger et al. (1983) listed *Rhodona officeri* McCoy, 1881, as a junior synonym of *L. punctatovittata* and noted that the type material of *officeri* had not been located (see also Coventry, 1970). However, McCoy's description and illustration of the holotype are detailed. The specimen agrees in all characteristics with *L. punctatovittata*, including having a monodactyl forelimb. We therefore concur with the synonymy of Cogger et al., (1983).

This study highlights the power of combining morphological character analysis with an independent genetic technique, such as allozyme electrophoresis, to assess the systematic significance of seemingly trivial morphological variation.

ACKNOWLEDGEMENTS

We thank Steve Wilson for the use of his photograph, Angus Emmott for finding many of the specimens, Robert Raven for drawing Fig. 4 and Neale Hall for typesetting the paper in Ventura. Ross Sadlier (Australian Museum) and Mark Hutchinson (South Australian Museum) gave us access to the collections in their care. Some of the frozen tissue specimens were collected with the assistance of an Australian Research Council grant awarded to M. Adams and P. Baverstock. We also thank Craig Moritz.

NEW RECORDS OF THE RARE GREEN-THIGHED FROG. *Memoirs of the Queensland Museum 33(1): 348. 1993:-* The Green-thighed Frog (*Litoria brevipalmata*) is a mysterious frog, populations of which apparently suddenly appear and disappear at a locality—sometimes the 'absences' are for many years (Tyler & Davie, 1985). These disappearances, however, do not appear to be part of the phenomenon of the 'disappearing frogs' (sensu Czechura & Ingram, 1991) because the species is still extant.

Until recently, the Green-thighed Frog was known from only three locations in Queensland. McDonald (1974) collected a specimen at Crows Nest National Park (NP 629: 27°15'S, 152°06'E) and another from Ravensbourne National Park (NP 492: 27°21'S, 152°12'E). Four years later, the species was collected near Jimna (26°39'S, 152°27'E) (Czechura, 1978) and in 1983 Chris Corben collected two specimens (Queensland Museum [QM] J42134, 42135) also near Jimna. All these records are from montane country.

Recently the senior author collected two male Green-thighed Frogs alongside Woogaroo Creek near Wacol, Brisbane (27°36'S, 152°54'E). These are the first coastal records for this frog in Queensland and add to the frog fauna of the Brisbane area. These records are reported here. Frog names follow Ingram et al. (1993).

First collection, 21 November 1992

At Woogaroo Creek near Wacol, heavy rain, with lightning, began falling at about 4.30pm and by 5.00pm there were radio reports of local flooding. Rain then reduced to a steady light fall with intermittent heavier showers. Observations began at about 8.00pm at a large L-shaped depression ('Ric's Ditch'), some 40m in length, alongside Woogaroo Creek and some 30m from the main creek-line. From previous experience, this depression became an ephemeral pool after good rain. On the day before, considerable rain had fallen in the afternoon and evening but not enough to produce free-standing water. By contrast, the rainfall of the 21st resulted in 85cm of water at the deepest point of the depression.

Amongst the extremely loud chorus of a large number of frogs, an unfamiliar call was heard. This proved to belong to a male *L. brevipalmata*, which was immediately captured (QM J56813). Several more calling males were observed but not collected and, judging from their calls, about 20 males were present at the site; no females were observed. Typical calling sites were in leaf litter about 0.5-0.9m from the water's edge. No Green-thighed Frogs were found away from the depression.

The following species of frogs were also noted: *Limnodynastes ornatus, L. peronii, Litoria caerulea, L. fallax, L. gracilenta, L. rubella, Adelotus brevis and Mixophyes fasciolatus.* Curiously, although the Cane Toad (*Bufo marinus*) was seen well away from the site on a nearby sealed road, none was heard calling or seen in the depression despite what appeared to be ideal breeding conditions.

The vegetation surrounding Ric's Ditch is open dry sclerophyll forest with a sparse, predominately acacia understorey and a ground cover of exotic herbs and grasses. Closer to the creekline there is a heavy infestation of Chinese Elm (*Celtis sinensis*), Camphor Laurel (*Cinnamomum camphora*), a dense understorey of Bush Lanata (*Lantana camara*) and a variety of native species that form depauperate, dry rainforest.

No frogs were observed at the site on the two following nights (22, 23 November), although calls of *Adelotus brevis* and *Limnodynastes peroni* were heard. Within ten days, there was no follow-up rain and the depression became completely dry — all tadpoles apparently perishing.

From 21 November 1992 to 5 January 1993, some rain fell intermittently but not enough to produce any significant frog activity. However, on some occasions these falls were accompanied by, or quickly succeeded by, strong breezes and it is possible the accompanying noise hid the sounds of calling frogs. From 1 January 1993, rainfall was recorded near Ric's Ditch. On the evening of 4 January 1993, a very brief storm produced 0.6mm and on the next afternoon a more substantial storm resulted in 30mm. At Ric's Ditch, 30mm was insufficient to produce free-standing water. Apart from a brief call from a Naked Treefrog (*Litoria rubella*), the only active caller was the Red-backed Broodfrog (*Pseudophryne coriacea*), with about 30 frogs that called from small, natural tunnels in very porous substrate.

Second collection, 6 January 1993

In the late afternoon, a vigorous electrical storm resulted in a fall of 48.5mm and, by 8.00pm, a loud chorus of frogs came from Rics' Ditch. About a dozen Green-thighed Frogs were calling and another male was collected (QM J57285). The same species of frogs noted on 21 November 1992 were recorded again and Cane Toads were also absent.

The next day was overcast with occasional light rain. Very light rain was falling at about 7.30pm when Ric's Ditch was revisited. There were about twice as many males of Green-thighed Frogs calling compared to the night before and several of the these were much closer to the water, with one about 10 cm from shallow water. As before, no females were observed.

An immediate visit was made to the neighbouring Six Mile Creek some 8km distant and observations were made at several sites. A slightly different frog fauna was recorded. *Litoria nasuta* and *Crinia parinsignifera* were numerous in open grassy areas. In a melaleuca swamp, there were *Limnodynastes terraereginae* and *Litoria dentata*. In the Bracken Fern (*?Pteridium esculentum*) the Dusky Gungan (*Uperoleia fusca*) was recorded. However, despite considerable searching over a wide area, the Green-thighed Frog was not found.

Since 6 January, until now (22 May 1993), the Green-thighed Frog has not been met with at Woogaroo Creek, despite repeated visits.

EARLY PERMIAN INADUNATE CRINOIDS FROM THAILAND

GARY D. WEBSTER AND PETER A. JELL

Webster, G.D. & Jell, P.A. 1993 06 30: Early Permian inadunate crinoids from Thailand. *Memoirs of the Queensland Museum* **33**(1): 349-359. Brisbane. ISSN 0079-8835.

Eight species of Early Permian inadunate crinoids are described from Ko Muk, Ko Phi Phi, and Ko Yao Noi, islands off southern Thailand. These are the first Palaeozoic crinoids described from Thailand and support an Early Permian age for the Phuket Group and Rat Buri Limestone. New species described are *Kallimorphocrinus thaiensis*, *Apographiocrinus komukensis*, and *Contocrinus andamanensis*; five species are left in open nomenclature. □ *Permian, crinoids, inadunate, Thailand.*

Gary D. Webster, Department of Geology, Washington State University, Pullman, Washington 99164-2812, USA; Peter A. Jell, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; 1 March, 1992.

Permian rocks are widespread in Thailand (Waterhouse & Piyasin, 1970, fig. 1; Lumjuan & Lovacharasupaporu, 1984). Since 1960 systematic studies, including stratigraphic interpretations have concentrated on brachiopods (Yanagida, 1984), fusulinids (Toriyama, 1984; Ingavat, 1985), and bryozoans (Sakagami, 1984). This paper is the first to describe Permian crinoids from Thailand.

LOCATION AND STRATIGRAPHY

Crinoids were derived from five localities on the islands of Ko Muk, Ko Phi Phi, and Ko Yao Noi northwest of Kan Tang in the Andaman Sea off southern Thailand. Maps of the islands showing general position of fossil localities are as follows: 1, upper Phuket Group, SW side of Ko Muk, with stratigraphic sections (Waterhouse, 1982, figs 2b,3,4); 2, upper part of Phuket Group and 3, basal part of Rat Buri Limestone, Ko Phi Phi, indicated on measured section of Tong Lang Bay (Waterhouse, 1982, fig. 2a); 4, Rat Buri Limestone, Ko Muk, U.S. National Museum locality 9271 (Grant, 1976, fig. 7); and 5, Rat Buri Limestone, Ko Yao Noi, (Waterhouse et al., 1981), fig. 4. An unsuccessful attempt was made to locate the calyx reported by Waterhouse (1982, p. 339), from the Phuket Group on Ko Phi Phi for inclusion in this study.

In southern Thailand Phuket Group brachiopods are considered Sakmarian (Waterhouse et al.,1981; Waterhouse,1982). The Rat Buri Lst has been considered Artinskian (Sakagami,1970; Yanagida,1970; Grant,1976), late Early Permian (Yanagida,1984), Kazanian (Waterhouse & Piyasin,1970) or Kungurian (Waterhouse,1981).

The Rat Buri Limestone has been applied somewhat indiscriminately to Permian limestones throughout Thailand (Grant, 1976). Diversity of carbonate microfacies within the Rat Buri Limestone is reflected in the reports of many beds with restricted faunas, i.e., fusulinids with rare or no brachiopods or abundant brachiopods and bryozoans with no fusulinids (Grant, 1976). Fusulinids are virtually unknown in the Rat Buri Limestone in peninsular Thailand (Toriyama, 1984, fig. 1), but in central and northern Thailand fusulinids range from Sakmarian to Dorashamian (Ingavat, 1985). A Sakmarian ammonoid fauna occurs in the basal Rat Buri Limestone in central Thailand (Glenister et al., 1990). Waterhouse (1981) correlated the Rat Buri Limestone of southern Thailand with the Bitauni Beds of Timor. However, the Bitauni Beds are considered Artinskian based on ammonoids (Glenister & Furnish, 1987).

Considerable work remains in determining stratigraphic relationships of the Rat Buri Limestone throughout Thailand. However, sufficient palaeontological information is available to evaluate the age of the unit at most localities. Based on fusulinids and ammonoids the base of the Rat Buri Limestone in central and northern Thailand is Sakmarian or Artinskian. In peninsular Thailand we consider the Rat Buri Limestone to be of Artinskian age based on data of Sakagami (1984) and Yanagida (1984) and correlation of the brachiopod faunas with the Timorese Bitauni fauna (Grant, 1976; Waterhouse, 1981).

Clastic sediments of the Phuket Group have been referred to as cool water deposits equivalent to glaciomarine deposits of Gondwanaland (Waterhouse, 1982 among others). Altermann (1986) considered these deposits to represent deposition on a continental margin lacking sufficient evidence to interpret them as glaciomarine. Brachiopods from a carbonate band within the pebbly

mudstones in the upper part of the Phuket Group were interpreted by Waterhouse (1982) as mostly cool temperate genera. Brachiopods from the Rat Buri Limestone were interpreted (Grant, 1976) as tropical with marine connection to cooler water. Waterhouse (1982) considered the brachiopod faunas of the Rat Buri Limestone to have a stronger cool temperate composition.

FAUNAL SIGNIFICANCE

All crinoids reported are allagecrinid or advanced poteriocrinitid cladids. The allagecrinid *Kallimorphocrinus* occurs in the Carboniferous and Permian in North America, the Carboniferous of Europe and Permian of Timor and Russia (Bassler & Moodey, 1943; Webster, 1973, 1977, 1986, 1988). *K. thaiensis* and *K.*? sp.nov. from the Phuket Group are related to Permian *Kallimorphocrinus* and *Wrightocrinus* from Timor.

The dorsal cup from the Phuket Group, assigned to *Cymbiocrinus* is the second report of the genus from the Permian and outside North America. Cymbiocrinids are considered the ancestral stock of the calceolispongiids, a Tethyan family restricted to the Permian of Australia, Timor and India (Moore & Strimple in Moore & Teichert, 1978). The bulbous basals of *Cymbiocrinus* are considered a continuation of the cymbiocrinid lineage in parallel with the calceolispongiids which had branched off earlier.

The other advanced poteriocrinitids from the Rat Buri Limestone are small specimens, perhaps not fully mature. They belong to genera that are relatively small but typically larger than these specimens. *Apographiocrinus* is known from the Upper Carboniferous and Lower Permian of North America and the Permian of Russia, Timor and Western Australia (Bassler & Moodey, 1943; Webster, 1973, 1977, 1986, 1988). *A. komukensis* is most similar to *A. pumilus* of the Early Permian Callytharra Formation of Western Australia (Webster, 1987) and Permian Basleo Beds of Timor (Wanner, 1916). The partial crown questionably assigned to *Apographiocrinus* has a more elongate cup than is typical in the genus. This may reflect immaturity as height:width ratio of the cup may decrease with growth as in other inadunates (Pabian & Strimple, 1985).

Contocrinus is known only from the Late Carboniferous and Early Permian of North America (Webster, 1973, 1977). The advanced condition of the anal interarea in *Contocrinus andamanensis* sp.nov. suggests a Permian age. The partial crown questionably assigned to the Clathrocrinidae has arm structure similar to the Late Carboniferous *Clathrocrinus* known only from North America (Webster, 1977, 1986). Cup features suggest advanced morphology common in Late Carboniferous or Permian poteriocrinids.

None of the three poteriocrinid genera from the Rat Buri Limestone are restricted to the Permian; they occur in the Late Carboniferous and Permian or Late Carboniferous only. The lack of strong ornament on the cladids may indicate they are farther offshore or deeper water forms (Pabian & Strimple, 1985). Preservation of crowns with proximal columnals attached implies little if any postmortem transport.

Crinoid ossicles are common elements with brachiopods and bryozoans in shallow shelf carbonates and marls in the late Palaeozoic (Lane & Webster, 1980; Pabian et al., 1989). All Thai crinoids discussed were associated with brachiopods and bryozoans. However, crinoids were sparse in residues from the Phuket Group and the Rat Buri Limestone. Some samples were totally lacking in crinoidal debris. This is considered a reflection of some paleoecologic control, perhaps water temperature.

SYSTEMATIC PALAEONTOLOGY

Morphologic terminology follows Moore & Teichert (1978). Specimens are reposited in the: United States Nation Museum (USNM), University of Tasmania (UT) and University of Queensland (UQ).

Kallimorphocrinus Weller, 1930

TYPE SPECIES

K. astrus typicum (=*K. astrus astrus*) Weller,1930 from the Late Carboniferous Perth Limestone, Indiana; by original designation.

Kallimorphocrinus thaiensis sp.nov.
(Fig. 1A–F)

ETYMOLOGY.

From Thailand.

MATERIAL AND LOCALITY

Holotype UQF79668; paratypes UQF79669, 79670, silica replacements of thecae from a Permian unit, probably the Rat Buri Limestone, on Ko Muk.

DIAGNOSIS

Radials gently rounded, tumid. Thecal outline rounded pentalobate in oral view.

DESCRIPTION.

Theca bowl-shaped, higher than wide, greatest width just above midheight, incurved to radial summit, rounded pentalobate in oral view. Dorsal cup tumid, flat-based, bowl-shaped, finely pitted.

BB 2 or 3, sutures obscured by silicification, forming lower 1/3 of cup height in lateral view, RR 5, approximately twice as long as wide, narrower at base than radial summit, convex horizontally and longitudinally, prominently rounded tumid at 3/4 length, subequal in size, becoming wider with increasing facets. Radial summit horizontal, 1-3 facets per radial. Facets with well developed transverse ridge; muscle field in moderately deep depression sloping inward to ambulacral canal. Anal facet small, equidimensional, on left shoulder of C radial. OO 5, well elevated, slightly inset on radial summit, forming a quarter thecal height, dart-shaped, shaft sides vertical, oral surface with two faint ridges parallel to sides, extending nearly to centre of circlet. Posterior oral largest, separating BC and DE orals, probably bearing hydropore or madreporite. Proximal columnal circular transversely, much wider than high.

MEASUREMENTS OF HOLOTYPE (mm)

Thecal height, 3.1; maximum width, 2.6; height BB circlet, 0.9; radial length 1.6, width, 1.4; height OO circlet 0.7; proximal columnal diameter 1.3, height 0.2.

REMARKS.

The description is based on the holotype, a specimen with 9 arm facets, 2 on A and B radials, 1 each on the C and E radials, and 3 on the D radial, and the paratype, a partial theca lacking the basal circlet and adjacent basal ends of the radials. The paratype bears one arm facet on each radial and the A facet appears to have the initial stage of a second facet developing on the right side. Both specimens fit the generic definition as revised by Lane & Sevastopulo, 1982.

Kallimorphorinus thaiensis is distinguished by the rounded protuberance of the radials being greatest at 1/2 thecal height. The Early Carboniferous, *K. astrus* and *K. piasaensis*, also have their greatest protuberance below the radial facet but their protuberance is much sharper making their thecae more pointed pentalobate in lateral and oral views. The only other Permian species, *K. eaglei* (Strimple, 1966), from Oklahoma and Nevada has exceedingly bulbous radials and much lower basals.

An abberant specimen with four orals is assigned to *K. thaiensis*. It has no arm facet on the A radial and the EA and AB orals are fused. There are two arm facets each on the B and D radials, and one each on the C and E radials. The BC oral is not preserved but facets for its articulation are visible on the specimen. The A radial is narrower than the other radials and narrowest at the top where it abuts the abnormal oral. The orals are larger and higher than those of the types.

Silicification has obliterated details of ornament and oral and radial facets. All are judged to be immature as they retain the oral plates.

Kallimorphocrinus? sp.
(Fig. 1G–J)

MATERIAL AND LOCALITY.

UQF79666, 79667, silica replacements of thecae associated with *K. thaiensis* from the Early Permian Rat Buri Limestone, Ko Muk.

DESCRIPTION.

Theca truncate bowl-shaped, higher than wide in immature forms, wider than high in more mature forms, walls gently flared outward nearly to radial summit, widest just below radial summit. Dorsal cup rounded pentalobate in oral view, walls smooth.

BB circlet fused, low, forming lower 1/4 of cup in immature forms, shallowly concave on circular facet for stem attachment, flaring upward from edge of stem facet. RR 5, longer than wide, narrowest at base, flaring gently outward nearly to facet, moderately convex transversely; convexity increasing distal of facet, becoming wider with increasing number of facets. Radial facets with transverse ridges, outer ligament pits and muscle fields on deep pit sloping inward, with one or more facets per radial in adults. Anal notch small, on left shoulder of C radial.

OO 5, forming rounded dome; individually approximately dart-shaped, widest medially; walls straight, vertical; oral surface with shallow central depression bordered by narrow U-shaped rim closed on aboral end.

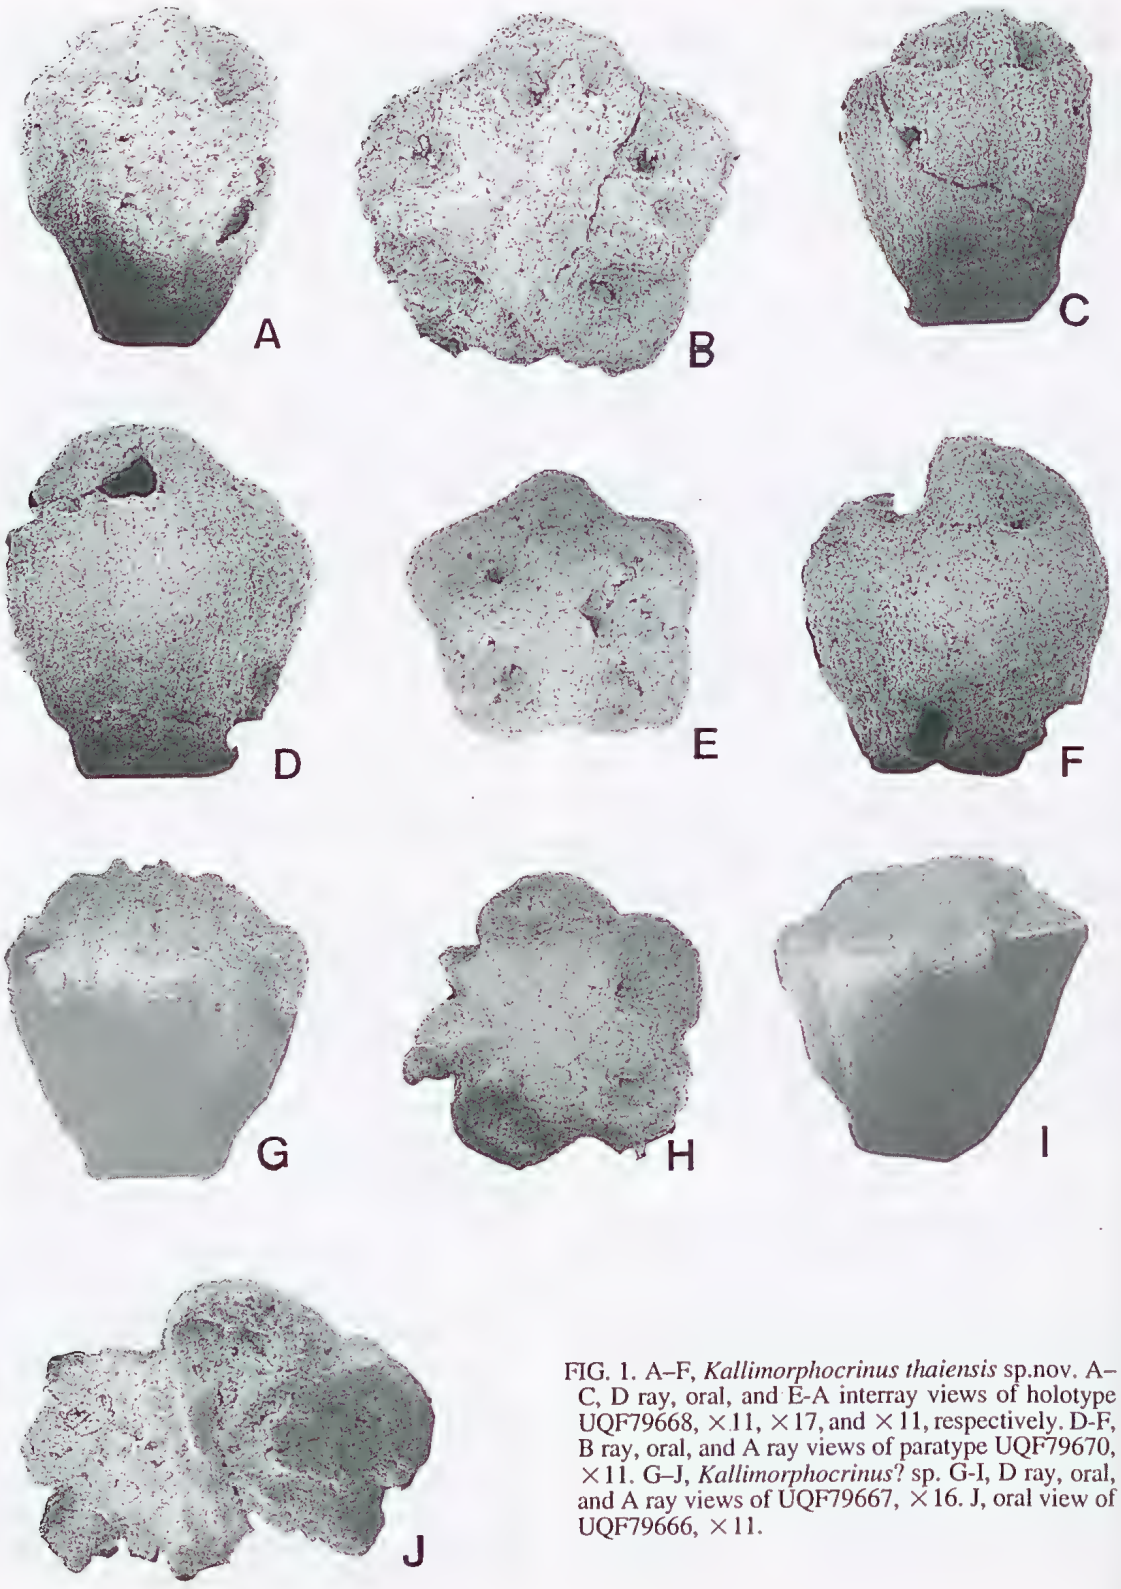

FIG. 1. A–F, *Kallimorphocrinus thaiensis* sp.nov. A–C, D ray, oral, and E-A interray views of holotype UQF79668, ×11, ×17, and ×11, respectively. D-F, B ray, oral, and A ray views of paratype UQF79670, ×11. G–J, *Kallimorphocrinus*? sp. G-I, D ray, oral, and A ray views of UQF79667, ×16. J, oral view of UQF79666, ×11.

REMARKS

The description is based on an immature five-armed theca lacking a small part of the outer wall of the C radial and a larger partial theca lacking virtually all the A radial, most of the B radial, and subjacent part of the basal circlet. This second specimen has one arm facet on the E radial, two on the D radial, one, two or three on the C radial, and at least one on the B radial. Silicification has obliterated some details of the oral plates and radial facet.

Doubts about generic assignment stem from two features. The anal notch could be a result of silicification on the smaller specimen and actually be an arm facet on the larger specimen. Secondly the radials closely resemble those of *Wrightocrinus jakovlevi*, to which this species could be related.

Kallimorphocrinus, as redefined by Lane & Sevastopulo, 1982, has up to 14 arms with only one arm in each of the C and E rays, an anal series, and loss of the orals in adults. Moore (1940) proposed *Wrightocrinus* as an allagecrinid with or without an anal series distinguished by the single arm on each of the B and E radials in adults. He designated *Allagecrinus jakovlevi* Wanner, 1929 as type. Wanner (1929) reported 125 specimens of *A. jakovlevi* and analysed 71 specimens as having 1 arm in each of the B and E rays with one exception having 2 arms in the B ray. Marez-Oyens (1940) reported an additional 199 specimens of *A. jakovlevi* with only 12 specimens having 2 (10 specimens), 3 (one specimen), or 4 (one specimen) arm facets on the B radial. It is possible that most of these exceptions are incorrectly identified and are actually kallimorphocrinids or other allagecrinids as they only have one arm facet on the C and E radials with one exception with two on the C radial.

The number of arms in each ray in adult microcrinoids may be generically diagnostic of some allagecrinids (Moore, 1940; Moore & Strimple in Moore & Teichert, 1978). For example, *Wrightocrinus* normally has only one arm in each of the B and E rays, whereas *Kallimorphocrinus* has one arm in each of the C and E rays, and both genera have more than one arm in each of the other rays. The radials of the two specimens assigned to *Kallimorphocrinus*? sp. are very similar in shape to those of *Wrightocrinus jakovlevi* (Wanner, 1929) a Permian form from Timor. If there were no question about the number of facets on the B and C radials in the larger specimen we would assign the specimens unquestioned to either *Wrightocrinus* or *Kallimorphocrinus*.

The only other species, previously assigned to *Wrightocrinus* is *Allagecrinus biplex* Wright, 1932 (designated genotype of *Thaminocrinus* Strimple & Watkins,1969), a Visean form from Scotland with an anal series. Moore (1940) considered the lack of an anal series in the Permian species to be an advanced evolutionary feature for the genus. Neither Wanner (1929) nor Marez-Oyens (1940) recognised specimens of *A. jakovlevi* with less than 9 arms, however, they both recognised specimens of *A. quinquebrachiatus* Wanner, 1929, a form with 5 arms and no anal series and a cup shape, radial form and oral configuration like that of *A. jakovlevi* but approximately one half the size. Strimple (1966) proposed *Metallagecrinus* designating *A. quinquebrachiatus* as type. If *A. quinquebrachiatus* is the immature form of *W. jakovlevi*, as we believe, then *Metallagecrinus* is a junior synonyum of *Wrightocrinus*.

Strimple (1966) assigned an additional 11 species to *Metallagecrinus* because they all lacked an anal series, retained the oral circlet, and had one arm per ray. Strimple & Sevastopulo (1982) reconsidered these assignments and suggested *M. multibrachiatus* (Yakovlev, 1927), *M. dux* (Wanner, 1930) and *M. inflatus* (Wanner, 1929) should be excluded because they differ in several respects from the type. We agree with this assessment and would transfer all other species [*M. acutus* (Wanner, 1929), *M. excavatus* (Wanner, 1929), *M. indoaustralicus* (Wanner, 1916), *M. quinquelobus* (Wanner, 1929), *M. procerus* (Wanner, 1929), *M. ornatus* (Wanner, 1929), *M. uralensis* (Yakovlev, 1927) and *M. uralensis nodocarinatus* (Yakovlev, 1927) as well as *M. palermoensis* Strimple & Sevastopulo, 1982 to *Litocrinus* Lane & Sevastopulo, 1982.

Order CLADIDA Moore & Landon, 1943

Superfamily SCYTALOCRINOIDEA
Moore & Laudon, 1943

Family and Genus uncertain

MATERIAL

One partly silicified dorsal cup, UQF79665, from acid residue of loose boulder of Rat Buri Limestone from the southeast part of small bay; Ban Hat Yao, on the northern end of Ko Yao Noi, southern Thailand.

REMARKS

This cup is 5.8mm wide, 3.4mm high, cone-shaped, with truncated base, steeply outflared plenary radial facets, with a single small anal in a notch shared by the C and D radials. Infrabasals small, slightly upflared. Ornament destroyed by silicification if present; stem facet round. Anal sac and arms unknown.

Advanced features present on the cup are the plenary facets and anal plate nearly out of the cup. A primitive feature retained is the conical shape. The specimen is questionably assigned to the scytalocrinoids because of its shape, radial facets, and number and position of the anal.

The specimen is not well enough preserved to be designated a type or effectively illustrated. It is mentioned because it adds to the generic diversity in the Permian of Thailand.

Superfamily DECADOCRINOIDEA Bather, 1890
Family CLATHROCRINIDAE Strimple & Moore, 1971

Clathrocrinid gen. et sp.nov.
(Fig. 2 O,P)

MATERIAL AND LOCALITY

One crown, USNM450329, from acid residue of the Rat Buri Limestone, locality USNM9271, northwest side of Ko Muk, NW of Kan Tang (Grant, 1976).

DESCRIPTION

Crown small, elongate, subcylindrical, with arm girdle at top of primibrachials, 10 arms slender with offset brachials in zig-zag pattern. Cup crushed, medium bowl; walls outflaring, gently convex; base invaginated; sutures flush; radial notches obvious; ornament lacking. IBB not visible in lateral view. BB 5, slightly longer than wide, gently convex transversely, strongly convex proximally, gently convex distally, proximal end forming base of cup. RR 5, wider than long, gently convex transversely and longitudinally; facet angustary, lacking prong-like internal extensions on lateral ends of upper surface; small gape with primibrachials at facet. Single anal relatively large, longer than wide, with proximal third below radial summit, sitting on top of truncated laterally symmetrical CD basal, with distal two-thirds incurved above radial summit, adjoined distally by two tube plates. IBrr one per ray, axillary, longer than wide, widest at base, laterally constricted in central three-fourths, strongly convex transversely, gently concave longitudinally, bearing prominent slightly upward directed spine at distal end. IIBrr elongate, cuneate, twice as long as wide proximally, three times longer than wide distally, widest on distal end, strongly convex transversely, longitudinally straight becoming concave distally, bearing prominent slightly upward directed spine on distal end. Pinnules large, could be considered ramules, elongate, strongly convex transversely, alternate on sides of arm, one per brachial on distal end of brachial.

MEASUREMENTS (mm)

Crown length 31.6 (incomplete), width 10.6; cup height 5.8, width 4.2 (estimated); BC basal length 3.6, width 3.5; E radial length 4.2, width 5.8; anal length 3.8, width 3.2; IBr1 length 4.1, width 3.8; IIBr1 length 5.8, width 2.8; IIBr5 length 4.6, width 1.7.

REMARKS

No name is given to this distinctive specimen because the cup is crushed. Infrabasals are not preserved; the BD, CD and DE basals and C, D and E radials are preserved.

Classification is based on arm structure. The angustary radial facets, elongate brachials, pinnules that are essentially ramules, zig-zag pattern of the brachials, and spine on the distal end of the brachials all have affinity with the Clathrocrinidae. Unlike *Clathrocrinus* only one anal occurs within the radial summit, indicating an advanced condition, and the zig-zag pattern of the brachials is not as widely spreading. We consider this specimen to have evolved from a clathrocrinid ancestor in Early Permian times. Range of the family is extended into the Permian and its distribution, previously confined to North America, is extended to Southeast Asia.

Superfamily ERISOCRINOIDEA Wachsmuth & Springer, 1886
Family GRAPHIOCRINIDAE Wachsmuth & Springer, 1886

Contocrinus Knapp, 1969

TYPE SPECIES
Graphiocrinus stantonensis Strimple, 1939 from the Upper Carboniferous Wann Formation, Oklahoma, by original designation.

Contocrinus andamanensis sp.nov.
(Fig. 2E–H)

ETYMOLOGY
For the Andaman Sea.

MATERIAL
Holotype USNM450326; paratype USNM450325, Rat Buri Limestone, locality USNM9271, NW side of Ko Muk, Thailand.

DIAGNOSIS
Small, with a shallow arm girdle, large elongate posterior basal, and anal distally adjoined by two tube plates.

DESCRIPTION
Crown elongate, slender, with slight arm girdle at base of secundibrachials, 10(?) arms. Cup medium bowl-shaped, widest slightly below radial summit, with moderate basal invagination; sutures between basals slightly impressed, sutures between radials deeply impressed; apical pits at top of basals and base of radials; granular to vermiform ornamentation. IBB 5, small, slender, strongly tapering, downflaring, not visible in lateral view, covered by proximal columnal. BB 5, outflaring, strongly convex longitudinally and transversely, slightly wider than long, proximally forming base of cup; posterior basal larger, more elongate. RR 5, slightly outflaring, wider than long, strongly tumid. Radial facets plenary, sloping outward, with moderate gape; outer ligament area wide, with pit; transverse ridge full width of facet. Anal slightly longer than wide, proximally adjoining truncated transversely symmetrial CD basal, distal end projecting slightly above radial summit, followed by two tube plates. IBrr one per ray, axillary, medially constricted, strongly convex transversely, gently concave longitudinally, slightly wider proximally than distally. IIBrr slightly longer than wide, slightly cuneate, strongly convex transversely, weakly convex longitudinally; sutures slightly impressed. Proximal columnals heteromorphic, transversely round, latus convex, symplexy articulation; lumen not preserved.

MEASUREMENTS (mm).

	U S N M 450325	U S N M 450326
Crown length (incomplete)	14.0	15.0
Cup height	2.0	3.4
Cup width (through A-CD)	5.9	7.3
Diameter IBB circlet		0.9
AB basal length	1.8	2.4
AB basal width	1.9	2.8
A radial length	1.7	2.4
A radial width	2.8	3.2
IBR1 length	2.9	4.5
IBR2 width	2.8	3.7
IIBR1 length	1.9	2.3
IIBR1 width	1.7	2.2
IIBR5 length	1.2	1.4
IIBR5 width	1.0	1.9
Anal length	1.8	1.6
Anal width	1.4	1.5
Diameter proximal columnal	1.5	1.3

REMARKS
There are probably 10 arms. The D and E rays are not preserved on the paratype and the A, B and E rays are not preserved on the holotype. All preserved rays bear 2 arms. Pinnules are not preserved on either specimen but articular facets for the pinnules are poorly preserved on the distal outer corner of some of the distal secundibrachials. Noditaxis patterns are not well developed on the proximal pluricolumnal segment, but variable thicknesses of the 6 columnals suggest a simple heteromorphic Type 1 pattern of Webster (1974). Ornamentation is more finely granular on the holotype than the paratype.

These specimens are transitional between the graphiocrinids and apographiocrinids. The arm girdle and two tube plates adjoining the anal plate relate the specimens to the apographiocrinids. However, plenary radial facets and lack of prong-like extensions on the radials between the facets show affinity to the graphiocrinids. We consider the plenary radial facets to be of greater importance in classification than the number of tube plates adjoining the anal plate.

Contocrinus andamanensis has less tumid cup plates and a longer posterior basal than the most similar *C. scopulus* (Lane & Webster, 1966). Both

species are smaller than Pennsylvanian species; because both are based on few specimens, it is not known if they are mature or not.

This is the first report of *Contocrinus* outside North America, although graphiocrinids, i.e. *Permiocrinus* Wanner,1949 is known from Timor. Most Timor species initially assigned or transferred to *Graphiocrinus* by Wanner, 1949, have been assigned to other families of advanced poteriocrinids (Webster, 1987, among others).

Superfamily APOGRAPHIOCRINOIDEA Moore & Laudon, 1943
Family APOGRAPHIOCRINIDAE Moore & Laudon, 1943

Apographiocrinus Moore & Plummer, 1940

TYPE SPECIES

A. typicalis Moore & Plummer, 1940 from the Pennsylvanian Plattsburg Limestone, Kansas, U.S.A., by original designation.

Apographiocrinus komukensis sp.nov.
(Fig. 2A–D)

ETYMOLOGY

From the island of Ko Muk.

MATERIAL

Holotype USNM450328 and paratype USNM450327 from acid residues of Rat Buri Lst at locality USNM9271, NW side of Ko Muk.

DIAGNOSIS

High cup, with less tumid plates, ornament variable, finely granular to vermiform.

DESCRIPTION

Cup medium bowl-shaped, nearly twice as wide as high; walls gently convex, outflared; base with moderately deep invagination; sutures weakly impressed; apical pits shallow; ornament very fine and granular. IBB 5, small, dart-shaped, downflaring, not visible in lateral view. BB 5, slightly wider than long, gently convex transversely and longitudinally, proximal end forms base of cup and edge of basal invagination. RR 5, wider than long, gently convex longitudinally, strongly convex transversely; facets angustary, sloping outward; internally extending prong-like ridges separating facets; well developed radial notches in lateral view. Anal slightly longer than wide, proximal end adjoins truncated laterally symmetrical CD-basal, distal third extends above radial summit, facets for two adjoining tube plates distally. IBrr one per ray, slightly longer than wide, constricted medially, transversely convex, longitudinally concave; axillary, isotomous branching. Stem impression round.

MEASUREMENTS (mm)

Anal length	2.1	—
Anal width	1.6	—
IBR1 length	—	2.9*
IBR1 width	—	2.7

*estimated

REMARKS

The paratype has more tumid cup plates, some vermiform ornamentation, more impressed sutures, and a lower, more outflaring bowl configuration than the holotype. Although possibly distinct species we consider them one on available material. Angustary radial facets, prong-like projections between radial facets, and facets for two tube plates distal to the anal relate these forms to *Apographiocrinus*.

Three species of *Apographiocrinus*, *A. pumilus*, *A. quinquelobus*, and *A. rugosus*, although initially assigned to other genera, were reported from Permian strata of Timor by Wanner, 1916. All three species have much coarser ornament, ornament of a different type, or much more tumid basals and radials than *A. komukensis*. Late Carboniferous species of *Apographiocrinus* known from North America have less tumid cup plates, are much larger, and have more outflared cup walls than *A. komukensis*.

Apographiocrinus? sp.nov.
(Fig. 2L–N)

MATERIAL AND LOCALITY

One partial crown, UTGD124566 from the basal part of the Rat Buri Limestone from Ko Phi Phi, an island northwest of Kan Tang, recovered by Clive Burrett. Sample No KP(B).

E-G, A ray, basal, and posterior views of holotype USNM450326, ×2.5. H, A ray view of paratype USNM450325, ×2.5. I–K, *Calceolispongia*? sp.nov. posterior, D-E interray, and basal views of UTGD124567, ×1.8. L–N, *Apographiocrinus*? sp.nov. posterior, B-C interray, and A ray views of UTGD124566, ×32. O,P, *Clathrocrinid* gen. et sp.nov. E ray and posterior views of USNM450329, ×2.5.

DESCRIPTION

Partial crown elongate, slender, 12.8mm preserved. Cup bowl-shaped, wider (8.9mm) than high (6.8mm). IBB 5, not visible in lateral view, mostly covered by proximal columnal. BB 5, EA subequal (4.3mm), DE longer (5.0mm) than wide

(4.8mm), convex proximally forming basal plane, gently convex and subvertical distally. Posterior basal heptagonal, truncated distally for reception of anal. RR 5, A radial wider (4.8mm) than long (3.5mm), moderately convex transversely, gently convex longitudinally, subvertical to slightly incurved distally, lateral sutures impressed. Radial facets peneplenary, sloping gently outward, low lateral prongs extending internally as lateral ridges with adjoining radials. Single anal longer (2.9mm) than wide (2.1mm), gently convex transversely and longitudinally, proximal 3/4 below radial summit, adjoins 2 tube plates distally.

IBrr one per ray, axillary, longer (6.5mm) than wide (4.5mm) widest at base, longitudinally convexo-concave, transversely convex, constricted below distal facets, unequal in length, ?A ray IBr longest. Proximal columnals heteromorphic, transversely rounded, latus gently convex, lumen ?pentalobate.

REMARKS

The specimen is silicified and slightly distorted basally. Parts of B radial and AB through CD basals not preserved. Only A and E IBr complete, C & E IBr partly preserved. The infrabasal circlet is not visible but internal walls of etched basals show two facets for attachment to infrabasals. There were probably 5 small infrabasals down-flared or subhorizontal.

The arms branch isotomously on the E and A primibrachs, suggesting 10 arms if the same branching pattern occurred in all rays.

The specimen is referred to the Apographiocrinidae because it has peneplenary radial facets, lateral prongs on the radial facets, and 2 tube plates distal to the single anal. The cup is more elongate than in the rest of the family, indicating a less advanced form than might be expected in a Permian member. Constriction in the distal part of the primibrachs suggests development of an arm girdle. It is left in open nomenclature in hope of future recovery of additional specimens.

Cymbiocrinus? sp.nov.
(Fig. 2I–K)

MATERIAL AND LOCALITY

Partial crown, UTGD124567, found by Clive Burrett in the upper Phuket Group on Ko Phi Phi. It occurs in a unit with Early Permian brachiopods considered to indicate a temperate climate (Waterhouse, 1982).

DESCRIPTION

Partial crown crushed subparallel to anterior-posterior plane of symmetry. Cup moderate bowl-shaped, with shallow to moderate basal invagination; plates bulbous, not ornamented. IBB not preserved. BB 5, strongly convex in all directions, subequal length (8.4mm) and width (8.1mm), forming basal plane, hexagonal except heptagonal posterior basal truncated for anal plate. RR 5, half again wider (10mm) than long (6.3mm), convex longitudinally and transversely. Radial facets plenary.

Single large anal, essentially below radial summit, gently convex longitudinally and transversely, longer (4.7mm) than wide (4.6mm). IBrr 2 in B ray, wider (9.7mm) than long (5.2mm) gently convex longitudinally and transversely. IBr2 axillary. C ray IBr larger, 10.2mm wide, 5.8mm long, non-axillary. Additional brachials and stem not preserved.

REMARKS

Specimen replaced by hydrous iron oxides, B radial lost, some loss by solution of plates adjacent to B radial. Radial facets well developed and sloping inward but solution has destroyed details of exposed surfaces. Infrabasals lost, small, probably 5 and down flared or subhorizontal, mostly covered by proximal columnals. Pluricolumnal segments in the matrix block are transversely rounded but not attached to the cup. It is not certain that they were part of the original animal but it seems likely.

The bulbous basals and large radianal suggest relationship with the calceolispongiids. However, branching on the second primibrach is unknown in the calceolispongiids but is typical of *Cymbiocrinus* which has a single anal. We consider the calceolispongiids to have evolved from the Cymbiocrinids adapting to cooler water clastic dominated environments of the Permian of Australia. The specimen is left in open nomenclature in hope of a future discovery of a better specimen to serve as holotype.

ACKNOWLEDGEMENTS

Our appreciation is extended to Richard E. Grant, Clive Burrett, and Bruce Waterhouse for the loan of material. Frances G. Stehli provided funding and aided in the collection of the material reposited in the USNM.

LATE TRIASSIC HOMOPTEROUS NYMPH FROM DINMORE, IPSWICH BASIN. *Memoirs of the Queensland Museum 33(1): 360. 1993*:- This well-preserved homopterous nymph was collected by Mr Robert Knezour from plant fossil-rich mudstone underneath powerlines in a quarry (Queensland Museum [QM] L471) at the end of Roberts St, Dinmore in the Ipswich Basin (27°31'S, 152°51'E). The sediments belong to the Blackstone Formation of the Ipswich Coal Measures. Palynological data suggest a Late Triassic (Carnian) age (deJersey,1970). Details of stratigraphy and age were given by Rozefelds & Sobbe (1987) who noted other insects (Blattodea, Hemiptera and Coleoptera) in association with a typical *Dicroidium* macroflora.

Order HEMIPTERA
Suborder HOMOPTERA
Superfamily UNCERTAIN

The head with the rostrum arising from the frons near the rear of the head suggests an homopterous form but its relationships are uncertain because comparable nymphs are extremely rare in the fossil record. Of the several homopterous nymphs known (Riek,1974 and references therein) none are similar to the new form being mainly Sternorrhyncha whereas this fossil is more like Auchenorrhyncha nymphs (Carpenter, [1992] did not report any nymphs in families referable to the Auchenorrhyncha). Because several critical features are unclear on the fossil, comparison with nymphs of Recent forms can only be superficial and therefore inconclusive. However, it does suggest similarity to Fulgoroidea. The excessively long rostrum, patches of sensory abdominal tubercles, and long coxae based well away from the midline are known in modern Fulgoridae. However, unlike the fossil described here, coxae of the third fulgorid leg are fixed in the sternite and the free part of the leg begins at the tibia. Familial assignment must remain open.

Knezouria gen.nov.

Type species. Knezouria unicus sp.nov.

Remarks. Although it is possible that this nymph belongs to a named fossil species, there is no way of determining its morphogenic development and no way of relating it to an adult. Therefore, a separate binomial name is justified for a fossil that cannot be assigned to an existing taxon and that is likely to be referred to often.

Knezouria unicus sp. nov. (Fig.1)

Etymology. Latin *unicus*, sole, one only.

Material. Holotype QMF18850a,b (part & counterpart), ventral surface only.

Description. Nymph with rudimentary wings (most obvious posterolaterally on thorax); 13mm long; 7mm wide, abdomen half length of animal. Frons large, diamond-shaped, with subtle transverse and longitudinal ridges meeting at midpoint; rostrum very slender, extending beyond the posterior margin of the abdomen (preserved as an indistict ridge curving off the midline along the thorax then crossing the midline near abdominal midlength); posterior of head indistinct.

Legs with long, stout, oblique coxae, based away from midline and running to midline; femora strong, similar, running obliquely to margin; tibia long, slender, may have fine spines on inner edge; tarsi 0.3 length of tibia, gently curved; pretarsus with two claws.

Fig.1. *Knezouria unicus* gen. et sp. nov. holotype, part and counterpart of ventral surface, ×4.

Abdomen inverted beehive shape, 8 segments clearly evident, with distinct, narrow, median longitudinal ridge, with paired areas of small tubercles on each segment (each one associated with a sensory hair, by analogy with modern Homoptera). Terminal (8th) segment with anal and genital structures in median line well forward of margin, in form of two pairs of lobes directed posteriorly, each pair forming an indistinct U-shaped structure.

Acknowledgements

I am grateful to Mr Robert Knezour for donating the specimen and allowing me to describe it.

SURVEY OF THE VERTEBRATE FAUNA OF THE DOTSWOOD AREA, NORTH QUEENSLAND

STEVE WILLIAMS, RICHARD PEARSON & SCOTT BURNETT

Williams, S., Pearson, R. & Burnett, S. 1993 06 30: Survey of the vertebrate fauna of the Dotswood area, north Queensland. *Memoirs of the Queensland Museum* **33**(1): 361-378. Brisbane. ISSN 0079-8835.

The results of a survey of mammals, birds, reptiles, amphibians and fish of the Dotswood area west of Townsville are presented. Habitats included in the survey were woodland, open forest, tall open forest, closed forest (rainforest), riparian forest and rocky outcrops. A total of 297 species of vertebrates were observed using a variety of survey techniques including live trapping, pit trapping, observational transects, mist netting and spotlighting. Exact locations of observations and indices of relative abundance of each species are included.
☐ *Survey, vertebrate, mountain, Dotswood, north Queensland, Australia.*

Steve Williams, Richard Pearson & Scott Burnett, Australian Centre for Tropical Freshwater Research, James Cook University of North Queensland, Queensland 4811, Australia;
15 November, 1993.

Fauna surveys, although mostly descriptive, are a basic necessity in the understanding of the ecology of any area. This paper describes a broad survey of the vertebrates in a variety of habitats west of Townsville, undertaken to provide baseline information prior to the proposed development of military training facilities. Despite its proximity to and accessibility from Townsville, the survey area, which includes Dotswood Station, Star Station, High Range Training Area and sections of the Bluewater Range, had never been the subject of any intense biological studies. Consequently, very little published biological information exists for the area. Not only is information on the area poorly represented in the literature, but the wet-dry tropical environment of north Queensland which typifies much of the Dotswood and High Range areas is very poorly understood. This reflects the concentration of Australian zoological and ecological research effort in southern regions and the tropical coastal zone in the past.

The study area is located within the Shire of Dalrymple to the south-west of Townsville (Fig. 1), with the north-eastern and eastern boundaries following the escarpments of the Paluma and Hervey's Ranges. The western boundary is to the west of the Star River and the southern boundary follows the boundary between Dotswood Station and Fanning River Station (Fig. 2).

The total study area of about 2320km^2 comprises the following land tenures:

High Range Training Area (HRTA) 48,669ha
Dotswood Pastoral Lease (No. 44/3176). 155,000ha
Special Lease RAAF training area (N 44/45266) 27,300ha
Occupational License (No. 510) 907ha
Total study area approximately 232,000ha

The landscape descends from the escarpments and hills of Paluma and Hervey's Ranges (altitude c.800m) in the north and east to a complex of dissected plateaux and tablelands with steep slopes to the south, through to areas of low relief (altitude c.250m) in the south-west. The study area is drained by the Star River, Keelbottom Creek, Fanning River and the Reid River. Drainage direction is generally to the south, with all drainage systems except the Reid River draining into the Burdekin River. The Reid River flows into the Haughton River.

The emphasis of the study was on recording the diversity of the vertebrate fauna in each of the major habitat types of the study area, with some regard to relative abundances. Sampling methods were therefore designed to record as many species of mammals, birds, reptiles, amphibians and fish as was possible. Additionally, literature on the study area was reviewed and a reasonably comprehensive species list of the area was compiled.

Additional sources of information included rare and threatened species lists from Queensland National Parks and Wildlife Service (QNPWS); endangered species list from ANZECC (Anon, 1991); assessments of status and lists of rare, endangered, vulnerable and poorly known vertebrates of Queensland, and location records of mammal, bird, reptiles and frogs from the Queensland Museum database (Ingram & Raven,

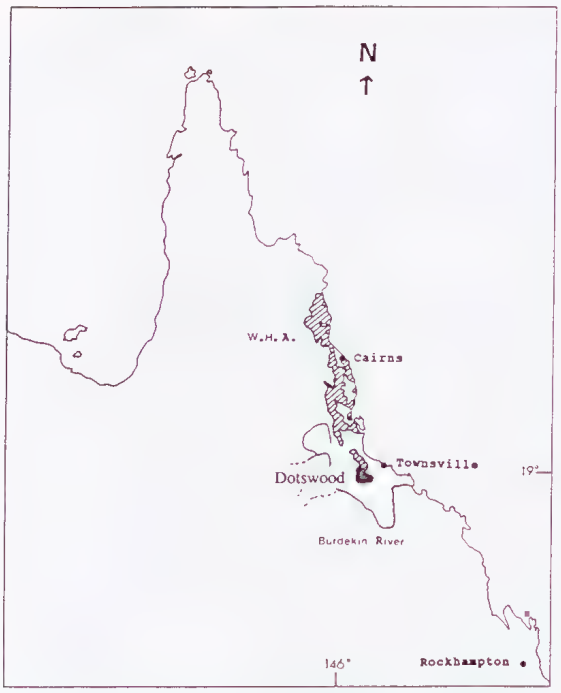

FIG 1. Map of north Queensland showing location of study area.

1991), the most up-to-date assessment of the status of vertebrates in Queensland; species records from the Wildlife Preservation Society of Queensland; Williams et. al., (1993); Ben Lomond . (Hollingsworth, 1980); Brouwer & Garnett's (1990) annotated list of threatened birds of Australia; and a variety of personal communications with staff at James Cook University and the QNPWS.

LITERATURE REVIEW

BIRDS

Most bird records from the region are from the coastal plains and ranges. Lavery & Johnson (1968) provided a list of observations from the Townsville area, from Mt Spec in the north to 'St Helliors' near Cape Cleveland in the south. This study identified 229 species from the area. Blakers et. al. (1984), which provided Australia-wide maps for all the Australian birds mapped in 1°×1° squares (19°S 146°E), recorded 256 spp. from the region encompassing the study area. Nix & Switzer (1991) gave locality and expected ranges of all vertebrates considered to be endemic to the wet tropical rainforest. Steve Garnett (pers. comm.) listed 365 species from the Townsville area and Hollingsworth (1980) listed 64 bird species at the Ben Lomond mine on Dotswood. Queensland Museum specimen records are scanty, including only three species from the Dotswood area.

Due to the relative ease of observation and identification of birds, they feature strongly in the lists of amateur wildlife groups, such as, the Townsville Bird Banding Group, which has undertaken a long term study in tall open forest west of Paluma, and the Wildlife Preservation Society of Queensland, which provides bird lists in excursion reports from the Townsville area, including Bluewater and Hervey's Ranges and Fanning River. In addition, QNPWS provide bird lists for national parks of the area including Mt Spec and the Townsville Town Common. Where relevant, species recorded by these sources have been included in this report.

Ecological studies in the area are much scarcer than simple records of occurrence. Apparently no studies have been conducted within the study area itself or within equivalent open forest in the region. Keast et. al. (1985), however, bring together information on eucalypt forest birds, some of which may be applicable to this area (e.g. Keast, 1985; Recher, 1985).

Rainforest birds have received more attention in north Queensland. Kikkawa (1982) examined the community structure of rainforest birds in relation to rainforest physiognomy and Crome (1978) examined the feeding ecology of birds in lowland rainforest. Although these studies were conducted at lower altitudes than the study area their results should be applicable to rainforest on the Bluewater Range. However, while some studies have been conducted in comparable areas and may be applicable to the study area, information on habitat utilisation, particularly the role of wet refugial areas (i.e. riverine and vine thicket habitats, and responses to disturbance) is scanty. Stocker & Irvine (1983) and Crome & Moore (1990) have discussed the ecological role of the Southern Cassowary in dispersal of rainforest seeds.

MAMMALS

Winter et. al. (1984) provided a list of 16 rainforest mammal species either recorded or expected from the Bluewater region which is partly contained within the RAAF training area. Lavery & Johnson (1968) gave a list of 71 mammals from the coastal plains and ranges of the Townsville area. No equivalent published lists are available from the drier habitats that typify most of the study area, although Hollingsworth (1980) listed

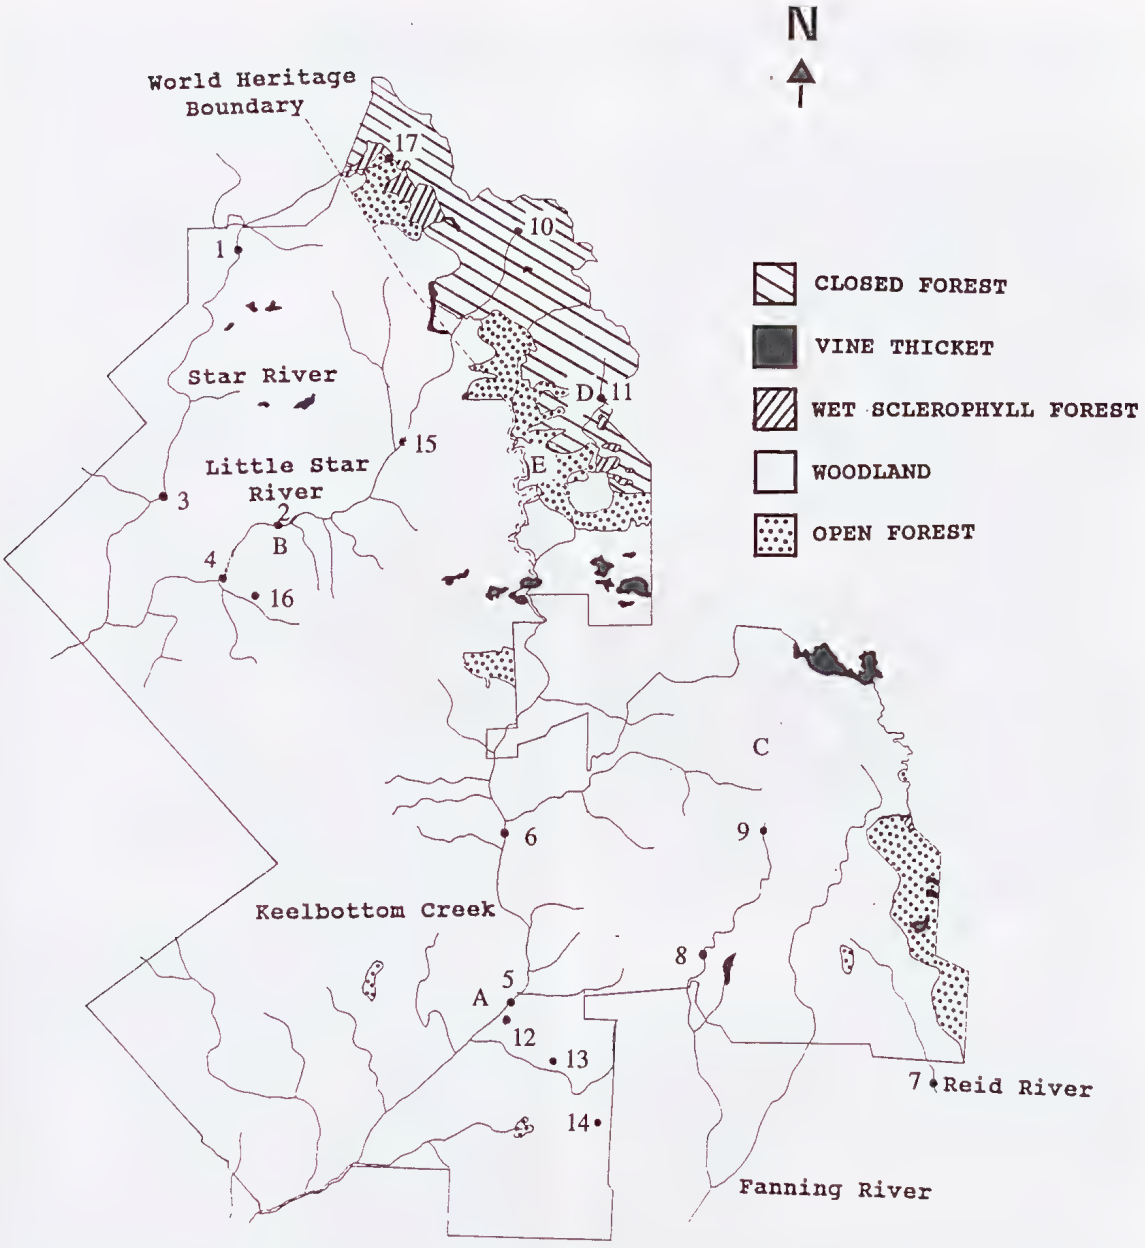

FIG 2. Map of the study area showing site locations and major fauna habitat types and streams (riparian habitat). Major vegetation boundaries after Power & Jackes (1992).

13 mammal species, five of which were introduced, at the Ben Lomond mine site on Dotswood. A QNPWS survey of the Dalrymple Shire covers an area of comparable habitats to the west of the study area, but the results of this survey were not available.

Queensland Museum records provide a list of nine species from Hervey's Range and areas on Dotswood Station while QNPWS provide lists for Mt Spec National Park and Townsville Town Common Environmental Park, which may be applicable to wetter parts of the Dotswood area. At Mt Spec, near Paluma, Williams (1990) examined the relationships between mammal commu-

nities and vegetation in wet forests similar to those in the study area at Bluewater State Forest.

Reptiles

Like mammals, reptiles are mostly cryptic and there is considerable confusion surrounding the taxonomy of many groups. Therefore it is not surprising that, until recently, very little had been published on the distribution and population and community ecology in this group (Strahan, 1985). However, Greer (1989) provided summaries of information on species biology for the lizards.

Queensland Museum records list 27 species of reptiles from the Bluewater/Hervey's Range/Dotswood area and Hollingsworth (1980) listed 23 species at Ben Lomond mine on Dotswood. Both these numbers are probably poor reflections of the true reptile diversity of the area as gleaned from distribution maps (Cogger, 1992; Wilson & Knowles, 1988).

The recent upsurge in interest in the wet tropics has led to increased collecting activity in the area. As a result, the distribution and status of rainforest species is generally better understood than for the species of the drier forest and woodland to the west (e.g. Nix and Switzer 1991). However, for the vast majority of reptiles from this area, and indeed from most of Australia, very little is known of community ecology or of specific habitat requirements (e.g. Wilson & Knowles 1988). The responses of species and communities to natural and human disturbances is unknown.

Amphibians

A considerable increase in interest in frog ecology and taxonomy has happened in the past 20 years (McDonald, 1992; Covacevich & McDonald, 1991; Ingram & Raven, 1991). This increase is reflected in an increase in the number of taxonomic studies (e.g. Czechura et. al., 1987; Liem 1974; Zweifel 1985) and, coupled with recent interest in the wet tropics, has lead to a reasonable understanding of rainforest frog distribution patterns. McDonald (1992) provided a list of 23 rainforest species, 21 of which were endemic to tropical rainforest in north Queensland. Of this list, five, all with conservation prognoses of very good or excellent, are recorded from the Bluewater Range. A further five species are recorded on Queensland Museum lists from the drier areas of the study area and six species are listed from the Ben Lomond mine site on Dotswood Station (Hollingsworth, 1980).

Tyler (1979) described our knowledge of Australian frogs as abysmal and, although they have received much more attention since that time, our understanding of population and community ecology is still at a basic level, especially in the wet/dry tropics. He listed potential impacts of humans on frogs including deforestation, land drainage, introduction of predators (including aquatic predators), and siltation of water bodies. Some species have benefited through human activities including provision of water bodies in dry areas. Habitat utilisation, including, for example, the importance of wet refugial areas, is not known.

Fish

Published material on the aquatic biota of the region is scarce. Pearson (1991a) reviewed much of the available information and discussed some of the major research needs for the wet tropics forest area. There is some information produced by the QNPWS for the coastal wetlands near Townsville, mostly on the avifauna, and one or two publications on the limnology of the Ross River Dam (e.g. Finlayson & Gillies, 1982). However, these coastal wetlands are not comparable with the natural aquatic habitats in the study area. The ecology of the middle Burdekin River has been studied by a research team at James Cook University, but apart from a short report (Pearson, 1991b) this work remains unpublished. Current studies on fish communities in the Star and Fanning Rivers include sites within the study area, but the work is incomplete and unpublished (B. Pusey, pers. comm.).

Studies of streams in the drier areas comparable with the study area are limited. They include the work on fish communities in the Black River (Beumer, 1980), on catfish populations in Campus Creek, an intermittent stream on James Cook University campus (Orr & Milward, 1984), and on the invertebrate communities of Campus Creek (Smith & Pearson, 1984, 1987).

It is clear, therefore, that the wet/dry forests and woodlands to the west of the wet, coastal ranges have been largely ignored in comparison to the rainforests. Additionally Ridpath (1985) noted that far less research has been conducted into ecological processes of the wet/dry tropics than in temperate or arid regions of Australia. He also pointed out the dangers in trying to apply models from these areas to the wet/dry tropics.

SAMPLING SITES

Terrestrial

Site selection was aimed at replicated sampling of the maximum number of habitat types possible

within the constraints of time, equipment and personnel. The following broad habitat types were identified within the study area from the vegetation map by Power & Jackes (1992) (Fig. 2) and their detailed vegetation descriptions:

CF: closed forest;

TOF: tall open forest or 'wet sclerophyll forest';

OF: open forest;

W: woodland;

R: riverine (riparian) forest;

RK: rocky outcrops;

SW: swamps and other water bodies;

G: grasslands, mostly artificially cleared;

A pilot survey was used to ground-truth the habitat types and to select sampling sites within each broad vegetation type (Fig. 2). Within each of these sites, three or four different sub-sites were selected for intensive sampling. These sub-sites were chosen to maximise the diversity of habitats sampled within each broad vegetation type. The sites were (grid references refer to Australian 1:50 000 topographic maps, series R733):

SITE A: Woodland (W) , vicinity of Dotswood homestead. This site is representative of the large areas of *Eucalyptus crebra* open woodland that cover most of the study area. Three sub-sites were: A1 - riparian vegetation along Keelbottom creek (19°37'S 146°19'E; grid ref. DU 247293); A2 - open woodland with grass understorey (19°36'S 146°17'E; grid ref. DU 227314); and A3 - open woodland with a shrub layer of *Acacia* sp. and grass understorey (19°35'S 146°15'E; grid ref. DU 216330).

SITE B: Woodland (W), between Star homestead and Ponto Hut. This second open woodland site was selected because this vegetation type covered a large proportion of the study area and the fauna might differ between the northern (site B) and southern (site A) areas. Three sub-sites were: B1 - low open *E. shirleyi* woodland with low shrubs along small dry gullies (grid ref. DU 151635); B2 - riparian vegetation (R) along the Little Star river and *E. platyphylla* woodland with dense grass layer (*Heteropogon* sp.)(19°18'S 146°12'E; grid ref. DU 149647); B3 - *E. crebra* open woodland with grassy (*Heteropogon sp.*) understorey (19°19'S 146°18'E; grid ref. DU 206645); B4 - mixed *Eucalyptus* open forest with sparse grass, predominantly *Themeda* sp.

SITE C: Open forest and woodland (OF and W) in the High Range training area. This area consists of denser vegetation than sites A and B with a greater tree diversity. The area is hilly with some rocky outcrops. Four sub-sites were: C1 - *Melaleuca* swamp with sedge and blady grass understorey (19°23'S 146°29'E; grid ref. DU466554); C2 - riparian vegetation along Stake Creek (major tributary of the Fanning river)(19°27'S 146°30'E; grid ref. DU 480481); C3 - Rocky outcrop (19°27'S 146°30'E; grid ref. DU 402482); C4 - open eucalypt forest with grass (*Themeda triandra*) understorey (19°31'S 146°33'E; grid ref. DU 532427).

SITE D: wet sclerophyll forest (TOF) and closed forest (CF) (Bluewater State Forest). This transitional habitat is very narrow and patchy and not readily distinguished in air photos. Dominant tree species are *Syncarpia glomulifera*, *Allocasuarina* sp. and *E. grandis* and there are also several other eucalypts and a variety of rainforest species. The rainforest species often form a shrub layer under the emergent sclerophyll species. This habitat represents an ecotonal area between rainforest and the open eucalypt forest to the west. Three sub-sites were selected on the basis of differing vegetation structure: D1 - closed *Allocasuarina/Syncarpia* forest with dense shrub layer and very little ground cover (19°14'S 146°24'E; grid ref. DU371734); D2 - *Allocasuarina/Syncarpia/Eucalyptus* forest with some shrubs (predominantly rainforest species) and short, dense grass (19°14'S 146°23'E; grid ref. DU 365731); D3 - *Syncarpia/E.grandis/Allocasuarina* forest with dense ground cover of blady grass and sedges and also some patches of dense shrubs (19°14'S 146°23'E; grid ref. DU 359725). D4 - *Allocasuarina/ Eucalyptus* open forest with dense ground cover of *Xanthorrhoea*, *Imperata* and areas of shrubs. *Pandanus* sp. occur in low lying wetter areas. A rainforest sub-site was not sampled due to previous survey work on Mount Halifax which is less than 1km outside the study area (Williams et. al., 1993).

SITE E: open Forest (OF) (19°17'S 146°22'E) on the western side of the Bluewater range. This site is a transitional zone between the dense, wet sclerophyll forest of site D and the eucalypt woodland of site B. The vegetation grades from Tall Open forest with *Eucalyptus grandis*, *Syncarpia glomulifera* and *Allocasuarina torulosa* dominants, through a mixed eucalypt open forest (*E. citriodora, E. peltata, E. shirleyi* and others) to Ironbark woodland near West Keelbottom creek. Riparian vegetation along the creek consists of patches of closed *Tristaniopsis exiliflora* gallery forest and more open *Callistemon* spp./ *Melaleuca* spp. forest. Further upstream there are several vine thickets, which were investigated. The various areas sampled at this site have been combined because of their close proximity and because the site was only sampled once.

Major terrestrial habitat types and associated samples were therefore as follows:

Open woodland: A2, A3, B1, B3

Open forest: B4, C1, C4, D4, E

Tall open forest/closed forest: D1, D2, D3

Riparian: A1, B2, C2, E

TABLE 1. Fish sampling sites and their major physical characteristics. Rocky outcrops: C3

Observations were not restricted to these sites, however, and our records are supplemented by information from extensive observations across the study area. For example, while there was only one rocky outcrop sampling site, general observations were made wherever rocky outcrops were encountered, and are incorporated in our composite species lists.

The extent of some habitat types did not warrant

the status of major sites, and were therefore only sampled opportunistically. For example, grassland had mostly been previously cleared land and was not extensive.

Streams

Because of the highly seasonal climate, the streams are seasonal, and surface flow ceases in most of them in the dry season. However, most of the streams have permanent pools. The streams range from upland, rocky, high gradient channels under complete canopy cover to the low gradient, open sandy channels on the south western plain.

Seventeen major sites were selected (Fig. 2) to represent stream and other wetland types across the study area. The grid references and major physical features of the sites are listed in Table 1. In April the streams were running well. In the second survey (September 1991) most streams had ceased to flow and remained only as pools.

The major stream sites were located, from north west to south east, on the Star River (sites 1 and 3), the Little Star River (sites 2, 4 and 10), Keelbottom Creek (sites 5, 6 and 11), Fanning River/ Stake Creek (sites 8 and 9) and Reid River (site 7).

The data in Table 1 broadly illustrate the range of sites sampled, from the low pH, low conductivity, cool rainforest streams in the north (sites 10 and 11) to the warmer, high pH, high conductivity woodland streams in the south east (sites 7, 8 and 9). Differences between the sites reflect several variables, including climate and vegetation, and geology. For example, the streams in the south east included deposits of calcium carbonate in their catchments, which leads to the alkaline water with high conductivity, while those in the rainforest were based on granitic bedrock and soils and had low levels of dissolved substances in them.

SAMPLING METHODOLOGY

Terrestrial Fauna

The sampling strategy was designed to capture or observe the highest diversity of vertebrates possible. Given the time constraints, assessments of absolute densities were given lower priority. A variety of techniques were employed, all of which proved to be useful. Sampling effort was standardised in order to render intersite data as comparable as possible. However, differences in weather, terrain and vegetation all affect the efficiency of sampling. These effects include greater difficulty of observation within dense forest, reduced visibility and/or animal activity during periods of rain or heavy mist, reduction of frog and reptile activity as the weather became cooler and drier, and inability to sample intensively in areas where vehicular access was not possible.

Two surveys were conducted: 8 April-3 May 1991 (site A-D); and 7 August-25 October 1991 (sites A-E). A total of 63 days were spent in the field (approximately 146 person days).

Literature consulted to aid identification were Strahan (1983), Cogger (1986), Hall and Richards (1979), Kitchener and Caputi (1985), Simpson and Day (1984), and Pizzey (1980).

Trapping

Three trapping techniques were utilised:

Elliot traps - 100 elliot traps (type A), divided equally between the sub-sites, were set over three or four nights at each site. Traps were set 10m apart and alternatively baited with oats and vanilla essence, or oats and peanut butter or oats/peanut butter/sardines. These traps are designed for capturing mammals up to the size of rats. Twenty 20 cage traps (bandicoot size) were set with the Elliot traps, equally divided among sub-sites and equally spaced along the trapping lines. These traps were baited with sardines, rolled oats and vanilla essence and were designed to capture medium-sized mammals, e.g. *Isoodon macrourus*. Additionally, 20 large cage traps (cat size) were used at site D in the rainforest. These traps were baited with meat, in an attempt to capture large predators, specifically quolls (*Dasyurus maculatus*), which were known from anecdotal evidence to have occurred at Paluma at least until the 1950's.

Pit traps are suitable for capturing a variety of small mammals, reptiles and amphibians and 30 (20 litre drums) were installed at sites A and B. Five drift fences 10m long and each with two pits were set up at each sub-site (i.e. 10 pits per sub-site × 3 sub-sites = 30 pits and 150m of drift fence per site) at sites A and B. Pit trapping had also been conducted previously in rainforest on Mt Halifax, just outside the study area (Williams et. al., 1993). Pit traps were not used on the other sites because it was found during the first survey of sites A and B that the results were not sufficient to justify the time spent installing them.

Spotlighting

Spotlighting was conducted every night in the field and totalled eight nights per site. Each sub-site was spotlighted at least one night per trip for approximately 1.5hr. Additionally general sur-

TABLE 2. The diversity of vertebrate fauna within the study area. Species previously recorded in the region and which possibly occur within the study area are included (sources of previous records include Lavery & Johnson 1968,1969, Blakers *et. al.* 1984, Winter 1984, Queensland Museum records, QNPWS Mt Spec species list, Garnett (pers. comm.). Sources of possible records are Strahan, 1983; Cogger, 1986; Readers Digest, 1976; Simpson and Day, 1984. Species listed as previously recorded have not necessarily been recorded within the study area, but have been recorded in the near vicinity. Only records of species which are likely to be present (on the basis of available habitat types) have been included.

veys were conducted at each site. Most of the spotlighting was conducted along tracks using a 150w handheld spotlight from a vehicle, this being the best method for arboreal mammals in the open woodland. Walking transects, using two 30w handheld spotlights and low power torches were conducted in areas inaccessible by vehicle (e.g. along the creeks) and in areas of denser vegetation.

Mist-Netting

Mist netting was undertaken every night in the field to capture bats, but was limited by time and the availability of suitable sites, namely potential flight corridors and water bodies. Netting was conducted for about 2hr commencing at dusk. The nets were usually set above a suitable creek or dam, or across a road (in rainforest at Bluewater). Sites netted were: Keelbottom creek (site A, 19°37'S, 146°17'E; grid ref. DU 247293); Cockatoo dam (site A, 19°34'S, 146°15'E; grid ref. DU 206359); Sandy creek (site A, 19°30'S, 146°15'E; grid ref.DU 215339); Little Star river (site B, 19°18'S, 146°12'E; grid ref. DU 151635); Dinner Creek (site B, 19°23'S, 146°11'E; grid ref. DU 154566); Star River (site B, 19°17'S, 146°07'E; grid ref. DU 081670); Stake Creek (site C, 19°27'S, 146°30'E; grid ref DU 479481); Dip Creek (site C, 19°26'S, 146°32'E; grid ref. DU 509511); Keelbottom creek - Bluewater (site D, 19°14'S, 146°23'E; grid ref. DU 365731); Bluewater forestry road (site D, 19°14'S, 146°24'E; grid ref. DU 375732); unnamed creek (Star 8159-3, 19°30'S, 146°15'E; grid ref. DU 206443).

Birds

Bird species were recorded on a daily basis using several methods. Early morning (dawn) observations were made at each site using both calls and direct observation. Observations were also made while clearing the trapping lines each morning. Each sub-site was also sampled by at least one complete afternoon of bird censusing. Nocturnal birds were recorded using calls and during spotlighting transects. All incidental bird observations were also recorded. Any accessible dams or swamps were visited to record water birds.

Active Searching

Active searching is simply a collective term for a number of activities aimed at finding and capturing cryptic fauna. This includes miscellaneous observations from vehicles or on foot, as well as rolling logs and rocks, searching under bark and inside hollow limbs of dead trees, capturing by hand any lizards or snakes seen, searching hollow trees and under bridges for bats, and searching any piles of tin or timber. These activities are difficult to standardise, but nevertheless are very useful in supplementing species records (especially reptiles).

While every effort was made to standardise sampling within and between sites, it should be noted that spatial and temporal variation in climate, geography and vegetation affected the visibility and/or catchability of different species as well as imposing differing logistic constraints on our sampling routine. For example, at site E, vehicle access was extremely limited and so subsites were much closer together than at other sites.

Fish sampling was done at 11 stream sites and during both surveys, in April and September. Four sampling methods were used:

Seine netting: pools were swept 2-5 times using an 8.0m seine of 10mm mesh. The success of the seine netting was variable, depending on the physical characteristics of the individual pools.

TABLE 3. Number of species of terrestrial vertebrates (excluding feral species) observed during field surveys of the study area by site (habitat).

	SITE A	SITE B	SITE C	SITE D	SITE E
	Ironbark Woodland	Mixed Eucalypt Forest	Wet Sclerophyll Forest	Mixed OF/W	
MAMMALS	27	15	22	16	10
Ex bats	14	11	15	10	8
BIRDS	79	84	82	92	52
Ex open water	79	64	70	90	49
REPTILES	13	8	13	15	8
AMPHIBIANS	9	8	8	4	5
TOTAL	128	115	125	127	75

However, most of the small active fish were recorded using the seine nets.

Fixed net: a 50m fixed net (50mm mesh) was employed at any site which had a large enough pool. The fixed net was useful in catching some of the larger fish and turtles.

Baited lines: baited lines were used in larger pools and were also useful in catching some of the larger species of fish, turtles and eels.

Dip net: weed beds and snags were swept with a hand held dip net to catch small fish such as gudgeons, ambassids, hardyheads and catfish.

Following identification, fish were returned to the water.

In general no voucher specimens were taken. However, specimens of difficult to identify species were taken and checked by dissection (small mammals and fish). The small mammals (*Rattus fuscipes*, *Melomys cervinipes*,and *M. burtoni*) were sent to the Queensland Museum.

RESULTS AND DISCUSSION

A total of 297 species of vertebrates from 91 families were recorded during the fauna surveys. This diversity is not surprising considering the large area and the diversity of habitats included in the area. High diversities of mammals (50 species) and birds (180 species) were recorded, but the diversities of reptiles and amphibians were certainly underestimated because the surveys were conducted outside the wet season. Table 2 summarises the diversity of vertebrate fauna by major taxonomic groups including those species previously recorded in the region and which are likely to occur within the study area.

Table 3 summarises the diversity of terrestrial vertebrates observed by site. In effect, this partly summarises diversity by habitat type, as sites A and B represent Ironbark woodland, site C represents the mixed eucalypt open forest, and sites D and E are a mixture of closed forest and tall open forest (i.e. the transitional zone between rainforest and open forest).

Total numbers of terrestrial vertebrates was surprisingly similar for sites A, B, C and D. The diversity was lowest at site E, but this was primarily due to a lower sampling intensity.

MAMMALS

The 50 species recorded during the surveys (Appendix 1), plus the 11 extra species from other records represent a large proportion (80%) of approximately 76 species that might possibly occur in the area. Mammal diversity was highest in the more open woodland and eucalypt forests of sites A, B and C. This was due to higher observed diversities of bats, arboreal marsupials and macropods in the open forest/woodland sites.

BIRDS

Bird diversity was highest in the wet sclerophyll forest of site D. The higher bird diversity of this forest is especially noticeable if waterbirds are removed from consideration. The number of species recorded during this study (180) (Appendix 1) represents 64% of the 282 species known from all sources to occur in, or in similar habitats close to, the study area. Given (i) the extent and duration of the survey, (ii) the high mobility of birds (which usually leads to a large number of vagrants being recorded in geographical species lists) and (iii) the absence of a number of summer species during the period of field work, this species count is high.

A sighting of a Grey Falcon in open forest at site E was the only observation of a bird listed as rare. Two other rare species previously recorded in the vicinity are the Red Goshawk and Square-tailed Kite. Southern Cassowaries are presently listed as vulnerable.

There are 13 species of bird which are endemic to the north Queensland tropical rainforest (Crome & Nix 1991), and 11 of these were observed during the survey: Mountain Thornbill,

Bridled Honeyeater, Macleay's Honeyeater, Pied Monarch, Bowers Shrike-thrush, Grey-headed Robin, Northern Logrunner, Victoria's Riflebird, Fernwren, Tooth-billed Bowerbird and the Lesser Sooty Owl. An additional species, the Golden Bowerbird, has been previously recorded in the vicinity. Of the 13 species of rainforest endemics, only the Atherton Scrubwren is not likely to be present.

Of ten subspecies endemic to north Queensland (Crome & Nix, 1991) nine were observed within the study area during this study. These were the northern subspecies of King parrot, Pale-yellow Robin, Yellow-breasted Boatbill, Grey Fantail, Eastern Whipbird, Brown Warbler, Northern Catbird, Satin Bowerbird and Boobook Owl (Crome & Nix, 1991).

Reptiles

Reptiles recorded during the study area surveys are listed in Appendix 1. The 38 species observed represent 59% of the 64 species recorded from the study area and its immediate environs. It is likely that a large number of reptile species present in the study area were not recorded because of their cryptic behaviour and lower activity levels in the dry season. Nevertheless, the species list in Tables 6 represent a substantial diversity of reptiles, distributed fairly evenly among wooded habitats.

Amphibians

Amphibian diversity appears to be highest in the open forest/woodland sites, primarily the riparian sub-sites, but this result could change considerably if a wet season amphibian survey was undertaken. Despite the rather poor conditions for observing amphibians, 16 species were recorded for the study area (Appendix 1) with Queensland Museum records increasing the total to 22 species. Most species were recorded in the riparian zones and at dams. However, it is likely that in the early wet season greater numbers of frogs would be observed in the areas away from permanent creeks.

No rare or uncommon species of amphibians were recorded. However, two species of rainforest endemic frogs were recorded (*Cophixalus ornatus* and *Sphenophryne robusta*), and two other species have been recorded previously and are likely to be present (*Nyctimistes dayi* and *Mixophyes schevilli*).

Fish

Fish species recorded in the two surveys are shown in Appendix 1. All, apart from the Eel, are regarded as principal freshwater species, meaning that they undergo their whole life cycle in fresh water. The eel is diadromous, i.e. it has to migrate to the sea to breed.

Diversity at each site varied according to the size of the stream. In the small rainforest streams either no fish were found (site 11) or only the Purple-spotted Gudgeon occurred (site 10). This is similar to the pattern in other rainforest streams: for example, other than the eel, there are no fish in Birthday Creek (R.G. Pearson, unpubl. data) and only the gudgeon in Yuccabine Creek (Pearson et. al., 1986). Further downstream, the sites had a larger complement of fish species with the addition rather than replacement of species - as is the case elsewhere, eg. the Annan River, near Cooktown (Hortle & Pearson, 1990).

It is of interest to compare the diversity of fishes between systems. This is best done using principal freshwater species, and by referencing the sizes of catchment areas, because larger catchments tend to accommodate more species (Welcomme, 1979). The area of the Star catchment sampled was about 1100km^2, that of Keelbottom Creek also about 1100km^2, and that of the upper Fanning River about 200km^2 (Qld Water Res. Comm. data). The fish survey recorded, respectively, 10, 8 and 8 principal freshwater species from these systems, and a total of 11 species. This compares with 12 species in the Black and Alice Rivers (about 300km^2) near Townsville (Beumer, 1980) and 15 species in the Annan River (about 1000km^2) (Hortle & Pearson, 1990). These figures are based on two years' monthly sampling of five sites in the Black/Alice and two sets of samples from 17 sites in the Annan. Comparison with middle Burdekin River samples (Pearson, 1991a) shows that there are only a few extra species recorded or missing from the river.

Given the different sampling intensities and catchment areas of the different systems, it appears that diversity of the fish fauna in the study area compares favourably with other stream systems in northern Queensland. Most of the species recorded have a broad distribution in eastern or northern Australia. Allen (1989) lists species within different status categories (endangered, vulnerable, potentially threatened, indeterminate, restricted and uncertain). The only species to appear on any of these lists and in the records from the study area streams is the Small-headed Grunter, which is listed as restricted. This species is only known from the Burdekin River system. It was not collected during the present survey, but Pusey (pers. comm.) has collected it from Run-

ning River, near the study area, and Pearson (1991b) recorded it from the middle Burdekin River. Otherwise there is no indication of any species of threatened status in the study area. However, samples of gudgeons, provisionally ascribed to *Hypseleotris compressa*, are currently under review.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the assistance and support of their field and laboratory assistants and of staff of the ACTFR, the Department of Botany and the Department of Zoology at James Cook University, especially Steve Comport, Jacqui Coughlan, Kylie Freebody, Martin Cohen and Steve Richards.

APPENDIX 1

Part 1. Mammal species of the study area. The table lists numbers observed during the April/May field trips (nos. before the "/") and the August/September field trips (nos. after the "/"). A - Open woodland (Ironbark) in the southern study area, B - Open woodland (Ironbark) northern study area, C - Open Eucalypt forest (High Range training area), D - Wet sclerophyll/mixed open forest at the R.A.A.F. training area at Bluewater State forest, E - Transitional area between the Wet sclerophyll forest of site D and the open woodland of site B. Observational techniques include E - Elliot traps, C - Cage traps, P - Pits traps, H - by hand, S - spotlighting/miscellaneous observation, F - faecal pellets, M - mist netting, * - presence recorded, but not counted. Species names follow Ingram & Raven (1991).

SPECIES	COMMON NAME		A	B	C	D	E
Tachyglossidae							
Tachyglossus aculeatus	Short-beaked Echidna	S	-/1	-/-	-/-	-/-	-
Dasyuridae							
Antechinus flavipes	Yellow-footed Antechinus	EPHS	-/-	-/-	-/-	2/1	1
Peramelidae							
Isoodon macrourus	Northern Brown Bandicoot	CES	-/-	2/2	1/5	-/3	-
Perameles nasuta	Long-nosed Bandicoot	CS	-/-	-/-	-/-	3/2	2
Phascolarctidae							
Phascolarctus cinereus	Koala	S	-/-	3/-	-/-	-/-	-
Petauridae							
Petaurus breviceps	Sugar Glider	S	1/2	-/1	1/1	-/1	1
Petaurus norfolcensis	Squirrel Glider	S	-/-	-/-	7/2	-/-	-
Pseudocheiridae							
Petauroides volans	Greater Glider	S	3/4	5/10	15/12	-/-	5
Pseudocheirus peregrinus	Common Ringtail Possum	S	-/-	-/-	19/15	-/-	1
Phalangeridae							
Trichosurus vulpecula	Common Brushtail Possum	SC	1/1	1/-	19/17	-/-	3
Potoroidae							
Aepyprymnus rufescens	Rufous Bettong	CS	1/6	3/7	-/-	-/-	1
Macropodidae							
Macropus agilis	Agile Wallaby	S	5/1	-/-	-/-	-/-	-
Macropus giganteus	Eastern Grey Kangaroo	S	6/5+	-/20	2/*	-/-	-
Macropus parryi	Whiptail Wallaby	S	-/2	-/3	-/-	-/-	-
Macropus robustus	Wallaroo	S	-/2	1/-	2/*	-/-	-
Petrogale assimilis	Allied Rock Wallaby	CSF	-/3	-/-	1/5	-/-	-
Wallabia bicolor	Swamp Wallaby	S	-/1	-/-	-/-	-/-	-
Pteropidae							
Nyctimene robinsoni	Queensland Tube-nosed Bat	M	1/-	-/-	-/-	-/-	-
Pteropus alecto	Black Flying-fox	S	1/-	-/*	-/-	-/-	-
Pteropus scapulatus	Little Red Flying-fox	S	-/1	-/*	-/6	-/3	-
Syconycterus australis	Queensland Blossom-bat	M	-/-	-/-	-/-	-/1	-
Mollossidae							
Mormopterus loriae	Little Northern Mastiff-bat	M	3/-	-/-	-/-	-/-	-
Rhinolophidae							
Rhinolophus megaphyllus	Eastern Horseshoe-bat	H	-/-	-/-	-/1	-/-	-
Rhinolophus philipinensis	Large-eared Horseshoe-bat	M	-/-	-/-	-/1	-/-	-
Vespertilionidae							
Chalinolobus gouldii	Gould's Wattled Bat	M	4/4	-/-	-/3	-/-	-
Chalinolobus morio	Chocolate Wattled Bat	M	-/1	-/-	-/-	-/-	-
Chalinolobus nigrogriseus	Hoary Bat	M	3/2	-/-	-/-	-/-	-
Miniopterus australis	Little Bent-wing Bat	M	-/-	-/-	-/1	1/1	-
Miniopterus schreibersii	Common Bent-wing Bat	HM	1/1	-/-	-/2	-/3	-
Myotis adversus	Pond Bat	M	6/-	-/-	-/-	-/2	2
Nyctophilus bifax	North-Queensland Long-eared Bat	M	1/-	-/-	-/1	-/1	2
Nyctophilus geoffroyii	Lesser Long-eared Bat	M	-/-	-/3	-/-	-/-	-
Scoteanax rueppellii	Greater Broad-nosed bat	M	8/-	-/-	-/-	-/-	-
Scotorepens balstoni	Western Broad-nosed bat	M	-/1	-/1	-/-	-/-	-
Scotorepens sanborni	Little Northern Broad-nosed bat	M	-/1	-/1	-/-	-/-	-
Leporidae							
Oryctolagus cuniculus	Rabbit	S	5/2	-/2+	1+/*	-/-	-
Muridae							
Hydromys chrysogaster	Water Rat	CS	3/*	4+/*	2/2	-/1	-
Melomys burtoni	Grassland Melomys	E	-/-	-/-	4/2	3/2	-
Melomys cervinipes	Fawn-footed Melomys	CE	-/-	-/-	9/6	16/12	-
Pseudomys gracilicaudatus	Eastern Chestnut Mouse	E	2/2	1/1	3/2	-/-	-/3
Rattus fuscipes	Bush Rat	EC	-/-	-/-	-/-	28/9	-
Rattus lutreolus	Swamp Rat	E	-/-	-/-	-/-	3/2	-
Rattus rattus	Black Rat	ECS	4/-	-/-	1/1	-/-	-
Uromys caudimaculatus	White-tailed Rat	CSE	-/-	-/-	-/-	5+/-	-
Zyzomys argurus	Common Rock-rat	E	-/-	-/-	4/5	-/-	-
Canidae							
Canis familiaris dingo	Dingo	S	*/*	1/*	1/-	-/-	-
Felidae							

APPENDIX 1 cont.

SPECIES	COMMON NAME		A	B	C	D	E
Felis catus	Feral Cat	S	-/1	-/*	-/-	-/-	-
Equidae							
Equus caballus	Feral Horse	S	-/-	-/-	-/*	-/-	-
Suidae							
Sus scrofa	Feral Pig	SF	*/*	*/*	*/*	*/*	*

Part 2. Bird species of the study area. The index of abundance is based on the following criteria: (-) not observed at this site; 1 - observed on one occasion during the field trip; 2 - observed several times; 3 - common, observed most days; 4 - abundant, observed a number of times every day, usually at several different places. Names follow Ingram & Raven (1991). For further explanation see Part 1.

SPECIES	COMMON NAME		A	B	C	D
Casuariidae						
Casuarius casuarius	Southern Cassowary		-/-	-/-	-/-	-/1
Dromaius novaehollandiae	Emu		-/2	1/2	-/-	-/-
Podicipedidae						
Podiceps cristatus	Crested Grebe					
Poliocephalus poliocephalus	Hoary-headed Grebe		1/-	1/1	-/-	-/-
Tachybaptus novaehollandiae	Australasian Grebe		2/1	1/1	-/1	-/-
Phalacrocoracidae						
Phalacrocorax carbo	Great Cormorant					
Microcarbo melanoleucos	Little Pied Cormorant		-/-	3/1	-/2	-/-
Hypoleucos sulcirostris	Little Black Cormorant		-/-	1/1	-/-	-/-
Anhingidae						
Anhinga novaehollandiae	Australian Darter		-/1	1/1	-/2	-/-
Ardeidae						
Casmerodius alba	White Egret		1/1	1/1	-/-	-/-
Egretta intermedia	Plumed Egret		3/1	2/1	-/-	-/-
Ardea novaehollandiae	White-faced Heron		-/-	-/-	-/3	-/-
Ardea pacifica	White-necked Heron		1/1	1/1	1/-	-/1
Dupetor flavicollis	Black Bittern		1/-	-/-	-/-	-/-
Nycticorax caledonicus	Nankeen Night Heron		-/-	-/1	-/-	-/-2
Theskiornithidae						
Platalea flavipes	Yellow-billed Spoonbill		-/1	-/-	-/-	-/-
Platalea regia	Royal Spoonbill		-/-	-/-	-/1	-/-
Threskiornis spinicollis	Straw-necked Ibis		-/1	2/3	-/1	-/-
Anatidae						
Anas gracilis	Grey Teal		1/-	1/1	-/-	-/-
Anas superciliosa	Black Duck		1/-	3/1	2/2	-/-
Aythya australis	White-eyed Duck		-/1	-/1	-/-	-/-
Chenonetta jubata	Wood Duck		2/-	1/1	1/1	-/-
Dendrocygna arcuata	Wandering Whistling-Duck		2/-	2/1	2/-	-/-
Nettapus coromandelianus	White Pygmy-Goose		1/-	-/1	-/-	-/-
Accipitridae						
Accipiter cirrhocephalus	Collared Sparrowhawk		-/-	-/-	-/-	1/-
Accipiter fasciatus	Brown Goshawk		-/-	-/-	1/1	1/-
Accipiter novaehollandiae	Grey Goshawk		-/-	-/-	-/-	1/1
Aquila audax	Wedge-tailed Eagle		2/2	-/-	2/2	-/-
Aviceda subcristata	Crested Hawk		1/-	3/1	-/-	1/-
Circus assimilis	Spotted Harrier					
Elanus notatus	Black-shouldered Kite		-/1	-/-	1/-	-/-
Haliaeetus leucogaster	White-bellied Sea-Eagle		-/-	1/1	-/-	-/-
Hieraaetus morphnoides	Little Eagle		-/1	-/-	1/-	-/-
Milvus migrans	Fork-tailed Kite		-/-	-/1	1/1	-/-
Haliastur sphenurus	Whistling Kite		1/2	3/3	1/1	-/-
Falconidae						
Falco berigora	Brown Falcon		1/-	1/1	1/1	-/-
Falco cenchroides	Nankeen Kestrel		1/1	1/2	1/2	-/-
Falco hypoleucos	Grey Falcon		-/-	-/-	-/-	-/-
Falco longipennis	Little Falcon		-/-	1/-	-/-	-/-
Megapodiidae						
Alecturi lathami	Brush Turkey		-/-	-/-	-/1	2/1
Phasianidae						
Synoicus australis	Brown Quail		-/-	1/2	1/1	-/1
Gruidae						
Grus rubicundus	Brolga		-/-	1/-	-/-	-/-
Rallidae						
Fulica atra	Eurasian Coot		1/1	-/1	-/-	-/-
Gallinula tenebrosa	Dusky Moorhen		1/1	1/1	-/1	-/-
Rallina tricolor	Red-necked Crake		-/-	-/-	-/-	-/1
Otididae						
Ardeotis australis	Australian Bustard		-/-	-/-	1/1	-/-
Jacanidae						
Irediparra gallinacea	Comb-crested Jacana		1/-	1/1	-/-	-/-
Burhinidae						
Burhinus grallarius	Bush Thick-knee		2/-	-/1	1/2	-/2
Charadriidae						
Elseornis melanops	Black-fronted Plover		1/-	-/-	-/-	-/-
Vanellus miles	Masked Lapwing (Plover)		1/-	-/3	1/-	-/-
Columbidae						
Chalcophaps indica	Green-winged Pigeon		-/-	-/-	-/-	-/2
Columba leucomela	White-headed Pigeon		-/-	-/-	-/-	1/-
Geopelia placida	Peaceful Dove		-/-	2/3	3/3	-/-
Ocyphaps lophotes	Crested Pigeon		4/-	4/4	1/1	-/-
Petrophassa scripta	Squatter Pigeon		-/-	2/3	1/1	-/-

APPENDIX 1 cont.

SPECIES	COMMON NAME		A	B	C	D
Todirhamphus macleayii	Forest Kingfisher		-/-	-/-	2/2	-/2
Todirhamphus pyrrhopygius	Red-backed Kingfisher		-/-	1/-	-/-	-/-
Todirhamphus sanctus	Sacred Kingfisher		1/-	1/-	-/1	-/-
Meropidae						
Merops ornatus	Rainbow Bee-eater		2/-	-/-	3/-	1/3
Pittidae						
Pitta versicolor	Noisy Pitta		-/-	-/-	-/-	1/2
Campephagidae						
Coracina novaehollandiae	Black-faced Cuckoo-Shrike		2/2	3/1	3/2	-/1
Coracina papuensis	Little Cuckoo-Shrike		2/3	1/-	-/1	1/2
Lalage leucomela	Varied Triller		-/-	-/-	-/-	1/1
Orthonychidae						
Orthonyx spaldingii	Northern Logrunner		-/-	-/-	-/-	3/2
Psophodes olivaceus	Eastern Whipbird		-/-	-/-	-/-	4/2
Pomatostomidae						
Pomatostomus temporalis	Grey-crowned Babbler		1/3	1/2	-/-	-/-
Sylviidae						
Cinclorhamphus mathewsi	Rufous Songlark		2/1	1/-	-/-	-/-
Megalurus timoriensis	Tawny Grassbird		-/-	-/-	-/-	-/-
Maluridae						
Malurus melanocephalus	Red-backed Wren		1/-	-/-	3/3	-/2
Acanthizidae						
Acanthiza katherina	Mountain Thornbill		-/-	-/-	-/-	1/-
Acanthiza nana	Little Thornbill		1/3	1/2	-/-	-/-
Oreoscopus gutturalis	Fernwren		-/-	-/-	-/1	-/-
Gerygone fusca	Western Warbler		1/-	-/-	-/-	-/-
Gerygone mouki	Brown Warbler		-/-	-/-	-/-	3/-
Gerygone olivacea	White-throated Warbler		-/-	-/1	-/1	-/-
Gerygone palpebrosa	Fairy Warbler		-/-	-/-	-/1	1/1
Sericornis citreogularis	Yellow-throated Scrubwren		-/-	-/-	-/-	-/1
Sericornis frontalis	White-browed Scrubwren		-/-	-/-	-/-	1/1
Sericornis magnirostris	Large-billed Scrubwren		-/-	-/-	-/-	1/1
Monarchidae						
Arses kaupi	Pied Monarch		-/-	-/-	-/-	4/1
Machaerirhynchus flaviventer	Yellow-breasted Boatbill		-/-	-/-	-/-	1/1
Monarcha trivirgatus	Spectacled Monarch		-/-	-/-	-/1	4/3
Myiagra cyanoleuca	Satin Flycatcher		-/-	-/-	1/1	1/-
Myiagra rubecula	Leaden Flycatcher		-/-	1/-	1/4	-/2
Rhipidura fuliginosa	Grey Fantail		4/4	4/3	4/4	4/2
Rhipidura leucophrys	Willie Wagtail		3/3	4/3	2/-	-/-

SPECIES	COMMON NAME		A	B	C	D
Macropygia phasianella	Brown Pigeon		-/-	-/-	-/-	1/-
Phaps chaloptera	Common Bronzewing		-/2	1/-	-/-	-/-
Ptilinopus magnificus	Wompoo Pigeon		-/-	-/-	-/-	-/2
Ptilinopus superbus	Purple-crowned Pigeon		-/-	-/-	-/-	-/2
Loriidae						
Trichoglossus chlorolepidotus	Scaly-breasted Lorikeet		-/-	-/-	1/2	-/2
Trichoglossus haematodus	Rainbow Lorikeet		3/4	1/3	3/3	1/3
Cacatuidae						
Cacatua galerita	Sulphur-crested Cockatoo		3/3	4/3	-/1	1/3
Calyptorynchus magnificus	Red-tailed Black Cockatoo		1/1	-/-	1/-	2/1
Psittacidae						
Alisteris scapularis	King Parrot		-/-	-/-	-/-	-/1
Aprosmictus erythropterus	Red-winged Parrot		1/2	1/1	-/1	-/-
Platycerus adscitus	Pale-headed Rosella		3/2	4/3	3/2	-/-
Platycerus elegans	Crimson Rosella		-/-	-/-	-/-	1/-
Cuculidae						
Centropus phasianinus	Pheasant Coucal		2/1	3/3	2/1	-/1
Chrysococcyx basalis	Horsfield's Bronze-Cuckoo		-/-	-/-	-/1	1/-
Chrysococcyx russatus	Rufous-breasted Bronze-Cuckoo		-/-	-/-	-/-	1/-
Chyrsococcyx lucidus	Shining Bronze-Cuckoo		-/-	-/-	-/-	1/-
Cacomantis flabelliformis	Fantail Cuckoo		-/-	1/1	1/-	4/2
Tytonidae						
Tyto alba	Barn Owl		-/1	-/-	-/-	-/1
Tyto multipunctata	Lesser Sooty Owl		-/-	-/-	-/-	1/2
Strigidae						
Ninox connivens	Barking Owl		-/-	-/1	-/-	-/1
Ninox boobook	Boobook		2/2	-/1	-/-	-/1
Podargidae						
Podargus papuensis	Papuan Frogmouth		-/-	-/-	-/-	1/-
Podargus strigoides	Tawny Frogmouth		-/1	1/1	-/1	-/-
Aegothelidae						
Aegotheles cristatus	Australian Owlet Nightjar		2/-	3/1	-/-	-/-
Caprimulgidae						
Caprimulgus macrurus	Large-tailed Nightjar		-/-	-/-	-/-	-/2
Eurospododus mystacalis	White-throated Nightjar		-/-	-/-	-/-	-/2
Eurostopodus argus	Spotted Nightjar		-/1	-/-	1/-	-/-
Alcedinidae						
Ceyx azureus	Azure Kingfisher		2/-	3/1	1/3	1/1
Ceyx pusillus	Little Kingfisher		-/-	1/1	-/-	-/1
Dacelo leachii	Blue-winged Kookaburra		1/-	-/3	1/3	-/-
Dacelo novaeguineae	Laughing Kookaburra		3/2	3/3	2/3	-/2

APPENDIX 1 cont.

SPECIES	COMMON NAME		A	B	C	D
Melaphaga notata	Yellow-spotted Honeyeater		-/-	-/-	-/1	1/1
Melaphaga lewinii	Lewins Honeyeater		-/-	-/-	-/-	4/3
Melithreptus albogularisi	White-throated Honeyeater		2/4	4/2	4/4	-/-
Melithreptus lunatus	White-naped Honeyeater		-/-	-/-	-/-	-/1
Myzomela obscura	Dusky Honeyeater		-/-	-/1	-/1	-/3
Myzomela sanguinolenta	Scarlet Honeyeater		-/1	-/1	1/1	-/3
Philemon argenticeps	Silver-crowned Friarbird		1/-	-/-	-/-	-/-
Philemon citreogularis	Little Friarbird		-/4	-/3	-/-	-/-
Philemon corniculatus	Noisy Friarbird		-/4	-/3	-/3	-/-
Ramsayornis modestus	Brown-backed Honeyeater		-/-	-/-	-/2	-/-
Xanthotis macleayana	Macleay's Honeyeater		-/-	-/-	-/-	2/2
Estrildidae						
Lonchura punctulata	Spice Finch		-/-	1/-	-/-	-/-
Neochmia temporalis	Red-browed Finch		-/-	-/-	3/3	1/-
Taeniopygia bichenovii	Double-barred Finch		1/-	-/-	-/-	-/-
Oriolidae						
Oriolus sagittatus	Olive-backed Oriole		-/1	1/-	-/-	3/1
Dicruridae						
Dicrurus bracteatus	Spangled Drongo		-/-	-/1	1/-	-/1
Grallinidae						
Grallina cyanoleuca	Peewee		3/4	4/3	2/3	-/-
Corcoracidae						
Corcorax melanorhamphos	White-winged Chough		-/-	2/1	1/2	-/-
Struthidea cinerea	Apostlebird		4/2	2/2	-/1	-/-
Artamidae						
Artamus leucorhynchus	White-breasted Woodswallow		-/-	-/1	-/-	1/1
Cracticidae						
Cracticus nigrogularis	Pied Butcherbird		2/3	4/4	1/2	-/-
Cracticus torquatus	Grey Butcherbird		3/3	3/3	1/2	-/-
Gymnorhina tibicen	Australian Magpie		4/4	4/4	3/4	-/-
Strepera graculina	Pied Currawong		1/1	1/1	3/3	2/2
Ptilonorhychidae						
Ailuroedus melanotis	Spotted Catbird		-/-	-/-	-/-	1/-
Chlamydera nuchalis	Great Bowerbird		3/1	1/-	-/1	-/-
Ptilonorhynchus violaceus	Satin Bowerbird		-/-	-/-	-/-	1/-
Paradisaeidae						
Ptiloris victoriae	Victoria's Riflebird		-/-	-/-	-/-	3/3
Corvidae						

SPECIES	COMMON NAME		A	B	C	D
Rhipidura rufifrons	Rufous Fantail		-/-	-/-	-/-	1/3
Eopsaltridae						
Eopsaltria australis	Eastern Yellow Robin		-/-	-/-	-/1	4/3
Heteromyias cinereifrons	Grey-headed Robin		-/-	-/-	-/-	1/1
Microeca flavigaster	Lemon-breasted flycatcher		-/-	-/-	-/3	-/-
Microeca leucophaea	Jacky Winter		2/-	-/-	-/-	-/-
Tregellasia capito	Pale-yellow Robin		-/-	-/-	-/-	2/3
Pachycephalidae						
Colluricincla boweri	Bowers Shrike-Thrush		-/-	-/-	-/-	1/-
Colluricincla harmonica	Grey Shrike-Thrush		-/-	-/-	-/-	2/1
Colluricincla megarhyncha	Rufous Shrike-Thrush		-/-	-/-	-/-	4/4
Pachycephala pectoralis	Golden Whistler		-/-	-/-	-/-	4/3
Pachycephala rufiventris	Rufous Whistler		2/4	1/2	4/4	1/1
Neosittidae						
Daphoenositta chrysoptera	Sittella		-/-	-/-	-/-	1/-
Climacteridae						
Climacteris picumnus	Brown Treecreeper		-/-	1/-	-/-	-/-
Cormobates leucophaea	White-throated Treecreeper		-/-	-/-	-/-	4/3
Dicaeidae						
Dicaeum hirundinaceum	Mistletoebird		-/1	-/-	-/-	3/1
Pardalotidae						
Pardalotus punctatus	Spotted Pardalote		-/-	-/-	-/-	2/1
Pardalotus striatus	Striated Pardalote		4/4	4/4	4/3	2/-
Zosteropidae						
Zosterops lateralis	Silvereye		-/-	-/-	-/-	3/3
Meliphagidae						
Acanthorhynchus tenuirostris	Eastern Spinebill		-/-	-/-	-/-	-/1
Cissomela pectoralis	Banded Honeyeater		-/-	-/-	-/2	-/-
Entomyzon cyanotis	Blue-faced Honeyeater		4/4	3/3	2/2	-/-
Meliphaga chrysops	Yellow-faced Honeyeater		-/-	-/-	-/-	1/3
Meliphaga flavescens	Yellow-tinted honeyeater		-/-	-/-	-/-	-/-
Meliphaga flava	Yellow Honeyeater		-/-	-/-	1/-	-/-
Meliphaga frenata	Bridled Honeyeater		-/-	-/-	-/-	-/1
Meliphaga fusca	Fuscous honeyeater		-/-	-/-	-/-	-/-
Lichmera indistincta	Brown Honeyeater		-/-	-/1	1/3	1/2
Manorina flavigula	White-rumped Miner		2/4	4/3	-/-	-/-
Manorina melanocephala	Noisy Miner		2/3	2/4	-/3	-/-

APPENDIX 1 cont.

SPECIES	COMMON NAME		A	B	C	D
Corvus coronoides	Australian Raven		-/3	-/-	-/-	-/-
Corvus orru	Australian Crow		4/3	4/3	3/3	-/2

Part 3. Reptiles of the study area. The index of abundance is based on the following criteria : (-) not recorded at this site; 1 - observed once during the field trip; 2 - observed several times; 3 - common, observed most days; 4 - abundant, observed a number of times every day, usually at several locations. For further explanation see Part 1. Species names follow Ingram & Raven (1991).

SPECIES	COMMON NAME		A	B	C	D	E
Gekkonidae							
Diplodactylus steindachneri		HP	1/1	-/-	-/-	-/-	HP
Gehyra dubia		H	-/1	2/1	1/1	-/-	-
Heteronotia binoei	Bynoe's Gecko	H	3/3	-/2	2/2	-/-	-
Oedura castlenaui	Northern Velvet Gecko	H	-/-	2/2	-/-	-/-	-
Scincidae							
Carlia rostralis		H	-/-	-/-	-/-	-/-	1
Carlia jarnoldae		H	-/-	-/-	-/1	-/1	1
Carlia munda	HP	1/1	-/-	2/2	-/-	-	
Carlia mundivensis		H	-/1	-/-	2/2	-/-	-
Carlia rubigularis		H	-/-	-/-	-/-	3/3	-
Cryptoblepharus virgatus		H	3/-	2/2	2/2	-/-	2
Ctenotus spaldingi		H	-/-	-/-	-/-	-/1	-
Egernia striolata	Tree Skink	H	-/-	1/-	-/-	-/-	-
Sphenomorphus quoyii	Water Skink	SH	-/-	-/-	-/-	1/2	-
Lampropholis basiliscus		H	-/-	-/-	-/-	1/1	-
Lygisaurus foliorum		H	-/-	-/-	-/-	-/1	-
Menetia greyii		HP	1/1	-/-	-/-	-/-	-
Morethia taeniopleura	Fire-tailed Skink	HP	3/1	-/-	3/2	-/-	-
Agamidae							
Pogona barbata	Bearded Dragon	HS	-/-	1/1	-/-	-/-	-
Diporiphora australis	Two-line Dragon	HS	-/-	-/-	1/1	-/-	-
Physignathus lesueurii	Water Dragon	HS	-/-	-/-	-/-	2/1	1
Varanidae							
Varanus scalaris	Spotted Tree-monitor	H	1/-	-/-	-/-	-/2	-
Varanus varius	Lace Monitor	H	-/-	-/-	-/1	-/1	1
Boidae							
Aspidites melanocephalus	Black-headed Python	H	1/-	-/-	-/-	-/—	
Morelia amethistina	Amethystine Python	H	-/-	-/-	-/-	1/-	-

VERTEBRATE FAUNA OF THREE MOUNTAIN TOPS IN THE TOWNSVILLE REGION, NORTH QUEENSLAND: MOUNT CLEVELAND, MOUNT ELLIOT AND MOUNT HALIFAX

STEVE WILLIAMS, RICHARD PEARSON AND SCOTT BURNETT

Williams, S., Pearson, R. & Burnett, S. 1993 06 30: Vertebrate fauna of three mountain tops in the Townsville region, north Queensland: Mount Cleveland, Mount Elliot and Mount Halifax. *Memoirs of the Queensland Museum* **33**(1): 379-387. Brisbane. ISSN 0079-8835.

Vertebrate fauna surveys were carried out on the summits of Mount Cleveland, Mount Elliot and Mount Halifax in north Queensland. The main focus was on mammals and birds, but observations on all vertebrate groups are included. Habitats included rainforest and open eucalypt/casuarina forest. The surveys recorded a total of 136 species of vertebrates including 17 mammal, 77 bird, 32 reptile and 10 frog species. Habitat descriptions and measures of relative abundance for mammals and birds are included. □ *Survey, vertebrate, mountain, north, Queensland, Australia.*

Steve Williams, Richard Pearson & Scott Burnett, Australian Centre for Tropical Freshwater Research, James Cook University of North Queensland, Queensland 4811, Australia; 15 November, 1992.

This paper reports the findings of vertebrate fauna surveys conducted on three mountain tops in the Townsville region of north Queensland. Most of the effort of the survey was directed at mammal and bird communities. However, all vertebrates were recorded and the data are included here. Reptiles, amphibians and invertebrates are dealt with in detail by Graham (1991). The fauna surveys were part of multidisciplinary fieldwork examining the suitability of Mount Elliot, Mount Cleveland and Mount Halifax for the placement of a radar tower by the Civil Aviation Authority.

Mountain top habitats are usually restricted and isolated from other patches of similar habitat. As well, there are usually endemic species associated with these restricted areas of habitat and, because endemic species were of special concern, fieldwork was mostly concentrated on the summit and the high ridges and saddles of the mountains.

The primary aim of the surveys was to provide a baseline description of the fauna of these mountain tops. Therefore, sampling was designed to record the presence of as many species as possible. This was achieved by using a variety of techniques in as many different micro-habitats (or habitat patches) as possible. Intensive sampling was conducted in each patch of different habitat within each study area. Selection of specific subsites was primarily based on vegetation, topography and substrate types. The vegetation classifications used were those of Walker & Hopkins (1990). Each mountain was sampled twice, during the early wet season (December 1990) and again in the early dry season (April 1991).

Previous mammal and bird surveys were carried out in the area by Lavery (1968) (birds), Lavery & Johnson (1968) (mammals), Lavery & Johnson (1974) (mammals) and Lavery & Seton (1974) (birds).

SITE DESCRIPTIONS

MOUNT CLEVELAND

Mount Cleveland (19°20'S, 147°03'E) is situated within Bowling Green Bay National Park, approximately 25km east of Townsville (Fig. 1). At 558m it is substantially lower than other mountains in the vicinity. Average annual rainfall is approximately 1000mm most of which occurs during the months December to March.

The vegetation at the summit of Mount Cleveland primarily consists of a relatively dense tree layer of *Allocasuarina torulosa* and mixed eucalypts, a dense middle layer of *Xanthorrhoea johnsonii* and a ground layer dominated by Blady Grass (*Imperata cylindrica*), over a rocky substrate.

Sub-sites selected for intensive sampling on Mount Cleveland were (topographic map used was Bowling Green 1:50 000, Sheet 8359-111, Edition 1-AAS, Series R 733):

C1 Mount Cleveland summit (Grid ref. 030706, altitude 558m): Mammal traps were laid in a circle around the summit ridge. The terrain was steep with large boulders and rock overhangs. Vegetation classification: very tall *Xanthorrhoea* shrubland above tall grassland (X4V/G3M). There was also dense vegetation, including some

rainforest taxa, in the gaps between the large boulders.

C2 Saddle between camp and summit (Grid ref. 033708, altitude 480m): the saddle was mostly flat with relatively few rocky outcrops. Vegetation classification: *Allocasuarina torulosa* dominated mid-high open forest with sclerophyll emergents over a very tall *Xanthorrhoea johnsonii* dominated shrubland (ALTOR ET6M/X4S). There were also patches of dense Blady Grass (*Imperata cylindrica*) in the more open areas.

C3 Rainforest (Grid ref. 034706, altitude 460m): Rainforest (c.2ha) was present in the catchment area of several rocky gullies just to the south of site C2. Vegetation classification: simple notophyll mixed tall closed forest (T7D S5M6).

C4 Rocky ridge (Grid ref. 036710, altitude 470m): The area was very rocky with outcrops of large granite boulders. The vegetation here is classified the same as site C2 (ALTOR ET6M/X4S), but it was much more rocky, the *Xanthorrhoea* was not as dense, and there were no significant areas of Blady Grass.

Mount Elliot

Mount Elliot (19°30'S, 146°57'E) is situated approximately 30km south-east of Townsville (Fig. 1) and, with an elevation of 1221m, is the highest mountain in the Townsville region. The group of mountains associated with Mount Elliot runs almost due north-south and hence they are influenced by the southeasterly trade-winds which blow up the Queensland coast. The area receives approximately 1200mm of rainfall annually, although the mountain top could be expected to receive considerably more than this due to its greater elevation. The majority of rainfall occurs during the months December to March.

Mount Elliot is entirely within Bowling Green Bay National Park and appears on the register of the National Estate. Unlike most areas to the north, Mount Elliot appears not to have been logged and, hence, remains relatively undisturbed. The rainforest on Mount Elliot is not contiguous with the northern forest and represents an island of forest surrounded by dry open woodland.

Sub-sites selected for intensive sampling on Mount Elliot were (topographic map used was Mount Elliot (Special), Edition 1, Series R733, 1:50 000.):

E1 (Grid ref. 109582, Altitude 1200m): narrow, steep summit ridge with Simple notophyll tall mixed closed forest with *Archontophoenix alexandrae* emergents (AT7D S5M6). This area was typical of the summit with a rocky substrate and a well developed understorey vegetation.

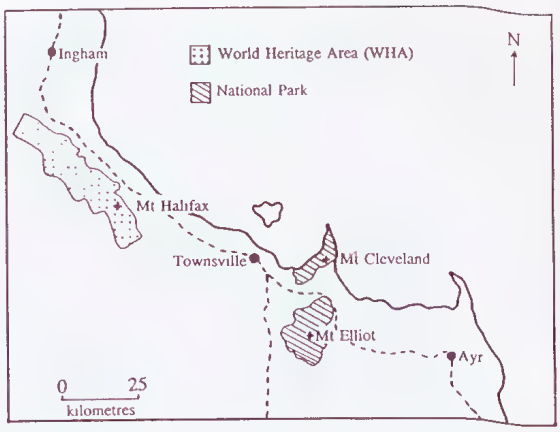

FIG.1. Map of Townsville region showing the locations of the study sites.

E2 (Grid ref. 109581, Altitude 1200m): ridge top clearing, classified as Dwarf closed vineland with *Archontophoenix alexandrae* and *Cyathea sp.* emergents (AL4D). This site was representative of a number of similar clearings near to the summit of Mount Elliot, with a very dense ground cover of vines and scramblers about 1m thick. There is virtually no canopy except an occasional palm.

E3 (Grid ref. 112576, Altitude 1150m): wide ridge top with Simple notophyll mixed very tall closed forest (T8D S5M2). The vegetation at this site has a more open understorey than site E1.

E4 (Grid ref. 114574, Altitude 1150m): headwaters of eastern catchment area. The forest here was taller with fewer small saplings and a distinctive middle layer of the tree fern *Cyathea rebeccae*. Classification was Simple notophyll mixed very tall closed fern forest (T8D S5M2).

Mount Halifax

Mount Halifax (19°07'S, 146°22'E), situated 50km west north-west of Townsville (Fig. 1), is the highest mountain, at 1064m, in the Paluma Range. It is a very wet area and the average annual rainfall for the region is approximately 2600mm, with the majority falling during the period December to March.

Sub-sites selected for intensive sampling were (Map used was Rollingstone, Series R733, Sheet 8159 1, Edition 3-AAS 1:50 000):

H1 (Grid ref. 341862, Altitude 1020m): wet, ridge-top rainforest (very wet due to almost continuous cloud drip) - the SE ridge from the summit.

Vegetation Classification: Simple Notophyll Mixed Tall Closed Forest T7D S5M6.

H2 (Grid ref. 340863, Altitude 1040m): drier rainforest on the western slope of the SE ridge. Vegetation classification: T7D S5M6.

H3 (Grid ref. 344861, Altitude 1020m): taller rainforest on narrow ridge and saddle SE of camp. Vegetation classification: Simple Notophyll Mixed Very Tall Closed Forest T8D S5M6.

H4 (Grid ref. 342862, Altitude 1040m): heath vegetation near summit ridge. Vegetation classification: mid-high *Leptospermum amboinense* Open Forest above a tall sparse heathland and mid-high closed forbland LEAMB T6M/Z4V/F2D.

H5 (Grid ref. 339864, Altitude 1060m): dense, low sclerophyllous vegetation on summit. Vegetation classification: Dwarf *Callistemon viminalis* closed forest with sclerophyll emergents above a mid-high closed forbland (ET4D/F2D).

METHODS

Identification

Voucher specimens of mammals, reptiles and amphibians that were difficult to identify were collected and lodged with the Queensland Museum (mammals) or with Queensland National Parks and Wildlife Service (reptiles and amphibians). Catalogue numbers are as yet unavailable as not all of the material has been sorted. Species worthy of special mention here are those bird observations which are range extensions (Victoria Riflebird, *Ptiloris victoriae*, Grey-Headed Robin, *Heteromyias cinereifrons*, Bridled Honeyeater, *Meliphaga frenata*, and Bower's Shrike-Thrush, *Colluricincla boweri*), and the small mammals *Rattus fuscipes* and *Melomys cervinipes*. No voucher specimens of birds were taken. Observations of Grey-Headed Robins and Bridled Honeyeaters were numerous and reliable, however only one sighting was made of Victoria's Riflebird and Bower's Shrike-thrush. *Rattus fuscipes* is very similar to *R. leucopus*. However, several skulls were examined from Mount Halifax and Mount Elliot and these proved to be *R. fuscipes*. In addition, two adult females on Mount Elliot had eight nipples (*R. fuscipes* has eight nipples while *R.leucopus* has six). As well, several specimens of *Melomys cervinipes* were identified on the basis of molar dentition and in the field on weight, fur texture and fur colour. The average weight of *M.cervinipes* on Mount Cleveland was 85g with an adult range of 70-115g. This differs from the range of 45-65g for *M.burtoni* (Strahan, 1983). Obviously these identifications do not preclude the possibility of either *Rattus leucopus* or *Melomys burtoni* being present. Also there is considerable evidence showing that in north Queensland *M. cervinipes* is a forest generalist rather than a closed forest specialist and has much broader habitat preferences than previously thought (Winter et. al., 1984; Williams, unpub. data).

Mammal Trapping

All of the sub-sites were trapped for four consecutive nights on each trip. Sub-sites C1, C2, C3 and C4 (Mount Cleveland) and sub- sites E1, E2, E3 and E4 (Mount Elliot) all had 25 Elliot "type A" traps and five wire cage "bandicoot" traps. Sub-sites H1, H2 and H3 (Mount Halifax) had 20 Elliot traps, while sub-site H4 and H5 had 10 Elliot traps and two cage traps. Traps were placed at 10m intervals with cage traps equally spaced along the transect. Traps were baited with a mixture of rolled oats, peanut butter and vanilla essence. Cage traps were also baited with sardines to attract carnivores (e.g. quolls). Two drift fence/pit trap lines were set up at Mount Elliot and Mount Halifax. Each drift fence consisted of 50m of fence (30cm high) with six pit traps (20 litre plastic drums) at about 7m intervals.

Data collected from trapped animals included species, sex, reproductive status and weight. Each animal was marked with a small notch in the right ear and then released.

Bird Observations

A walking transect (c.20min) was conducted at each sub- site for four consecutive mornings (in conjunction with clearing the mammal trap lines). An additional afternoon search (c.2hr) was conducted at each sub-site. This search included observations of birds, reptiles and amphibians. Three dawn choruses (1hr) per trip were also conducted at each mountain. All incidental bird observations were also recorded. Due to the high mobility of birds and the relatively short distance between sub-sites the avifauna was not separated into the different sub-sites for each mountain.

Walking Transects

Night

Spotlighting transects of 1-1.5hr were conducted in each of the sub-sites on each mountain on both trips for mammals, birds, reptiles and amphibians. Two spotlights (30w) were used in each survey.

Day

Daylight walking transects of c. 2hr were con-

ducted each day (once at each sub-site) to search for birds and reptiles.

RESULTS

Mount Halifax had the highest diversity of birds (55 species) (Table 1) and ground-dwelling mammals (seven species) with Mount Cleveland having the greatest diversity of reptiles (18 species). Mount Elliot was notable in that it had the lowest observed diversity of all groups (Table 1).

The diversity of terrestrial vertebrates observed during these surveys is summarised in Table 1 and a complete species list with an index of relative abundance for each species (mammals and birds) is given in Appendix 1. Detailed mammal trapping results for each sub-site are included in Appendix 2.

MT CLEVELAND

There were considerable differences between the small mammal assemblages of each sub-site on the upper ridges of Mount Cleveland (appendix 2):

(1) The summit (site C1) and the rocky ridge (site C4) supported a small mammal assemblage consisting of *Dasyurus hallucatus, Melomys cervinipes, Isoodon macrourus*, and *Petrogale inornata*. Neither *D. hallucatus* or *P. inornata* were observed at the other sites. This is not surprising given the preference of these species for rocky habitat.

(2) Site C2 was dominated by *Melomys cervinipes*. Its density was very high at this site (20 individuals) with new individuals still being trapped after four days. The high density of *Xanthorrhoea* could be one of the factors contributing to the this because several individuals of *M. cervinipes* were observed nesting within the head of the grass trees and also eating the seeds. No *D. hallucatus* or *P. inornata* were observed in this habitat.

(3) The rainforest (site C3) contained fewer *Melomys cervinipes* in comparison to the other sites. This area may be more important during the dry season when water is not readily available in the drier areas.

Forty-three species of birds were observed on Mount Cleveland (Appendix 1). There was a much higher level of bird activity in, and on the edge, of the rainforest than elsewhere on the mountain. Generally the bird community was typical of the open forest of the Townsville region. However, due to the presence of the rainforest patch, there were also a number of closed forest species present (e.g. Scrub Turkey, Purple-crowned Pigeon, Wompoo Pigeon, Noisy Pitta, and Bower's Shrike-thrush).

MT HALIFAX

The summit area of Mount Halifax was found to have a mammal community typical of rainforest in this region (Appendix 1 and 2). The rainforest small mammal community was dominated by *Rattus fuscipes* and the small patches of heath vegetation were dominated by *Melomys cervinipes*.

There were several species which were expected but were not observed during the field surveys. These include the Red-legged Pademelon (*Thylogale stigmatica*), Brushtail Possum (*Trichosurus vulpecula*) and Green Ringtail (*Pseudochirops archeri*).

There were several small areas of heath that were of local significance (summit - grid ref. 339864 and near campsite - grid ref. 342862). The heath represented a very different habitat from the surrounding rainforest and, as such, significantly increased the habitat diversity of the area. Although the areas were probably too small to support vertebrates unique to that habitat, such as mammals and birds, there was a significantly different small mammal community present (compare sites H4 & H5 to sites H1, H2 & H3 in Appendix 2). It is also highly likely that these patches of heath would support restricted and endemic invertebrates (Graham, 1991). The heath contained concentrations of myrtaceous plant species such as *Leptospermum amboinense* and *Callistemon* sp., which could be an important seasonal food source for nectivorous birds and mammals.

MT ELLIOT

The results of the mammal trapping indicate that the Mount Elliot rainforest has a relatively depauperate small mammal community (Appendices 1 and 2). Only two species, *Rattus fuscipes* and *Melomys cervinipes* were trapped regularly and only in low numbers (Appendix 2). A single *Planigale maculata* was caught in an insect formalin trap. No sampling was conducted in the open forest; however this area was sampled by Lavery & Johnson (1974).

DISCUSSION

The three mountains examined differ considerably in topography and vegetation. These differences are reflected in relative abundances and species diversities of mammals and birds. Gra-

ham (1991) has previously discussed the survey of reptiles and amphibians from this expedition. Mount Halifax had the most diverse vertebrate fauna overall, as might be expected from its position, which is contiguous with other mountains and comparable habitats in the Paluma range. Small patches of heath near the summit of Mount Halifax may increase the habitat heterogeneity enough to produce endemic arthropods (Monteith, pers. comm.), but the areas are probably too small to have a significant effect on vertebrate communities. Both Mount Cleveland and Mount Elliot are discrete mountains in which it may be expected that diversities would be lower due to smaller, more isolated summit habitats. The relatively high diversity at Mount Cleveland is probably due to high habitat heterogeneity on the summit ridges.

Mount Cleveland is an important part of Bowling Green Bay national park as the habitat on and near the summit is unique within the park and is not well represented elsewhere in the region. The habitat on the upper ridges (*A. torulosa/Xanthorrhoea* forest ALTOR ET6M/X4S) is not widespread and contains a faunal community which is unusual (*Dasyurus hallucatus* and a high density of *Melomys cervinipes*). This community/habitat is therefore of significant importance to biological conservation both within this national park, and to the region. Patches of closed forest (e.g. site C3) are of great local significance as they greatly increase the diversity of habitats and the associated flora and fauna (as can be seen by the presence of a number of rainforest birds) although the much larger area of closed forest on nearby Mount Elliot is probably of greater regional significance.

The summit of Mount Elliot contains the largest block of rainforest within the Bowling Green national park and is regarded as being the southern limit of tropical rainforest proper (Winter & Atherton, 1987). The vertebrate fauna and flora surveys undertaken during this study also indicate that the rainforest on Mount Elliot has a high degree of affinity with the tropical rainforest to the north of Townsville. Taxa collected or noted by previous studies (Lavery 1968; Lavery & Johnson 1968; Lavery & Johnson 1974: Lavery & Seton, 1974) also indicate strong affinities with the rainforests along the Paluma Range to the north. There is one microhylid frog, *Cophixalus mcdonaldi,* endemic to the rainforest of Mount Elliot (Nix & Switzer, 1991; Zweifel, 1985). Very little is known about the biology of this very restricted species. *C. mcdonaldi* was calling during December and it appeared to be very common throughout the forest on the summit of Mount Elliot. Eight individuals were found during March by actively searching (three in rotted tree stumps, one in a crack between rocks, two under a flat rock and two sitting on a clutch of at least eight eggs inside a small (2cm diameter) hole in a solid rock face). Another interesting record was the capture of a *Planigale maculata* within rainforest when this species is usually considered to be an open forest species. It was unusual that no White-tailed Rats (*Uromys caudimaculatus*) were trapped or observed while spotlighting, since they have been recorded at Mount Elliot in the past, and are usually easy to trap and to spotlight.

Three species of birds recorded on Mount Elliot have not been recorded this far south before: Victoria's Riflebird, Bridled Honeyeater and Grey-headed Robin. These records increase the evidence of an affinity in the vertebrate fauna between the rainforest of Mount Elliot and tropical rainforest further to the north.

Mount Elliot is known to have a number of

endemic insect species, despite generally lower diversities than in the rainforests to the north (Graham, 1991). Mount Elliot is important in any biogeographical study of latitudinal trends in tropical biota, and greatly increases the local and regional biodiversity due to the inclusion of an area of tropical rainforest in an otherwise dry region.

Comments on Techniques

All sampling techniques have inherent biases that vary between taxa, seasons, habitats and weather conditions. Small mammals differ markedly in their relative trappability as illustrated by the capture of *Planigale maculata* in an insect formalin trap, which was not trapped in the small mammal traps. Pit traps (Mount Elliot, Mount Halifax) were found to be inefficient with respect to the effort required to install the pit lines. The pit traps were most useful in catching large ground dwelling invertebrates. Weather can have a large affect on observation biases with rain and/or mist making spotlighting and visual bird observations very difficult. Conversely, wet weather will increase the possibility of observing most amphibians and many reptiles. Most amphibians and reptiles are also less active during the winter months (dry season) making summer (wet season) sampling essential in tropical rainforests.

Habitat differences can have a drastic affect on the biases involved in most techniques. Dense vegetation makes visual observation of birds difficult and results in an increased importance of call identification. However, during these surveys it was found that, although most of the records were based on calls for the first two days, all bird species had been visually confirmed within five days. Dense vegetation also makes spotlighting for arboreal mammals very difficult, especially where there are no tracks or roads.

In summary, it is vital for vertebrate surveys to use as many different techniques as possible, and to sample during both wet and dry weather conditions to maximise the efficacy of the survey.

ACKNOWLEDGEMENTS

We would also like to thank the staff of the Australian Centre for Tropical Freshwater Research, the staff of Hollingsworth, Dames and Moore Pty Ltd, Geoff Moore and Guy our trusty helicopter pilot. The survey was funded by the Civil Aviation Authority.

APPENDIX 1

List of vertebrates observed during the fauna surveys of Mount Cleveland (Clv), Mount Halifax (Hal) and Mount Elliot (Ell). An index of abundance is given for mammals and birds for both the first and second field surveys (separated by a '/'). '-' — not observed, '0' — not observed on this trip, '1' — uncommon/only seen once or twice, '2' — common/observed regularly, '3' — abundant/observed several times on every census, '*' — observed at least once at this site during the course of both surveys. Species names follow Ingram & Raven (1991).

SPECIES	COMMON NAME	Clv	Hal	Ell
MAMMALS				
Dasyuridae				
Antechinus flavipes	Yellow-footed Antechinus	-	2/2	-
Antechinus stuartii	Brown Antechinus	-	1/1	-
Dasyurus hallucatus	Northern Quoll	2/0	-	-
Planigale maculata	Common Planigale	-	-	0/1
Peramelidae				
Isoodon macrourus	Northern Brown Bandicoot	2/2	-	-
Perameles nasuta	Long-nosed Bandicoot	-	1/1	-
Macropodidae				
Macropus agilis	Agile Wallaby	1/1	-	-
Petrogale inornata	Unadorned Rock Wallaby	1/1	-	-
Pteropidae				
Nyctimene robinsoni	Queensland Tube-nosed Bat	0/1	-	-
Pteropus alecto	Black Flying-fox	1/1	-	-
Syconycterus australis	Queensland Blossom-bat	1/0	-	-
Muridae				
Melomys cervinipes	Fawn-footed Melomys	3/3	3/3	2/2
Mus musculus	House Mouse	-	-	0/1
Rattus fuscipes	Bush Rat	-	3/3	3/2
Uromys caudimaculatus	White-tailed Rat	-	2/2	-
Suidae				
Sus scrofa	Feral Pig	1/1	2/2	2/2
BIRDS				
Casuariidae				
Casuaris casuaris	Southern Cassowary	-	1/1	-
Accipitridae				
Accipiter fasciatus	Brown Goshawk	-	0/1	-
Accipiter novaehollandiae	Grey Goshawk	1/0	-	-
Aquila audax	Wedge-tailed Eagle	1/1	0/1	0/1
Haliastur indus	Brahminy Kite	0/1	-	-
Falconidae				
Falco peregrinus	Peregrine Falcon	-	1/0	-
Megapodiidae				
Alectura lathami	Brush Turkey	1/1	2/2	2/1
Megapodius freycinet	Scrubfowl	-	1/0	1/0
Phasianidae				
Synoicus australis	Brown Quail	0/1	-	-
Columbidae				
Chalcophaps indica	Green-winged Pigeon	-	2/2	1/0
Columba leucomela	White-headed Pigeon	0/1	1/1	1/1
Geopelia humeralis	Bar-shouldered Dove	1/0	-	-
Lopholaimus antarcticus	Topknot Pigeon	-	1/0	1/0
Macropygia amboinensis	Brown Pigeon	-	2/1	2/1
Ptilinopus magnificus	Wompoo Pigeon	1/0	1/1	2/3
Ptilinopus regina	Red-crowned Pigeon	-	1/0	-
Ptilinopus superbus	Purple-crowned Pigeon	1/0	1/0	2/0
Loriidae				
Trichoglossus chlorolepidotus	Scaly-breasted Lorikeet	-	0/1	-
Cacatuidae				
Cacatua galerita	Sulphur-crested Cockatoo	1/1	2/2	0/1
Psittacidae				
Alisterus scalularis	King Parrot	-	1/1	-
Platycerus elegans	Crimson Rosella	-	2/3	-
Cuculidae				
Centropus phasianinus	Pheasant Coucal	3/3	-	-
Chyrsococcyx lucidus	Shining Bronze-Cuckoo	-	1/1	-
Cacomantis flabelliformis	Fantail Cuckoo	-	0/2	0/3
Tytonidae				
Tyto multipunctata	Lesser Sooty Owl	-	0/1	-
Strigidae				
Ninox boobook	Boobook Owl	1/1	-	1/0
Podargidae				
Podargus strigoides	Tawny Frogmouth	1/0	-	-
Aegothelidae				
Aegotheles cristatus	Australian Owlet Nightjar	1/0	—	
Apodidae				
Apus pacificus	Fork-tailed Swift	-	1/0	-
Alcedinidae				
Dacelo leachii	Blue-winged Kookaburra	0/1	-	-
Dacelo novaeguineae	Laughing Kookaburra	3/3	-	1/0
Meropidae				
Merops ornatus	Rainbow Bee-Eater	-	3/3	-
Pittidae				
Pitta versicolor	Noisy Pitta	-	3/3	3/0
Campephagidae				
Coracina lineata	Barred Cuckoo-Shrike	-	1/0	-
Coracina tenuirostris	Cicadabird	0/1	-	-
Lalage leucomela	Varied Triller	2/2	-	-
Orthonychidae				
Orthonyx spaldingii	Northern Logrunner	-	3/3	-
Psophodes olivaceus	Eastern Whipbird	-	3/3	-
Maluridae				

SPECIES	COMMON NAME	Clv	Hal	Ell
Malurus elegans	Red-backed Wren	1/0	-	-
Acanthizidae				
Oreoscopus gutturalis	Fernwren	-	1/1	-
Gerygone mouki	Brown Warbler	-	0/2	0/1
Gerygone palpebrosa	Fairy Warbler	2/2	0/1	-
Sericornis citreogularis	Yellow-throated Scrubwren	-	1/1-	
Sericornis frontalis	White-browed Scrubwren	-	2/0	3/3
Sericornis magnirostris	Large-billed Scrubwren	-	1/2	0/2
Monarchidae				
Monarcha melanopis	Black-faced Monarch	-	0/1	1/0
Monarcha trivirgatus	Spectacled Monarch	1/1	1/0	-
Myiagra cyanoleuca	Satin Flycatcher	1/0	-	-
Myiagra rubecula	Leaden Flycatcher	2/1	-	-
Rhipidura fuliginosa	Grey Fantail	-	3/3	1/1
Rhipidura rufifrons	Rufous Fantail	-	1/1	-
Eopsaltridae				
Heteromyias cinereifrons	Grey-headed Robin	-	3/3	3/3
Tregellasia capito	Pale-yellow Robin	-	3/3	2/3
Pachycephalidae				
Colluricincla boweri	Bowers Shrike-thrush	0/1	-	-
Colluricincla megarhyncha	Rufous Shrike-Thrush	3/3	1/11/1	
Pachycephala pectoralis	Golden Whistler	-	2/2	2/1
Pachycephala rufiventris	Rufous Whistler	-	1/0	-
Pachycephala simplex	Grey Whistler	-	1/0	1/0
Dicaeidae				
Dicaeum hirundinaceum	Mistletoebird	-	0/1	-
Meliphagidae				
Acanthorhynchus tenuirostris	Eastern Spinebill	-	2/3	1/0
Meliphaga chrysops	Yellow-faced Honeyeater	-	-	1/0
Meliphaga frenatus	Bridled Honeyeater	-	2/2	2/0
Melaphaga gracilis	Graceful Honeyeater	-	1/0	-
Melaphaga notata	Yellow-spotted Honeyeater	3/3	1/0	-
Melaphagi lewinii	Lewins Honeyeater	-	3/3	2/2
Melithreptus lunatus	White-naped Honeyeater	1/0	-	-
Myzomela obscura	Dusky Honeyeater	1/0	0/1	-
Philemon novaeguineae	Helmeted Friarbird	1/0	-	-
Philemon corniculatus	Noisy Friarbird	3/0	1/0	-
Phylidonyris nigra	White-cheeked Honeyeater	-	0/1	-
Estrildidae				
Neochmia temporalis	Red-browed Firetail	1/0	-	-
Dicruridae				
Dicrurus bracteatus	Spangled Drongo	1/0	-	-
Cracticidae				
Strepera graculina	Pied Currawong	2/3	0/3	3/2
Ptilonorhynchidae				
Ailuroedus melanotis	Spotted Catbird	-	3/3	-
Scenopoeetes dentirostris	Toothbill Bowerbird	-	3/2	3/3
Paradisaeidae				
Ptiloris victoriae	Victoria's Riflebird	-	1/1	1/0

SPECIES	COMMON NAME	Clv	Hal	Ell
Corvidae				
Corvus orru	Australian Crow	2/0	-	-
REPTILES				
Gekkonidae

PREFACE

The preparation for this International Congress was superbly managed by two Organising Committees. All members worked very hard and I am very grateful for their cooperation. The Western Australian Museum was the centre of the Scientific and Publications Committee of Dr Mark S. Harvey, Dr Bill F. Humphreys, and Dr Barbara York Main. This group, lead by Mark Harvey, formed a fine team who very capably managed all scientific and publication matters from manuscript submission to acceptance through the Congress program and photographic awards.

The local Organising Committee included Dr Valerie Davies (Secretary), and Ms Tracey Churchill, Ms Jan Green, Ms Judy Grimshaw, Mr Phil Lawless and myself. That group managed diverse aspects of Congress organisation. Mr David Nebauer assisted committee members during the registration process. My preparation was initially assisted by Ms Julie Gallon. In July 1991, Mr Philip Lawless took up the reins from Julie and proved to be a very dedicated and astute lieutenant. Emeritus Professor George Davies assisted the Secretary throughout the entire Congress period.

Delegates from Russia, Kazakhstan, The People's Republic of China, Madagascar, Mexico, Hungary, India, Belgium, North America, Germany, and Namibia were provided with varying degrees of sponsorship by the Queensland Museum Board of Trustees and sponsors. Their travel arrangements, often highly complex and problem-rich, were very capably managed by Ms Joanne Lavelle, then of State of Corporate Travel. Many a Congress delegate will no doubt fondly remember the Committee reception at the International airport. Several appreciated the kind hospitality of Mr Tony Luck, Microrim (Australia), of Camira, in an 'Aussie barbeque' before the Congress.

Organisation of the Post-Congress tour to Cape Tribulation, was greatly facilitated by the much appreciated contributions of Ms Linda Stanley, Ms Esther Cullen, and Cliff and Gail Truelove.

Editorial assistance was provided by Ms Gudrun Sarnes, Philip Lawless and Mr Neale Hall.

The Congress organisers very gratefully acknowledge the financial donations of Australian Geographic Magazine, Western Australian Museum, Amalgamated Pest Control, Australian Museum, Museum of Victoria, South Australian Museum, Commonwealth Bank, University of Queensland–Entomology & Zoology Departments, Griffith University–School of Australian Environmental Sciences, QANTAS Airlines, Australasian Arachnological Society, CSIRO, Division of Entomology, and the British Council. Financial support was also received from International Conference Support (loan) and the Australian Tourist Commission. The Queensland Museum Board of Trustees provided generous support for the Congress and the publication of these proceedings.

Robert J. Raven
Chairman, XIIth International Congress of Arachnology

October 11, 1993

Chairman: Dr Robert Raven.

From the President's Desk

The XII International Congress of Arachnology was held at the Queensland Museum, Brisbane, from 12th to 18th July, 1992 under the joint auspices of the Trustees of the Queensland Museum and the Centre International de Documentation Arachnologique. More than 122 registrants from 32 countries and 37 accompanying persons participated.

The 114 presented papers covered nearly all fields of arachnological research, reflecting the progress in our knowledge of arachnids. This progress may encounter some scepticism from particularly the older, loyal participants since every president in each presidential report underlines the 'progress made during the last three years'. A congress program does not reflect the actual research level, but only the fields of interests of participants whose attendance at congress depends on economic or other factors. Real progress can be emphasised in the fields of biology, ecology, bio-indication and phylogeny. However, we might be regressing in taxonomy because the number of taxonomists remains stable while the numbers of identifications requested by ecological and other studies (raising new taxonomical problems) are increasing. Some arachnid groups will perhaps be 'orphaned' in the near future as specialists retire from active study.

Arachnids are fascinating animals of great biological importance. Is there any reason not to tell this more frequently to 'the public'? Ecologists should allow a reasonable fee for identification of their material when submitting grant applications.

At the meeting of CIDA members held during the Congress, Dr R. Jocqué was elected the new CIDA president.

The congress excursion was held mid-week at O'Reilly's, Lamington Plateau, where participants could discover the rich bird and arthropod fauna of the forest, stroll through the botanical garden or have an exciting canopy walk.

Brisbane was a marvellous occasion to meet friends and colleagues, but also (at least for me) a wonderful time to discover a fascinating continent and its plants and animals, and I am sure that we will come again. Thanks to all of the organising staff and the people we had the chance to meet for their friendliness and helpfulness.

'Le Roi est mort, vive le Roi'. Hopefully we will meet in Geneva in 1995.

Volker Mahnert

President, Centre International de Documentation Arachnologique 1989-1992

FOSSIL ARACHNIDS–RECENT ADVANCES AND FUTURE PROSPECTS

PAUL A. SELDEN

Selden, P.A. 1993 11 11: Fossil arachnids–recent advances and future prospects. *Memoirs of the Queensland Museum* **33**(2): 389-400. Brisbane. ISSN 0079-8835.

Until 5 years ago, the arachnid fossil record was sparse. It was dominated by a comparative wealth of forms in Carboniferous Coal Measure sediments, and near-modern forms from Palaeogene Baltic amber. Both these relatively well-documented sources and the few reported finds elsewhere in the record suffered from erroneous interpretations. In recent years, new interpretations of existing fossils and a few spectacular new finds have filled in the gaps in the record and changed our knowledge and views of the course of arachnid evolution. Particular examples are: Devonian pseudoscorpions and spiders, book-lungs in Carboniferous scorpions, Triassic mygalomorph spiders, and Jurassic and Cretaceous araneomorph spiders. Phylogenetic systematic analyses of extant arachnids have produced evolutionary scenarios which conflict with the observed fossil record in parts. The newly expanded knowledge of the fossil record allows better tests for the cladograms. Future work on reinterpretation of known Carboniferous and Palaeogene fossils, on rare Mesozoic arachnids, and on arachnids in the earliest known terrestrial ecosystems in the Silurian will add to our knowledge of the fossil record of the arachnids and further enhance testing of phylogenetic hypotheses.□*Aglaspidida, Arachnida, Chelicerata, palaeontology, phylogeny, Pycnogonida.*

Paul A. Selden, Department of Geology, University of Manchester, Manchester M13 9PL, United Kingdom; *10 November, 1992.*

For most of this century, one name dominated the literature on fossil arachnids, that of Alexander Petrunkevitch (1875-1964). Petrunkevitch (1955; in Størmer, 1955) summarized the arachnid fossil record to mid-century (Fig. 1) in the 'Treatise on Invertebrate palaeontology' and although he published on amber spiders after 1955, the broad view of the fossil record of chelicerates remained little changed until about a decade ago. Few workers either published on fossil arachnids or disputed Petrunkevitch's assignments during his lifetime. Only recently, during restudy of the fossils, have many errors and misinterpretations in his work come to light.

In the fossil chelicerate record published in the 'Treatise' (Fig. 1), the Merostomata (essentially aquatic chelicerates) are separated from the Arachnida. Second, most of the arachnid side consists of dashed lines converging towards the base of the Cambrian, indicating lack of fossil record and uncertainty of affinities respectively. Third, apart from one dubious palpigrade and some scorpions, there are no other records of Mesozoic (Triassic-Cretaceous) arachnids. Fourth, there is a clear pattern in the temporal distribution of the fossils: a concentration of records in the Upper Carboniferous, and many modern groups also occur in the Palaeogene (early Tertiary). The former records are from the Coal Measures of Europe and North America, for example: Mazon Creek, Illinois; Coseley, England; and Nyrany, Czechoslovakia. The Palaeogene occurrences are mainly from Baltic amber. Although Trigonotarbida and a questionable record of Araneae had been known from the Devonian Rhynie Chert of Scotland since Hirst (1923), they were omitted from the diagram. (In addition, Petrunkevitch knew of undescribed Lebanese amber opilionids and some Cretaceous spiders from Manitoban amber).

Petrunkevitch developed theories on the evolution of arachnids, which resulted in his superordinal classifications of 1945 and 1949. He recognized a number of 'evolutionary trends', such as the movement of the mouth rearwards from the Xiphosura to the arachnids, and the reduction of the metasoma to a tail or pygidium. One of the most important characters used in his classifications is the width of the connection between prosoma and opisthosoma, i.e. reduction of the first abdominal somite to a pedicel. Petrunkevitch (1945) divided the class Arachnida into two subclasses, Latigastra and Caulogastra, on the basis of a broad or a narrow prosoma-opisthosoma connection respectively. Later, Petrunkevitch (1949) added the subclass Soluta to the scheme to include solely his new order Trigonotarbida which he considered exhibit both wide and narrow junctions. Another subclass, the

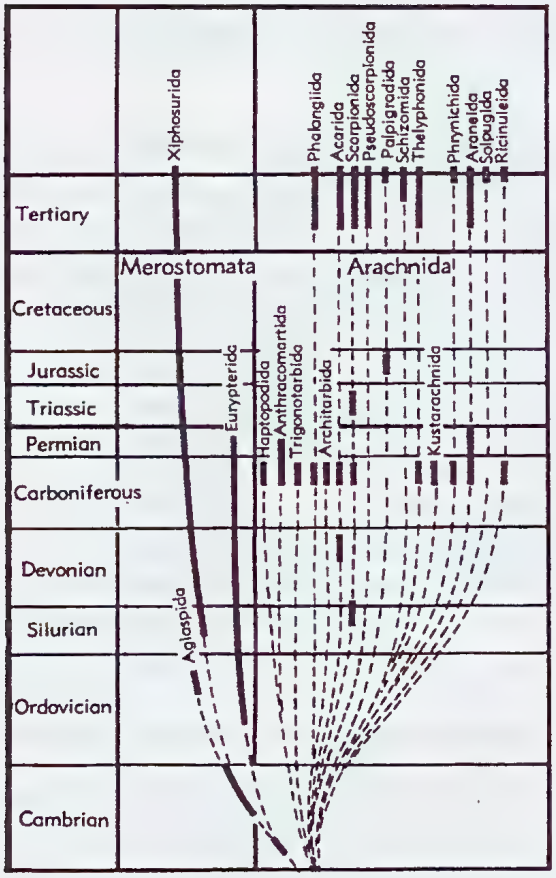

FIG. 1. Stratigraphic ranges of Chelicerata and Aglaspidida and presumed phylogenetic relationships (from Størmer, 1955).

Stethostomata, was created at this time to accommodate the orders Anthracomartida and Haptopoda which supposedly have a broad prosoma-opisthosoma junction and a unique coxosternal region. Petrunkevitch's (1949) classification scheme, used in the 'Treatise', has not stood the test of time. Weygoldt and Paulus (1979) noted its use in some textbooks but pointed out severe deficiencies in the scheme when other characters are taken into account.

Petrunkevitch was a devout proponent of the idea of the 'decoupling' of macroevolution and microevolution. He envisaged major features (those which define higher taxa) originating by mutation or other accelerated evolution, whereas minor morphological differences (those which separate species, for example) could provide only long, slow evolution and rarely produced higher taxa (Petrunkevitch, 1952, 1953). Petrunkevitch (1955) envisaged extinction occurring when irreversible evolutionary trends took groups down blind alleys–useful trends which proved lethal when taken to extreme or when environmental conditions changed. Characters could therefore be described as 'major' or 'minor', depending on the taxonomic rank they diagnose. Provided the 'rank' of a character is not decided *a priori*, there is no problem; however, difficulties arise when character states do not clearly change at taxon boundaries. For example, in a diagnosis of the subclass Soluta Petrunkevitch, 1949 is: 'abdomen composed of 8 to 11 segments' (Petrunkevitch, 1955, p. P107). Petrunkevitch described this variability as the character being in a 'labile' state. So, the subclass Soluta is diagnosed on the *labile condition* of the abdominal segmentation, the presence of *either* a broad *or* a narrow junction between the opisthosoma and prosoma (see above), and the *overall resemblance* of the coxosternal region to that in spiders [my italics]. Petrunkevitch (1955) argued that solutes are not spiders because of the combination of characters in the group, and additionally they showed a single series of marginal plates on the opisthosoma. Obviously, such a group could also be considered a collection of quite different animals placed together through their shared possession of a spider-like coxosternal region.

Restudy of fossil solutes reveals that the problem lies mainly in Petrunkevitch's inability to correctly interpret fossil material. The number of segments in the Soluta is invariably 11 (Shear *et al.*, 1987) but the number Petrunkevitch interpreted in each specimen differed according to its preservation. Thus, where a 2-segmented pygidium was preserved, then 2 additional segments were counted over specimens which did not preserve this organ, and the short first abdominal segment is not always visible in fossils. Similarly, the interpretation of the prosoma-opisthosoma junction depended on how closely these tagmata were conjoined in the fossil.

Petrunkevitch described *Trigonomartus pustulatus*, and noted (1913, p. 104): 'The cephalothorax being much harder, kept more or less its shape, and what appears on it as a median crest was in reality a median groove. The irregular, polygonal depressions were evidently thickened areas of the chitin and formed in life low elevations.' But, two pages before he had diagnosed the new genus thus: 'Carapace triangular with a median crest in the posterior half, covered with irregular polygonal depressions.' Thus he had recognized that the fossils were

external moulds but diagnosed the genus as if they were casts. The error perpetuated until 1955 when, in the 'Treatise' (p. P112), the diagnosis became 'Carapace triangular, high, with median crest and a pustulose surface, without eyes. Abdomen with pustulose surface' Thus, pustules were recognized but the median crest remained, without explanation for the emendation. Furthermore, eyes exist in *Trigonomartus* (Petrunkevitch, 1913, pl. 9, fig. 49, in the same place as in *Aphantomartus* (Pocock 1911, Pl. II, fig. 6). These two genera were synonymized by Selden and Romano (1983). As well as misinterpreting fossils, Petrunkevitch produced some illogical taxonomic arguments. In 1945, he erected the Aphantomartidae for eophrynids with 7 abdominal tergites (i.e. *Aphantomartus areolatus* Pocock, 1911). In 1949, he erected the Trigonomartidae, and, recognizing that *Aphantomartus* had 8 abdominal tergites, not 7, he stated (p. 256): 'This means that the Family Aphantomartidae becomes a synonym of Trigonomartidae, the number of abdominal segments having served as the only character of distinction.' Why not place the contents of the new 'Trigonomartidae' in the existing Aphantomartidae? Aphantomartidae has priority and was redefined by Selden and Romano (1983). Furthermore, illustrations purporting to differentiate *Aphantomartus* and *Trigonomartus* (Petrunkevitch 1955, figs 80, 1 and 3) are unrepresentative and merely emphasise different characters of the same genus. Fig. 80, 3 is not *Aphantomartus areolatus*, as stated in the text, but a copy from Pruvost (1919, fig. 42) of *A. pococki*, with eyes drawn on incorrectly!

Consider also the Phalangiotarbida. Kjellesvig-Waering redescribed this group just before his death in 1979, and the MS was being prepared for posthumous publication (see Kjellesvig-Waering, 1978). In the MS, Kjellesvig-Waering, a renowned taxonomic 'splitter', reduced Petrunkevitch's 10 genera and 13 species to four genera and five species. He stated in the introduction to his MS: 'Seldom, if ever, has a fossil group with such uncomplicated, mostly easily determinable morphological characters, been subjected to such misunderstanding and careless and erroneous work as has the order Phalangiotarbida Haase, 1890. The main reason for this state has been the complete failure of some of the workers in this group to understand fundamental paleontological principles of preservation, for example, molds and casts, external and internal, along with results of compaction and consequent reflection or impression of ventral into dorsal surfaces and vice versa.' Kjellesvig-Waering's conclusions on functional morphology and phylogeny, both in this MS and his other work, are not without dispute, but his long experience with the taxonomy of fossil chelicerates was generally reliable. Kjellesvig-Waering wrote in his MS: 'The question of whether Phalangiotarbida Haase, 1890, or Architarbida Petrunkevitch, 1945 is the proper name for this order of arachnids has not been settled, although it is difficult to understand why any question should have arisen in the first place.' What Petrunkevitch did was to substitute an existing name with one based on better preserved specimens of the order: 'What is more reasonable than to regard the Family Architarbidae as the most characteristic one of the Order and to emphasize this fact by using a proper derivative of the generic name for the Order?' (Petrunkevitch, 1945, p. 11).

The above examples show that much work is needed on fossil arachnids already in collections, in addition to study of the many new fossils awaiting description.

THE FOSSIL RECORD
(Fig. 2)

Arachnid Relatives

The extinct aglaspidids are probably not chelicerates since they bear neither chelicerae nor other features which would ally them with the Chelicerata over any other arthropod group (Briggs *et al.*, 1979). The fossil record does not help to determine the systematic position of the enigmatic pycnogonids. Chelicerae are not a prerequisite for a chelicerate. *Sanctacaris* Briggs and Collins, 1988 from the Middle Cambrian Burgess Shale of British Columbia lacks chelicerae but was included in the phylum because of a combination of characters unique to Chelicerata: six pairs of prosomal appendages, cardiac lobe, prosoma and opisthosoma, and anus at rear of last trunk segment. *Sanctacaris* was described as sister to all other chelicerates, but may not be the oldest chelicerate because a dubious xiphosuran carapace of Lower Cambrian age, *Eolimulus alatus* (Moberg, 1892) was recorded from Öland, Sweden. Xiphosura are the most primitive chelicerates in existence and, though previously allied with the Eurypterida in the Merostomata, most authors place Xiphosura with either the Scorpionida (Bergström, 1979, 1981; Bergström *et al.*, 1980; van der Hammen, 1985, 1986) or as sister to all other chelicerates (except

Sanctacaris) (Grasshoff, 1978; Boudreaux, 1979; Paulus, 1979; Weygoldt and Paulus, 1979; Weygoldt, 1980), thereby rendering Merostomata an unnatural group.

Scorpions

Scorpions are the arachnid group with the earliest known ancestors; the most ancient known scorpion is *Dolichophonus loudonensis* (Laurie, 1889) from the Llandovery of the Pentland Hills, near Edinburgh, Scotland. Kjellesvig-Waering (1986) proposed a controversial classification scheme. Stockwell (1989) produced a more acceptable classification scheme of Scorpionida which included fossils, but it has yet to be published formally. A linchpin of Kjellesvig-Waering's classification was the supposed Devonian gilled scorpion described as *Tiphoscorpio hueberi*. Restudy of this material (Selden and Shear, 1992) revealed that it is not a scorpion but an arthropleurid myriapod!

The early Silurian record of scorpions could be interpreted as representing the earliest terrestrial animals since all modern scorpions are terrestrial. However, all Silurian fossil scorpions occur in marine or marginal marine sediments, and morphological features suggest an aquatic mode of life. Petrunkevitch (e.g. 1953) considered all fossil scorpions were terrestrial, but other workers (e.g. Wills, 1947; Stormer, 1970; Rolfe and Beckett, 1984; Kjellesvig-Waering, 1986) argued for an aquatic habitat for Silurian scorpions at least. Evidence for aquatism among fossil scorpions are: gills and digitigrade tarsi, as well as the absence of terrestrial modifications such as coxal apophyses, stigmata, book lungs, trichobothria, highly developed pectines and plantigrade tarsi. There is overlap in the ranges of aquatic and terrestrial scorpions but the first terrestrial forms probably appeared the Devonian (Selden and Jeram, 1989). It is not easy to decide whether a given fossil had an aquatic or terrestrial mode of life; the original environment of the enclosing sediment is commonly the best clue, but a recent find is worthy of especial note: well preserved book lungs in a Carboniferous (Visean) scorpion from East Kirkton, near Edinburgh, Scotland (Jeram, 1990). Few new records of fossil scorpions have turned up in recent years although in the otherwise sparsely recorded Mesozoic, scorpions reported from the Triassic of France (Gall, 1971), and the Cretaceous of Brazil (Campos, 1986) are currently under study.

Pseudoscorpionida

Many pseudoscorpions are known from the Tertiary (mainly in ambers, e.g. listed in Schawaller (1982, table 1), and some are known from Cretaceous ambers of Lebanon (Whalley, 1980) and Manitoba (Schawaller, 1991). However, the most important fossil pseudoscorpions are well preserved specimens of *Dracochela deprehendor* (Shear *et al.*, 1989; Schawaller *et al.*, 1991), in the Upper Devonian mudstones of Gilboa, New York. Only protonymph and tritonymph are known which, though modern in many aspects, cannot be assigned with confidence to extant taxa because both diagnostic characters in the fossils and cladistic assessment of extant forms are lacking.

Solifugae

The Carboniferous solifuge, *Protosolpuga carbonaria* Petrunkevitch, 1913, was described as being in a very poor state of preservation. It is impossible to judge the validity of the identification from the published photograph and drawing. The only reliable fossil solifuge is *Happlodontus proterus* Poinar and Santiago-Blay, 1989, from Oligocene Dominican amber.

Opiliones

Until recently, Opiliones had a fairly typical arachnid fossil record, being known only from Upper Carboniferous strata and Tertiary ambers. In 1985 a specimen was discovered in Lower Carboniferous rocks of East Kirkton, near Edinburgh, Scotland (Wood *et al.*, 1985), and a year later, one was described from the Lower Cretaceous of Koonwarra, Victoria, Australia (Jell and Duncan, 1986). Both of these unnamed specimens are long-legged opilionids but no further identification is possible (pers. obs.).

The order Kustarachnida Petrunkevitch, 1913 is included with the Opiliones, following Beall (1986).

FIG. 2. Current knowledge of the fossil record of Aglaspidida, Pycnogonida and Chelicerata; data in Selden (1993). Solid lines denote actual occurrence in the stage(s) concerned; interrupted lines indicate presumed occurrence in intervening stages. ? denotes doubtful record. Note that taxon ranks are not equivalent; occurrences of important genera *Sanctacaris* (most plesiomorphic chelicerate) and *Attercopus* (oldest and most plesiomorphic spider) are shown separately. Stratigraphic resolution is to stage; abbreviations in second column refer to standard stage names (see e.g. endpapers of Briggs and Crowther, 1990).

Phalangiotarbida

The situation of the phalangiotarbids has been described above. This group is only known from the Upper Carboniferous but fossils are widespread in European and North American coalfields.

Ricinulei

Ricinulei are known only from the Upper Carboniferous of Europe and North America, and the New and Old World tropics at the present day (their range extends outside the tropics mainly by cavernicole species). A recent revision of the fossils (Selden, 1992) revealed a greater diversity in the Carboniferous than today, but based on an essentially similar body plan. It appears that the group has remained in warm, humid habitats (equatorial forest litter and caves) throughout its geological history.

Mites

The oldest mites are Actinedida (Prostigmata) from the Lower Devonian Rhynie Chert of Scotland (Hirst, 1923). Other Devonian Actinotrichida are known from Gilboa, New York (Norton *et al.*, 1988, 1989; Kethley *et al.*, 1989). A few Jurassic and Cretaceous Actinotrichida are known (e.g. Bulanova-Zakhavatkina, 1974; Krivolutsky and Ryabinin, 1976; Sivhed and Wallwork, 1978), but the majority of fossil mites are oribatids from Baltic amber (e.g. Koch and Berendt, 1854; Sellnick, 1918, 1931). Anactinotrichida are very poorly represented in the fossil record; there are no fossil Opilioacarida or Holothyrida and only a few, somewhat suspect, records of Ixodida (e.g. Scudder, 1890) and Gamasida (e.g. Hirschmann, 1971). Fossil mites are probably found routinely in palynological preparations but are unreported. With the growth of micropalaeontological techniques in the study of fossil arthropods it is likely that many more fossil mites will be identified.

Palpigradi

The preservation potential of palpigrades is even lower than that of mites. Their small size, thin cuticles and interstitial habitats makes them difficult objects of study when Recent or fossil. *Sternarthron zitteli* Haase, 1890, from the Jurassic lithographic limestone of Solnhofen, Germany, is doubtful; the only good fossil palpigrade is *Palaeokoenenia mordax* Rowland and Sissom, 1980, from the 'Onyx Marble' quarries (Pliocene) of Arizona.

Haptopoda

This monotypic order was established by Pocock (1911) on the basis of the subdivided tarsus of the first leg. Petrunkevitch (1949) cleaned and reexamined the specimens, and redefined the order based on a new interpretation of the abdominal segmentation. The group would repay restudy along with Anthracomartida and Trigonotarbida.

Anthracomartida

Together with Haptopoda, this order forms Petrunkevitch's 1949 subclass Stethostomata. In a discussion of the rationale for separating Stethostomata from Soluta (Shear and Selden, 1986; Shear *et al.*, 1987), it was concluded that the only feature separating anthracomartids from trigonotarbids is two versus one rows of marginal tergal plates on the opisthosoma. Again, this common Upper Carboniferous group needs careful restudy.

Trigonotarbida

Trigonotarbids are the best known extinct arachnid group on account of their excellent preservation in the Devonian Rhynie Chert of Scotland and Gilboa mudstones of New York and are among the first known land animals (Jeram *et al.*, 1990). First described from Upper Carboniferous rocks (Buckland, 1837; Fritsch, 1901; Pocock, 1902, 1903, 1911), Hirst (1923) described the first Devonian specimens (from Rhynie), and Størmer (1970) described forms from the Middle Devonian of Alken-an-der-Mosel, Germany. Trigonotarbida is one of the few arachnids groups found relatively frequently in Palaeozoic terrestrial rocks of from Argentina (Pinto and Hünicken, 1980), Spain (Selden and Romano, 1983), Czechoslovakia (Opluštil, 1985), and Germany (Jux, 1982).

The exquisite preservation of the Rhynie Chert meant that Hirst (1923) could describe minute details of the trigonotarbids from that deposit. Trigonotarbids from Gilboa (Shear *et al.*, 1987) not only confirmed Hirst's observations but also uncovered further morphological features of these interesting animals. Later work has shown that some of the species described as trigonotarbids in 1987 were really spiders or other pulmonate arachnids (Selden *et al.*, 1991), but the systematic position of the Trigonotarbida, sister to all other pulmonates, was strengthened. A trigonotarbid and centipedes, found together with early land plants in Silurian (basal Přídoli) sediments at Ludford Lane, Ludlow, England (Jeram

et al., 1990), pushed back the earliest record of land animals by around 16 million years and indicated that trigonotarbids were among the earliest terrestrial animals.

Araneae

Great strides have been made recently in spider systematics (Coddington and Levi, 1991) and concomitantly, new finds of fossil spiders have added to the geological record. The oldest spider is *Attercopus fimbriunguis* Shear, Selden and Rolfe, 1987, from Gilboa; supposed spiders from Rhynie (Hirst, 1923) and Alken-an-der-Mosel (Stormer, 1976) have been disproved (Selden *et al.*, 1991). *Attercopus* is sister to all other spiders; the patella-tibia joint is a rocking joint but in a more plesiomorphic state than other spiders, lacking the 'compression zone Y' of Manton (1977). Autapomorphies of the *Attercopus* clade are: fimbriate paired claws, spinules on the palpal femur, and lack of trichobothria; the latter feature is puzzling.

In spite of descriptions of Devonian and Carboniferous araneomorph spiders (Archaeometidae Petrunkevitch, 1949; Pyritaraneidae Petrunkevitch, 1953), none of those seen by the author could be proved to be a spider at all. Petrunkevitch seemed to concur with Fritsch (1904) and Pocock (1911) in their placement of fossils in the Araneomorphae without question, even if he disagreed with their detailed descriptions. All of these authors seemed to place fossils in Araneomorphae on the basis of their general resemblance to particular groups of araneomorph spiders rather than real characters. For example, Petrunkevitch (1953:107) defined Pyritaraneidae and redefined Arachaeometidae as araneomorph spiders with segmented opisthosomae, differing from each other by their laterigrade and prograde legs respectively. Nowhere is the identification as araneomorphs questioned. Eskov and Zonshtein (1990a) considered segmentation of the opisthosoma in the Pyritaraneidae to be an artifact, but agreed that this family belongs in Araneomorphae. Selden *et al.* (1991) studied *Archaeometa nephilina* Pocock, 1911 in the British Museum (Natural History) and a plaster cast of *A. devonica* Stormer, 1976 from the Senckenberg Museum, concluding that neither species was a spider and that *A. devonica* may not be an arachnid at all. Carboniferous Arthrolycosidae Fritsch, 1904 and Arthromygalidae Petrunkevitch, 1923 in the British Museum (Natural History) can be placed with the mesotheles because of the distinct tergites on their opisthosomae. Eskov and Zonshtein (1990b) argued for a new group of Carboniferous 'labidognathous liphistiomorphs' on the evidence that the fossils lacked chelicerae yet any spider with orthognath chelicerae would have them preserved if the carapace and palps were. This argument presupposes that orthognath chelicerae are always porrect, which they may not be. To argue morphology from preservation (or lack of it!) is a dangerous practice.

Until recently, no mygalomorph spider was known earlier than the Tertiary. Eskov and Zonshtein (1990a) described some mygalomorphs from Siberia and Mongolia, placing them in the modern Mecicobothriidae, Atypidae and Antrodiaetidae. They are exceptionally well preserved, but poorly illustrated and described; in contrast, the line drawings are of high quality. In 1992, with the description of a Triassic mygalomorph, *Rosamygale*, our knowledge of the antiquity of mygalomorphs was more than doubled (Selden and Gall, 1992). This was placed in the extant family Hexathelidae, and suggests a widespread distribution of the family across Pangaea before rifting of the supercontinent. Hexathelids show many plesiomorphic characters among mygalomorphs but nevertheless, mygalomorphs may yet be found in Palaeozoic rocks.

Mesozoic spiders have only recently been discovered. The oldest fossil araneomorph is *Juraraneus rasnitsyni* Eskov, 1984, placed in a new family, Juraraneidae, in the Araneoidea. *Juraraneus*, like the mygalomorphs described by Eskov and Zonshtein (1990a), is well preserved but rather poorly documented for such an important find, so it is difficult to be sure whether the placement is justified. Eskov (1987) has also described Archaeidae from the Jurassic of Kazakhstan from where Filistatidae are currently being described (Eskov, 1990).

Recent finds of Cretaceous araneomorphs have emphasized the diversity of a spider fauna of modern aspect during this period. Unfortunately, some show little morphological detail (Jell and Duncan, 1986), but Selden (1990a) described specimens from the Lower Cretaceous of northeast Spain, beautifully preserved in lithographic limestone. The specimens included a deinopoid and a tetragnathid, so both cribellate and ecribellate orb-web weavers were in existence at this time. In broad terms, by the Tertiary, the spider fauna was almost identical to that of today, and only 3 families are known to have become extinct since the Palaeogene (Eskov, 1990).

Uropygi

Well preserved uropygids are found in Coal Measure rocks in Europe (e.g. Brauckmann and Koch, 1983) and North America. All are placed in the modern Thelyphonidae.

Schizomida

Three species of schizomids are known from the Pliocene 'Onyx Marble' quarries of Arizona and one from the Oligocene of China (Lin *et al.*, 1988).

Amblypygi

Fossil amblypygi are known from the Coal Measures of Europe and North America and from Tertiary ambers (e.g. Schawaller, 1979). Amblypygi may be present in the Devonian of Gilboa: a possible pedipalp tarsus was figured by Shear *et al.* (1984) and *Ecchosis pulchribothrium* Selden and Shear, 1991 may belong in this group (Selden *et al.*, 1991).

ARACHNID PHYLOGENY

Selden (1990b) discussed three recent phylogenetic hypotheses with the evidence of the fossil record (Fig. 3). A cladogram which accurately reflects evolutionary events predicts that successive dichotomies should occur in ascending chronological order, and a complete fossil record should show this. Weygoldt and Paulus's (1979) analysis (Fig. 3c) predicts that palpigrades should occur in strata at least as old as Devonian because the more derived mites and pseudoscorpions occur in beds of that age. In their scheme, Opiliones occupy a derived position. Van der Hammen (1989; fig. 3b) suggested that Opiliones should occur the Cambrian since they are tentatively shown as sister group to Xiphosura + Scorpiones. Shultz (1989, 1990; Fig. 3a) also placed Opiliones in a position which predicts their presence in Silurian times. Since scorpions were aquatic then, so would opilionids have been.

None of the phylogenetic analyses (Fig. 3) incorporated extinct groups. Whilst it is impossible to include ancestors in cladistic analyses, there is no reason why well known extinct groups should not be included, say at the Carboniferous level. Apart from the enigmatic palpigrades and the highly derived Schizomida, for which fossil evidence is lacking, all arachnid orders were in existence by that time.

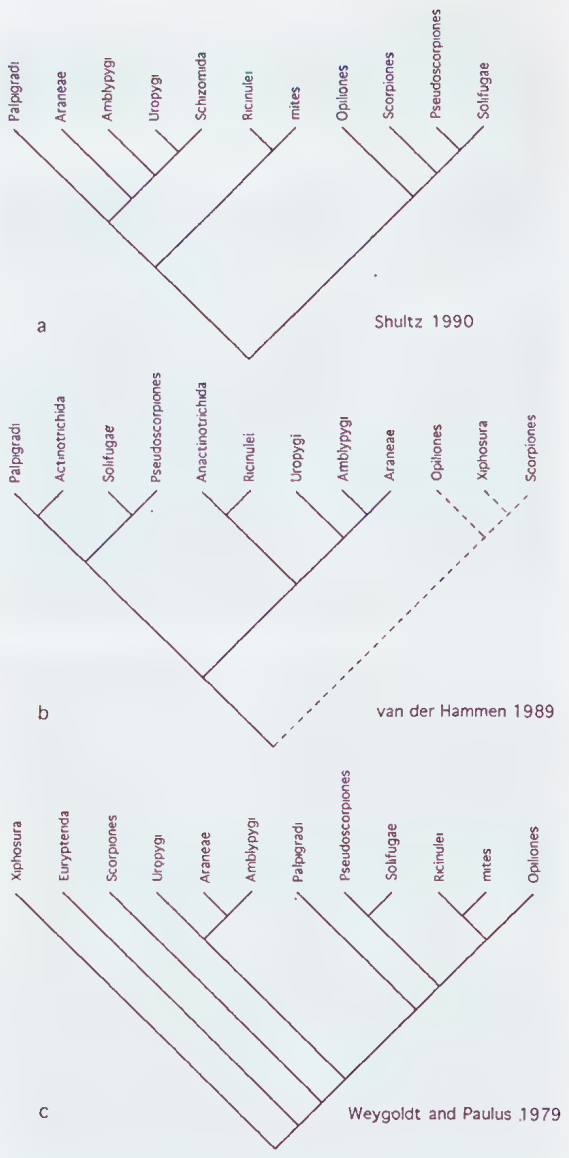

FIG. 3. Cladograms of relationships among the arachnid groups as viewed by a, Shultz (1990); b, van der Hammen (1989); and c, Weygoldt and Paulus (1979). Interrupted lines indicate uncertainty.

FUTURE PROSPECTS

Work in progress includes: palaeophysiology of early terrestrial chelicerates–aquatic and terrestrial adaptations in eurypterids, scorpions, and other Siluro-Devonian arachnids; palaeobiology of the Trigonotarbida; and Cretaceous spiders from Canadian amber and the Santana Formation of Brazil.

Much of Petrunkevitch's work needs revision. A new phalangiotarbid fauna has been collected in recent years from a coal mine tip in Somerset, England (Beall, 1991). Carboniferous Anthracomartida and Haptopoda need to be restudied, particularly in relation to the now extremely well known and possibly related trigonotarbids. The identity of described Amblypygi is in little doubt, but modern descriptions would be helpful. In need of critical examination are: the single fossil solifuge *Protosolpuga* from Mazon Creek, the supposed palpigrade *Sternarthron* from the Jurassic of Germany, and the amber spiders described by Petrunkevitch (e.g. 1942, 1950, 1958). The problem with these spiders is that over the years some of the supposed 'amber' in collections has discoloured, which suggests it may not be truly Palaeogene but rather more recent copal or other resins.

Successful palaeoarachnology requires knowledge of both Recent arachnids and understanding of styles of fossil preservation. Much previous work suffered from erroneous interpretations of one sort or another. Goals for future work are: to understand the origin of the present-day diversity of arachnids and the relationships among the various groups, and the reconstruction of ancient terrestrial ecosystems.

SCORPIONS AS MODEL VEHICLES TO ADVANCE THEORIES OF POPULATION AND COMMUNITY ECOLOGY: THE ROLE OF SCORPIONS IN DESERT COMMUNITIES

GARY A. POLIS

Polis, G.A. 1993 11 11: Scorpions as model vehicles to advance theories of population and community ecology: the role of scorpions in desert communities. *Memoirs of the Queensland Museum* **33**(2): 401-410. Brisbane. ISSN 0079-8835.

The diversity (5-16 species) and abundance (0.2-1.0 individuals/m^2) of scorpions suggest that they may be quite ecologically important in desert communities. Ecological importance is considered in terms of population energetics (the quantity of energy and mass flowing through populations) and of regulation of community structure and dynamics (influence on the distribution and abundance of other species). The energetic analysis provided three conclusions: 1) Scorpions monopolise a relatively large share of animal biomass, particularly relative to vertebrates and other arthropods. 2) This relative success is due to a suite of autecological traits (very low metabolism and very high assimilation efficiency leading to low energy requirements; and great tolerances to water stress, heat and starvation) that allows scorpions to prosper under the unpredictable and low food availability conditions that characterise deserts. 3) However, these traits lessen their impact on energetics, prey and competitors. Thus the importance of scorpions relative to homeothermic vertebrates is less than an analysis of density and biomass suggest because scorpions require and process prey in quantities relatively low to their biomass. Nevertheless, as a group, scorpions are probably important conduits of energy flow in deserts.

Research on the interactions among scorpions and between scorpions and spiders strongly suggests that scorpions can play key roles in the structure and dynamics of their communities. Studies in the deserts of California, Baja California and Namibia show that intraguild predation by scorpions is a major force determining the (temporal and spatial) distribution, abundance and age structure of populations of their competitors/prey.□*Araneae, Scorpionida, age structure, distribution, intraguild predation, population and community ecology.*

Gary A. Polis, Department of Biology, Vanderbilt University, Nashville, Tennessee 37235, U.S.A.; 26 October, 1992.

Ecology is a rapidly developing area with a great deal of internal argument and disagreement. As in other fields, theory has advanced far more rapidly than empirical work. Consequently, much theory is controversial and in need of empirical evaluation. Scorpions possess a number of characteristics that make them ideal models to test and advance ecological theory. Thus, it is relatively easy to collect rapidly great amounts of data and to manipulate experimentally individuals and entire populations. Research on scorpions has contributed to many areas of population, behavioral and community ecology: e.g., the evolution of life history theory (Polis and Farley, 1980), the evolution and ecology of age-structured populations (Polis, 1984a, 1988; McCormick and Polis, 1986a), the dynamics of cannibalism (Polis, 1980a, 1981, 1984b), the dynamics of intraguild predation (Polis and McCormick, 1986b, 1987; Polis *et al.*, 1989), the evolution and ecology of foraging strategies (Polis, 1980b; Bradley, 1988), patterns and processes in biogeography (Due and Polis, 1986) and the patterns and processes affecting community and food web structure (Bradley, 1983; Polis, 1991a).

In this paper I evaluate the 'ecological importance' of scorpions. Throughout, I indicate how research on scorpions has advanced our general understanding of ecology. Although scorpions occur in almost all non-boreal habitats, I focus on desert scorpions because much evidence suggests that they may be particularly important components of arid ecosystems and are a relatively 'successful' group. They are diverse, some taxa are extraordinarily abundant, and, as a group, they form a large proportion of the biomass of all desert arthropods and easily exceed the biomass of all desert vertebrates. Their success arises partially because they exhibit several physiological and ecological traits that pre-adapt them to the low and unpredictable food levels of deserts.

'Ecological importance' can be expressed in terms of either energetics and nutrient cycling

(the quantity of matter and energy flowing through a population or functional group) or regulation of community structure and dynamics (the impact on diversity, distribution and abundance of other populations).

ENERGETICS AND NUTRIENT CYCLING

The importance of desert scorpions on energy and nutrient cycling is a function of the quantity of prey biomass captured. The amount of captured biomass is a function of the density, population biomass, metabolism and efficiency of energy transfer. I now present a very rough approximation of the relative importance of scorpions to the flow of energy and nutrients in desert ecosystems. To approach this question, data were compiled from the literature reporting the diversity, density and biomass of various groups of desert taxa (see Polis, 1990, 1991b; Polis and Yamashita, 1991 for additional details). These data are not without bias and other problems. For example, studies are not usually conducted in areas where the focal taxon is absent or rare; nor are rare species studied as often as common ones. Consequently, the statistics presented here overestimate density and biomass and should be taken as a first approximation of actual parameters. However, the data are instructive and suggest that scorpions could be a major link in the flow of energy through desert communities.

Group	Density (no./ha)	Diversity (no. species)	n
Mammals	43±130	28.5±21.3	14
Birds	0.6±1.1	46.7±27.3	14
Lizards	36.8±43	12±4.6	12
Insects	35,100±54,600	592±796	10
Termites	4,025,000±2,793,000	9.1±15	7
Isopods	241,810±336,850	1.3±0.8	7
Millipedes	1150±214	2.4±2.1	7
Spiders	3220±8800	54.4±26.7	31
Solpugids		9.9±6.7	37
Scorpions	3210±3500	7.1±2.5	58

TABLE 1. Estimated average density and diversity of major taxa of desert macrofauna reported from the literature. Diversity is the mean number of species per taxon from local sites in different deserts. Density statistics were standardized to a per hectare basis. Means are reported with their standard deviations; n = sample size. Note that these statistics should be viewed as very rough approximations rather than absolute values. Note that data on ants were insufficient to include here (see Polis and Yamashita, 1991 for further details).

How do desert scorpions measure against other groups of consumers for these parameters? First, scorpions are relatively speciose in deserts. On the average, 7.1 species co-occur in desert throughout the world (range: 2-16 sympatric species, typically, 5-9 species; Polis, 1990) (see Table 1 for comparison with other desert taxa). Furthermore, populations are often quite dense, averaging>3200 individuals/ha with several species maintaining populations 5000-10,000/ha (e.g., Shorthouse, 1971; Lamoral, 1978; Polis and Farley, 1980; Polis and McCormick, 1986a; Bradley, 1986; Polis, 1990). On the average, scorpions are reportedly more dense than all other macroscopic animal taxa in these deserts except 'insects', termites, and isopods (ants are undoubtedly also more dense) (Table 1). Since scorpions are among the largest of all terrestrial arthropods (adults of most desert species = 0.5-10g; Polis and Farley, 1980), these high densities produce rather large estimates of standing biomass (= density of individual species x mass of individual animal). Each species population of desert scorpion averaged 7.15 kg/ha. Only termites (and probably ants) support a greater population biomass per

Taxon	Population per species	Biomass (kg/ha) per taxon	n
Mammals	1.40	39.9	29
Birds	0.02	0.9	25
Lizards	0.57	6.8	46
'Insects'	0.88	521.2	31
Termites	12.45	113.4	7
Isopods	9.91	12.8	2
Millipedes	1.15	2.8	2
Spiders	0.13	7.1	4
Scorpions	7.15	50.8	17
All vertebrates		47.7	
All arthropods		708.1	
All macrofauna		755.8	

TABLE 2. Estimated population biomass for various taxa taken from literature. Population biomass per species is average wet weight of one species per hectare. This statistic was sometimes reported; however, it was often calculated by multiplying the average mass of an individual times the density. Population biomass per taxa is calculated as the product of population biomass per species and average diversity of that taxon. Note that data on ants were insufficient to include. Additional information is reported in Polis and Yamashita (1991). n refers to the number of species in a particular taxon for which biomass data exist. Note that these statistics are only gross approximations of reality.

species or per taxon (from the ordinal level down) than scorpions (Table 2).

When the biomass of all scorpions living sympatrically in desert areas is calculated (= mass of individual species x average number of sympatric species), scorpions as a group exhibit a greater biomass (= 50.8kg/ha) than all other taxa except termites (=113.4Kg/ha) and the sum of all other insects (= 521.2kg/ha; Table 2). Note also that the population biomass of scorpions is higher than any one group of vertebrates (e.g., mammals and lizards average 39.9 and 6.8Kg/ha) or all vertebrates combined (47.7kg/ha). Overall, scorpions form 6.7% of the biomass of all macrofauna species combined, 7.1% of the biomass of all macroarthropods and 106% of the biomass of all vertebrates.

Thus it would appear that they are important conduits for energy transfer in deserts. However, two characteristics lessen their importance. First, they exhibit the highest ecological (production) efficiencies (percent assimilated energy incorporated into new biomass) of all taxa that live in the desert (Table 3). Second, they exhibit metabolisms that are extremely low relative to other poikilotherms and endotherms (Table 4). Although these features are powerful adaptations that allow efficient use of food and partially explain the success of scorpions in deserts, they also function to decrease the amount of energy transferred. Thus a gram of scorpion does not process as much food as a gram of arthropodivorous vertebrate. Overall then, desert scorpions are less important in energy and nutrient cycling than their diversity, abundance and biomass suggest.

How much energy do desert scorpions process? We have two estimates. Polis (1988) calculated that average populations of *Paruroctonus mesaensis* used 9000 grams of prey/ha/year. The Australian *Urodacus yaschenkoi* requires 7900g/ha/year; this translates into 98,400 ants or 31,570 medium sized spiders eaten per hectare per year (Shorthouse, 1971; Marples and Shorthouse, 1982). It is uncertain exactly how such figures for individual scorpions or for the sum of all sympatric species of scorpions compare to those for vertebrates. This is an interesting question to pursue.

Group	P/A%
Insectivorous mammals	0.86
Birds	1.29
Small mammals	1.51
'Other' mammals	3.14
'Homeotherms'	3.1
Fish	9.77
Social insects	10.3
Terrestrial invertebrates*	25.0
Solitary herbivorous insects	38.8
Solitary detritivorous insects	47.0
Solitary carnivorous insects	55.6
Spiders	45-60
Scorpions	68.2

TABLE 3. Ecological (Production Efficiency) of various animal taxa. This efficiency is equal tothe proportion of assimilated energy that is incorporated into new biomass (=Production/Assimilation). Note that the highest efficiencies are found in carnivorous insects, spiders and scorpions. *Terrestrial invertebrates do not include insects or arachnids. (primarily from Humphreys, 1979; see Polis and Yamashita, 1991 for further details).

INFLUENCE ON COMMUNITY STRUCTURE AND DYNAMICS

The second measure of ecological importance is to determine how a taxon influences the dynamics, distribution and abundance of other taxa. In theory, scorpions can influence desert communities in many ways: as predators affecting characteristics of their prey, as prey of other predators and as competitors of other arthropodivores.

One of the basic questions in ecology is: 'What factors determine the distribution and abundance of species?' To approach this question, researchers often focus on groups of similar species that use similar resources; especially those resources the supply of which may be limiting and in demand (e.g., food). Such species groups

Taxon	Metabolic rate ($ml/O_2/gm/hr$)
Homeotherms (basal rates)	
Mammals	0.07-7.4
shrew	7.4
rodents	1.80
elephant	0.07
Birds	2.3-4.7
Poikilotherms (at 25°C)	
Insects	1.665 ± 1.25
Spiders	0.92 ± 0.92
Scorpions	0.057 ± 0.048

TABLE 4. Metabolic rates of various animal taxa. The data are taken from many sources. The sample size for insects is 82 species; for spiders, 8 species; and for scorpions, 7 species. (see Polis and Yamashita, 1991 for further details).

are called guilds (= a group of species that use resources in a similar way and are thus potential competitors). For example, guilds of desert granivores (birds, ants, rodents) all eat seeds, regardless of specific differences in resource acquisition.

One approach to study guilds is to describe their patterns or structure. By guild structure, we mean the diversity and abundance of species members; spatial and temporal patterns and resource use (i.e., niche characteristics). However, such descriptive studies, although common, are not fully satisfying because they do not directly address the processes that produce the observed patterns.

An alternative approach is to determine if guild members interact, and if so, can such interactions significantly shape guild structure. There are several possible ways that guild members can interact. These range from cooperation and mutualism to competition and even predation. Such predation among guild members is called intraguild predation (Polis and McCormick, 1987; Polis *et al.*, 1989). Intraguild predation is an ubiquitous interaction among many assemblages of potential competitor but has received little formal attention from either theorists or empiricists (Polis *et al.*, 1989).

One major theme of my research with scorpions has been to analyze the characteristics and significance of intraguild predation. Many scorpion prey items (other scorpions, spiders and solpugids) are also potential competitors with scorpions (Polis, 1990; Polis, 1991a, b; Polis and Yamashita, 1991). I present information on three systems; in each, scorpions frequently eat species in the same guild of arthropodivorous predators and such intraguild predation significantly affects the distribution, abundance and population dynamics of these potential competitors. I used scorpions in these studies as models to delineate the characteristics and dynamics of intraguild predation. These studies illustrate how scorpions have proved to be extraordinarily amendable for ecological research: large amounts of data can be collected, interactions (e.g., feedings) observed and quantified relatively easily, and individuals or whole populations manipulated experimentally. For example, in the first study, field data were collected on 130,000 individuals, 2000 feedings and 6000 individual scorpions were manipulated in controlled field experiments.

INTERACTIONS AMONG SCORPIONS IN THE COACHELLA VALLEY

Four species of desert scorpion co-occur in sandy habitats on the floor of the Coachella Valley (Riverside County, California). Three are in the family Vaejovidae (*Paruroctonus mesaensis* Stahnke, *P. luteolus* Gertsch and *Vaejovis confusus* Stahnke); one (*Hadrurus arizonensis* Ewing), the Iuridae (Polis and McCormick, 1986a, 1987). *Paruroctonus mesaensis* form >95% of all individuals and occur at densities in the range of 0.2-0.5 individuals/ha; the other three species are relatively rare. Each species requires 2-5 years to mature and is composed of several distinctly sized year classes. Size changes greatly, e.g., *P. mesaensis* increase 60-80 times in weight from 0.03g (instar 2) to 2.0-2.5g (non-gravid adults). The year classes and species overlap to various degrees in use of insect and arachnid prey; average overlap among all species is moderate to high (0.67 [prey size] and 0.43 [prey taxa]). Thus, the scorpions potentially compete for food.

Extensive intraguild predation occurs among the four species; Table 5 presents a matrix of who eats whom. Several factors characterize this intraguild predation: 1) Each species was both an intraguild predator and prey. Such mutual predation occurs simply because the predator scorpion was always larger regardless of the species combination involved (n= 170 scorpion-scorpion predations). Thus scorpions of all species are vulnerable as they grow from small juveniles to full size adults and predatory reversals (mutual predations) are common. For example, young *P. mesaensis* scorpions are eaten by relatively larger adult *P. luteolus* and *Vaejovis confusus*; adult *P. mesaensis* prey on the (now) relatively smaller adults of these species. Thus age/size is a key

	PREY				
PREDATOR	*H.ari*	*P.lut*	*P.mes*	*V.con*	Total
Hadrurus	0.0	6.3	12.5	3.1	21.9
P. luteolus	0.0	33.3	6.7	6.7	46.7
P. mesaensis	0.4	0.5	5.0	8.3	14.2
Vaejovis	0.0	0.0	8.0	4.0	12.0

TABLE 5. Scorpion-scorpion predation in the Coachella Valley. The entries represent the percent of the diet that each species forms as prey for each of the four scorpion species. The diagonal represents intraspecific predation (cannibalism) (from Polis & McCormick, 1987). *H.ari=Hadrurus arizonensis; P.lut = Paruroctonus luteolus; P.mes= Paruroctonus mesaensis; V.con =Vaejovis confusus.*

determinate of intraguild predation: adults are the predators and immature individuals are the prey significantly more frequently than expected by chance. 2) The most common species (*P. mesaensis*) was the predator in 91% of all intraguild predations observed. Its average overlap in prey use (= 0.44) with other scorpion species was second highest. 3) Intraguild predation, at least by *P. mesaensis*, is significantly more frequent when prey availability was low: when <1% of the population was feeding, heterospecifics formed 35% of all diet items. In contrast when the percent feeding was >5%, only 3.2% of all prey were other species of scorpion. 4) Mortality caused by intraguild predation was generally an inverse function of the density of both *P. luteolus* and *V. confusus*; this resulted because much of the surface activity of these two species occurred during (less productive) periods when *P. mesaensis* was absent from the surface. 5) Intraguild predation is important in scorpion population dynamics. When analyzed as percent mortality of small species (here = total number of individuals eaten by *P. mesaensis* divided by the total number ever observed), intraguild predation by *P. mesaensis* killed 8% and 6% of all *P. luteolus* and *V. confusus* ever observed.

Can such high rates of mortality cause the rarity of these species? It is only possible to approach this question using field experiments. Removal of >6000 *P. mesaensis* (=3.2Kg) from 300 (100m^2) quadrats over a 29 month period demonstrated that the rarity of these species is caused substantially by intraguild predation from *P. mesaensis*. 6) Both *P. luteolus* and *V. confusus* (but not *H. arizonensis*) increased significantly (600% and 135%) in removal as compared with 60 control quadrats. It was speculated that the rarity of the largest species (*H. arizonensis*) is a result of a bottleneck in adult recruitment; predation by *P. mesaensis* killed >10% of all newborn *H. arizonensis* observed during the study. 7) The age structure of these smaller species was significantly different in removal areas: first year juveniles were 1.75 to 2.85 more abundant in removals versus controls. This suggest that the numerical response by the rarer species would be even more dramatic if this experiment continued beyond its 29 month period. Note that a plausible alternative hypothesis exists: removal of *P. mesaensis* relaxed exploitation competition and thus allowed the observed increases in density. A robust test failed to detect competition in this system (Polis and McCormick, 1986b, 1987).

Thus, intraguild predation by *P. mesaensis* significantly depressed the abundance of the rarer species. Does intraguild predation likewise affect their distribution? Since predation is apparently a key factor in the population dynamics of these species, natural selection is expected to favor adaptations that reduce the probability that an individual will encounter its predator. Indeed prey often avoid places and times that their predators frequent or where the probability of predation is high (see Polis and McCormick, 1987). Typically, the large predatory entity (e.g., scorpion species and/or age class) occurs in productive periods and microhabitats whereas smaller entities coexist by spatial segregation in a heterogeneous habitat and by temporal displacement.

The temporal and spatial distribution of smaller age classes and species of Coachella Valley scorpions reflect avoidance (in ecological and/or evolutionary time) of larger age classes and species. The overall distribution of *P. luteolus* and *V. confusus* tend to place these species on the surface during times (in winter, late fall) and in places (off sand) characterized by relatively low surface populations of adult *P. mesaensis*. These times and microhabitats support significantly less prey than those used by adult *P. mesaensis*; consequently *P. mesaensis* has a feeding rate (2.95%) significantly greater than all other species combined (1.70%). Further, the minority of *P. luteolus* and *V. confusus* that forage when and where *P. mesaensis* is active suffer a disproportionately greater chance of being eaten by *P. mesaensis*. Intraspecific predation (cannibalism) has produced similar patterns of temporal distribution, feeding and mortality patterns among age classes of *P. mesaensis* (Polis, 1980, 1984a).

Thus, intraguild predation is an important factor limiting the abundance and shaping the distribution of these scorpions. Many other assemblages of desert scorpions exhibit patterns that suggest that scorpion-scorpion predation is a major process shaping distribution and abundance (Polis and McCormick, 1987; Polis, 1990; but see Bradley, 1988).

INTERACTIONS AMONG SCORPIONS, SPIDERS AND SOLPUGIDS IN THE COACHELLA VALLEY

Scorpions also frequently eat competitors other than other scorpions. For example, the diet of the scorpion *P. mesaensis* consisted of 8% spiders and 14% solpugids (Polis and McCormick, 1986b). Does such intraguild predation sig-

nificantly affect the distribution and abundance of these unrelated taxa? Spiders responded in the above experimental removal of >6000 *P. mesaensis* by doubling in removal quadrats as compared to controls. Surprisingly, neither solpugids nor all insects combined increased significantly (all $p > .05$) in removal plots. These taxa did not increase either because individuals dispersed from removal areas, because the increase of spiders and smaller scorpions compensated for the removal of *P. mesaensis* by eating surplus arthropods, or simply that scorpions exerted little impact on insect populations. The first explanation is likely true for widely foraging solpugids and is possible but unlikely for the more sessile insects. The second explanation is unlikely: the biomass increase of spiders and scorpions represented <10% of the removed *P. mesaensis* biomass. The third explanation, difficult to accept, is nonetheless a real possibility: *P. mesaensis* may take such a small proportion of all insects that its removal does not affect insect density.

INTERACTIONS BETWEEN SCORPIONS AND SPIDERS IN THE NAMIB DESERT

Predation by scorpions on spiders also appears to be a key determinant of spider densities in the Namib Desert (Polis and Seely, unpublished research, 1988, 1989). Both the scorpion *Uroplectes otjimbinguensis* (Karsch) (Buthidae) and the spider *Gandanimeno echinatus* (Purcell) (Eresidae) live under loose bark on larger *Acacia* trees and are the major arboreal predators of insects on such trees. Populations of *G. echinatus* are severely reduced when they co-occur locally on *Acacia erioloba* trees with the scorpion *U. otjimbinguensis*. This system is a model example how predator-prey interactions are complicated greatly by patterns of local distribution. Not all suitable patches (*Acacia* trees) contain the full array of local species capable of existing within the patch. Trees grow along the banks of dry rivers (e.g., the Kuiseb) and become less dense and more sporadic with increasing distance from the river bed. The local abundance of scorpions and spiders on each tree is a function of differential dispersal, extinction and a predator-prey relationship with *U. otjimbinguensis* scorpions eating *G. echinatus* spiders. Although both species are found on river trees, *U. otjimbinguensis* is, with no exceptions, the numerically dominant species (10-50 scorpions/trees) and *G. echinatus* is relatively uncommon (5-20/tree). This occurs because scorpions are effective predators on these spiders.

However, this outcome is more variable on isolated trees further from the river and along smaller washes entering the river. On some trees close to the river, the abundance of scorpions and spiders is similar to that found in the river. However, some trees have no scorpions and great numbers of spiders (50-400/tree); some trees have neither scorpions nor spiders; and some, no scorpions and few (<20) spiders. Overall, trees without scorpions support significantly more spiders (112.3 ± 60.6, $n = 21$) than trees with scorpions (24.5 ± 14.3, $n = 20$) ($p < 0.001$; only experimental trees scored). This variation in abundance and these distributions exist because neither *U. otjimbinguensis* nor *G. echinatus* disperse far from the river, yet spiders disperse further than scorpions. Dense spider populations occur only in more isolated trees where scorpions are absent. In trees quite distant from the river, neither species occur.

Does intraguild predation by *U. otjimbinguensis* scorpions on *G. echinatus* spiders produce such patterns of distribution and abundance? Additions of *Uroplectes* over a one year period to scorpion-free trees ($n = 11$) highly significantly ($p < .001$) reduced *G. echinatus* populations to 42% of that on control trees ($n = 12$). Removal of scorpions from trees ($n = 8$) also produced a highly significant, 2.9 times increase in *G. echinatus* as compared to control trees ($n = 12$) with their full complement of scorpions.

These experiments showed that intraguild predation was concentrated on young spiders and could significantly alter age distributions ($p < .001$ for each of the following comparisons): The smallest size class of spiders on experimental trees represented 49% of the population ($n = 728$ spiders) one year after scorpions were removed compared to only 31% ($n = 221$) on control trees where scorpions remained; similarly, the smallest size class formed 48% of all spiders ($n = 903$) on trees where scorpions were not present compared to 34% ($n = 820$) on those trees to which scorpions were added.

Thus differential dispersal and semi-deterministic biotic interactions combined with differing isolation of patches are major determinants of the distribution, abundance and age structure of these species. In general, historical and stochastic dispersal events in patchy environments are a paramount factor explaining the distribution and abundance of predators and their prey and species of competitors (Polis, 1991b; Polis and

Yamashita, 1991). Such conditions can produce local extinctions or great variance in abundances via deterministic biotic interactions, but promote global coexistence. I suspect that such situations are normal among many species living in the notoriously heterogeneous desert. Many such assemblages occur in patches; differential dispersal, local extinctions and 'hide-and-seek' dynamics are undoubtedly extremely important in determining the exact structure of local assemblages. Unfortunately, little research has focused on these processes. The system with scorpions and spiders on *Acacia* trees is ideally suited to analyze such processes and represent another example of the use of scorpions to advance our comprehension of ecological processes.

INTERACTIONS BETWEEN SCORPIONS AND SPIDERS ON ISLANDS IN THE GULF OF CALIFORNIA

This system shows several of the same general processes as the one on *Acacia* trees in the Namib and illustrates the importance of predator-prey interactions occurring between spatially structured populations. Spider, scorpion and/or lizard populations on small islands (approximately $<1km^2$) are 1-3 orders of magnitude more dense than on larger islands (approximately 1-$1000km^2$) and the mainland; significant negative relationships occur between island size and density for each of these taxa. For example, the scorpion *Centruroides exilicauda* is 2-25 times more abundant on small islands. Three major variables likely explain the great variance in spider abundance: 1) the presence of scorpion predators (often absent from small islands); 2) the dispersal and colonizing ability of spiders relative to scorpions (better colonizers of small islands as compared to scorpions); and 3) differential energy flow from marine to terrestrial systems (much greater to small islands).

This research has been in progress for four years (1989-1992) in the Midrift area of the Gulf on 41 island and 6 mainland sites between Bahia de Los Angeles (Baja California del Norte, Mexico) and Guaymas (Sonora, Mexico) (Polis unpublished). Scorpion and spider abundance were quantified at each site; spiders were counted on >4000 cacti (one sample unit) and $>8000m^2$ of supralittoral shoreline (another sample unit). Insect abundance was estimated at these sites for >1000 trap days.

Small islands ($<1km^2$) exhibit highly significantly greater secondary production of arthropods than larger islands and mainland areas. However, high productivity is not from autochthonous primary production by terrestrial plants. Evidence strongly suggests that allochthonous production from the ocean is the prime source of productivity. Many islands are 'desert islands' with limited primary productivity from terrestrial plants. Several of the most productive small islands support 2-28 plants (individuals, not species) yet 200-1000 spiders can occur on a single cactus!

Small islands are more productive than large islands and mainland areas for two reasons. First, the Perimeter : Area ratio of an island decreases with size (perimeter is a linear function; area, a square function). Thus small islands have relatively more shoreline per unit area of land and consequently, receive relatively more nutrient and energetic input from marine drift (shore wrack–algal and animal detritus). Second, species-area relations are such that small islands lack predators of nesting marine birds; thus small islands support large colonies of pelicans, gulls, petrels and terns.

Marine detritus and material from nesting birds are eaten by many (semi-) terrestrial arthropods. Some arthropods eat dead bird tissue (eggs, chicks, adults) and fish scraps. However, dipteran parasites are dense consumers of nesting birds and form an important conduit of energy from the sea to spiders. Trapping shows that insect abundance is highly significantly ($p<0.001$, all comparisons) greater in both supralittoral zones and around nests than other areas on these islands and on islands with colonies of marine birds compared to those without colonies (also see Due and Polis, 1985). Dietary analysis shows that detritivorous and parasitic arthropods act as conduits of energy from the sea when converted to large populations of terrestrial spiders, scorpions and/or lizards. For example, spiders are 2-5 times more dense on islands with colonies of marine birds versus those without colonies.

Predation is also an extremely important variable determining the abundance of these taxa. On Gulf Midrift islands, spider abundance is significantly lower in the presence of scorpions and lizards (particularly, *Centruroides exilicauda* and *Uta stansburiana*; 1990: $0.19/m^3$ cactus; 1991: $2.5/m^3$) versus their absence ($63.4/m^3$; $28.2/m^3$; both $p<.005$). The importance of scorpions but not lizards on spider abundance is suggested by the analysis of 10 islands near Guaymas in Sonora. Here, spider density is 38 times less

(0.41/m^3 cactus) on all islands with *C. exilicauda* (n=8) compared to those with lizards (15.3/m^3 cactus; n=2).

The final variables in this system are spatial structure and colonization ability. Incidence functions (percent occurrence on islands classified by area) describe the ability of taxa to disperse to and successfully remain on islands of different sizes. The incidence curves suggest that relative ability to colonize small islands roughly can be ranked: Spiders> *Uta* lizards> Scorpions> Nest predators >Songbirds. Colonization would be deterministic if a particular taxon were always present or absent for all islands of a particular size class. In fact, incidence values for smaller island size classes are neither 0 nor 100%, suggesting that presence or absence of a particular taxon is somewhat stochastic. Thus some small islands exhibit high densities of spiders because scorpions are absent whereas other similar sized islands exhibit low densities of spiders because scorpions are present.

An integration of colonizing abilities, productivity and predation is required to understand the distribution and abundance of these taxa. Each factor varies more or less regularly with island size: generally, as size increases, secondary productivity decreases, predation increases and the importance of differential colonizing ability diminishes. Multivariate analysis allows statistical dissection to determine the relative contribution of each of these factors to the observed variance in spider density. This analysis (Table 6) shows that spider density is a significant positive function of prey availability and significantly depressed in the presence of scorpions. Arthropodivorous lizards are a seemingly unimportant factor, explaining almost none of the variance in spider abundance on Midrift islands.

1990 data with lizards	df	SS	MS	F	p>F

TABLE 6. Multivariate regression of factors that may influence spider abundance on islands in the Gulf of California in 1990 and 1991. The maximum R improvement technique is used; this produces the best model given all the independent variables. Independent variables include lizard presence, scorpion presence, perimeter: area ratio of island, mean cactus volume/island and prey availability/island. The best two variable model includes perimeter: area ratio and scorpion presence. Three variable models are presented with lizards. The effect of lizards is always non-significantly weak, regardless of what higher order model is used.

In summary: Productivity sets potential maximal population size. Small islands are much more productive than larger islands because of the relative greater input of marine allochthonous productivity from drift and marine birds. Colonizing ability establishes the insular species combinations; species-area relations show that larger islands are more diverse and support more types of predators. The realized abundance of terrestrial taxa is limited by (intraguild) predation. For example, if scorpion predators are absent, spiders are dense on small, high productivity islands. When scorpions are present, spider density is lower (but still higher than on large islands and the mainland) and the density of scorpions is relatively high. As island size increases, productivity decreases because nest predators are present (thus bird colonies disappear) and allochthonous detrital input decreases as a function of island Perimeter : Area ratio. Eventually, as island size increases (with decreases in productivity and increases in predation), the abundance of spiders, lizards and scorpions decreases until abundance on very large islands approaches that of the mainland. Strong predation from many sources occurs on the relatively low productivity mainland; consequently, populations of spiders, scorpions and lizards are quite low.

CONCLUSIONS

This paper presents various types of data to evaluate the 'ecological importance' of scorpions in deserts. Ecological importance was first considered in terms of population energetics (the quantity of energy and mass flowing through scorpion populations) and second, in terms of the regulation of community structure and dynamics (how intraguild predation by scorpions influen-

ces the distribution and abundance of their competitors/prey). The energetic analysis provided three conclusions: 1) Scorpions are quite diverse and abundant in deserts. They monopolize a relatively large share of animal biomass in desert communities, particularly relative to vertebrates and other arthropods. 2) Their relative success is due to a suite of autecological traits that are particularly suited to the harsh and variable climatic conditions of deserts. These traits (very low metabolism and very high assimilation efficiency leading to low energy requirements; and great tolerances to water stress, heat and starvation) preadapt them to prosper successfully under the unpredictable and low productivity food availability that characterize deserts. 3) However, these traits (low metabolism and high assimilation efficiencies) lessen their impact on energetics, prey and competitors. Thus the importance of scorpions relative to homeothermic vertebrates is less than an analysis of density and biomass suggest because scorpions require and process prey in quantities relatively low to their biomass. Nevertheless, as a group, scorpions are probably important conduits of energy flow in deserts.

The research on the interactions among scorpions and that between scorpions and spiders strongly suggests that scorpions can play key roles in the structure and dynamics of the communities in which they live. These studies showed that intraguild predation by scorpions was a major force determining the (temporal and spatial) distribution, abundance and age structure of populations of their competitors/prey. However, as an important caveat, these interactions must be viewed in the context of the environment in which they occur. Dispersal ability, spatial structure and productivity are just some of the possible important factors that moderate the predator-prey interaction between scorpions and their intraguild prey.

The role of all ecologists is to integrate these factors to produce a synthetic understanding of the processes and dynamics that structure natural communities. I suggest that scorpions are particularly suited for this task and will continue to be a productive vehicle to advance the theoretical and empirical body of ecology.

ACKNOWLEDGEMENTS

This paper highlights the results of 10-15 years of scorpion research. It is impossible to thank individually all the wonderful people that have contributed their time and energy to this work. Key colleagues include Sharon McCormick, Mary Seely, Steve Hurd, Rick Fleet, Mike Qinlan, Tracey Wadsworth, Victor Fet, Chris Myers, Denise Due, Tsunemi Yamashita and Sharon Lee-Polis. Bill Humphreys' careful reading has improved this paper greatly. I thank the fine staff at the Queensland Museum (especially Robert Raven) and the Western Australian Museum for orchestrating such a great congress and for providing support for my attendance.

INTER-SPECIFIC ASSOCIATIONS INVOLVING SPIDERS: KLEPTOPARASITISM, MIMICRY AND MUTUALISM

MARK A. ELGAR

Elgar, M.A. 1993 11 11: Inter-specific associations involving spiders: kleptoparasitism, mimicry and mutualism. *Memoirs of the Queensland Museum* 33(2): 411-430. Brisbane. ISSN 0079-8835.

Many spiders have life-styles that involve a relatively close and prolonged association with another species; for example, between a specialist predator and its prey species, or a species may rely on another for either protection from predators or providing a suitable place to live. In asymmetric relationships, where individuals of one species benefit at the expense of the other, each species may act as a selection pressure on the other species. This can result in the evolution of specific adaptations and counter-adaptations that are evident in at least three kinds of inter-specific associations between spiders. These associations, namely kleptoparasitism, mimicry and mutualism are reviewed here. Our understanding of the evolution of these fascinating systems remains limited, despite numerous anecdotal accounts, because only a few studies are experimental. The purpose of this review is two-fold: to illustrate the use of comparative and experimental studies for understanding the evolutionary significance of these inter-specific relationships, and to highlight those gaps in our knowledge that might benefit from this approach.□*Inter-specific associations, spiders, kleptoparasitism, mimicry, mutualism.*

Mark A. Elgar, Department of Zoology, University of Melbourne, Parkville, Victoria 3052, Australia; 18 January, 1993.

Individuals of one species can affect individuals of another as a result of competition, predation, parasitism or mutualism. The evolutionary implications of any association between two or more species depends critically on the frequency and nature of the interaction. For example, a species may be the prey of many species of generalist predators. While these predators may represent an important selective pressure favouring anti-predator responses in the prey species, the adaptations of the prey may have little impact on the reproductive success of the predators. In contrast, a predator that preys on only one species can be an important selective force favouring anti-predator adaptations in that species. In turn, the prey species anti-predator adaptations can exert a selective pressure on the predator, favouring improved predatory abilities. Thus, each species acts as a selection pressure on the other, favouring adaptations and counter-adaptations, perhaps leading to characteristics that are increasingly specific to the relationship. However, these improvements need not necessarily change the relative position of each protagonist (Dawkins and Krebs, 1979). The evolution of these specific adaptations and counter-adaptations depends on both the frequency of the interactions and the effects of each protagonist. Host- parasite systems provide a rich seam of examples of such evolutionary processes (e.g. Endler, 1986; Davies *et al.*, 1989; Toft *et al.*, 1991), but there is also some evidence for similar processes in predator-prey systems (e.g. Brodie and Brodie, 1991; Endler, 1991).

INTER-SPECIFIC ASSOCIATIONS IN SPIDERS

Research on the behaviour and ecology of spiders has, with a few notable exceptions, focussed on issues involving single species (e.g. Humphreys, 1988), including foraging behaviour (Reichert and Luczak, 1982; Vollrath, 1987a; Uetz, 1992), habitat choice (e.g. Reichert and Gillespie, 1986), intraspecific competition (e.g. Reichert, 1982), courtship and mating (e.g. Robinson and Robinson, 1982; Elgar, 1992) and social behaviour (Buskirk, 1981; Elgar and Godfray, 1987; Uetz, 1988). Nevertheless, some spiders have relatively specific and prolonged relationships with other species. These relationships often involve predation or avoiding predation, and perhaps a reason why inter-specific interactions involving spiders have been neglected is that spiders are frequently perceived as generalist predators; cursorial or wandering spiders attack any vulnerable prey that they can find, while web-building spiders simply capture any prey that is caught in their web. However, the view that spiders are generalist predators is mis-

leading. Many spiders prey on only a few species using foraging techniques that include building specialised webs; producing chemical compounds that attract prey; utilising the webs or capturing capabilities of other spiders; mimicking prey behaviour; and cooperative foraging (see reviews in Stowe, 1986; Nentwig, 1987). Clearly, the survival and reproductive success of both predator and prey will depend on their predatory and defensive behaviours, and the degree to which the predator depends on the prey as a source of food. Not all associations between spiders and other invertebrates are predator-prey relationships; some species depend on other species for protection from predators, or providing suitable places to live. This review will focus on three inter-specific relationships involving spiders: kleptoparasitism, mimicry and mutualism.

A detailed understanding of the nature of these inter-specific associations will benefit from both experimental and comparative studies. The former can provide insight into both the fitness effects of the association on individuals of each species, and the importance of particular species' traits for maintaining the association. Comparative studies can provide further insight into the selection pressures responsible for the evolution of the association; reveal the implications of these associations for other aspects of the species life-history characteristics; and help formulate ideas that can be subsequently examined experimentally (see Harvey and Pagel, 1992 for review). While emphasising the evolutionary dynamic nature of inter-specific associations, a central theme of this review is to illustrate the use of comparative and experimental studies for understanding these systems, and also to highlight those gaps in our knowledge of arachnid inter-specific associations that might benefit from this evolutionary approach.

KLEPTOPARASITIC ASSOCIATIONS

The webs of spiders are host to numerous insects, including flies, damselfies and wasps (see reviews in Vollrath, 1984, 1987b; Nentwig and Heimer, 1987). Most descriptions of these guests are anecdotal, and consequently the nature of the relationship is poorly understood. The webs of many spiders are also host to numerous other spiders that obtain food from prey caught in the host's web. These spider guests, commonly referred to as kleptoparasites, are represented in at least four families, including the Dictynidae, Mysmenidae, Symphytognathidae and Theridiidae (Table 1). Of these spiders, the genus *Argyrodes* (Theridiidae) is the best documented (see Vollrath, 1984, 1987b).

Evidence of Kleptoparasitism

Argyrodes were originally described as commensals: *Argyrodes* benefit by feeding on the prey items that are caught in the host's web, but the host is not disadvantaged because these prey items do not form part of its diet (e.g. Belt, 1874). However, subsequent behavioural and ecological studies revealed that individual *Argyrodes* remove prey that might otherwise be consumed by the predator. These observations suggest that the relationship between *Argyrodes* and their hosts is more accurately described as kleptoparasitic rather than commensal (see Vollrath, 1984, 1987b).

In fact, kleptoparasitism may also be an inappropriate description. A kleptoparasitic relationship implies that one partner in the symbiosis benefits at the expense of the other, and that the kleptoparasite has certain characteristics that are adaptations to this lifestyle. Studies of several species associations leave little doubt that the latter contention is correct. For example, the symphytognathid *Curimagua bayano* inhabits the webs of a large mygalomorph *Diplura*, either climbing about the funnel web or remaining on the host (Vollrath, 1978). After a *Diplura* has caught, masticated and enveloped a prey item in digestive fluids, the kleptoparasite descends to the prey item and imbibes the liquidized prey. Interestingly, the anatomy of the mouth of *C. bayano* apparently prevents it from being able to capture, hold or masticate its own prey, suggesting that it is an obligate kleptoparasite (Vollrath, 1978).

Several behaviours of *Argyrodes* appear to be adaptations that are specifically related to their kleptoparasitic lifestyle. These spiders can move throughout the web, apparently undetected by the host, and the attempts of the kleptoparasites to obtain prey items may vary according to the behaviour of the host (Vollrath, 1984, 1987b). There are several mechanisms by which kleptoparasitic *Argyrodes* avoid detection or capture by the host: many species drop from the web when challenged by the host, *A. antipodianus* swings away from the web when the host is agitated (Whitehouse, 1986), and *A. ululans* cuts holes in the tangle web of its social spider host *Anelosimus eximius*, forming a tunnel that apparently facilitates escape (Cangialosi, 1991).

Surprisingly, the evidence that the presence of *Argyrodes* has a negative effect on the reproductive success of the host has not been directly assessed. For example, there are no experimental evidence that the growth rate or fecundity of the host is reduced by the presence of *Argyrodes* (or any other genera of kleptoparasites). Instead, the negative impact of *Argyrodes* on its host has been inferred primarily from either the behaviour of the host (e.g. Larcher and Wise, 1985), or from estimates of the energetic costs derived from the loss of prey items obtained by *Argyrodes*. For example, the number of prey items consumed by *Nephila clavipes* is reduced with increasing numbers of *Argyrodes* on the web (Rypstra, 1981), and *A. ululans* removes around 26% of the prey items that are caught in the web of its host *Anelosimus eximius* (Cangialosi, 1990b). Vollrath (1981) examined the potential costs of *Argyrodes* by estimating the energetic requirements of a single kleptoparasite. The daily energy requirements of the 3-4 mg *A. elevatus* is 0.82 J, about 0.5% of the daily requirements of its 975mg (*Nephila clavipes*) host. This proportion increases with larger numbers of kleptoparasites per web; over 40 individuals have been counted on a single *Nephila* web (although the average is 2.2 kleptoparasites per web), suggesting a potentially high energetic cost of this relationship (Vollrath, 1981).

If kleptoparasites exact a cost on host reproductive success, then selection should favour any trait that enables the hosts to reduce that cost. There are several mechanisms by which hosts might reduce the cost of kleptoparasitism: recovering the prey from the kleptoparasite; reducing the kleptoparasites access to the prey; or simply abandoning the web and building another elsewhere. Interestingly, hosts appear to be inefficient at recovering prey (Vollrath, 1979a, b; Rypstra, 1981) although several host species reduce access to their prey by chasing the kleptoparasites (Cangialosi, 1990b) or concealing the prey in retreats (see Cangialosi, 1990b). Larcher and Wise (1985) demonstrated experimentally that hosts are more likely to abandon webs when *Argyrodes* are present than absent. *Nephila clavipes* relocates its web when it is infested with large numbers of kleptoparasites (Rypstra, 1981), although the behaviour of *N. clavipes* may be a response to lower feeding rates, rather than to numbers of kleptoparasites.

Social or communal spiders appear to have fewer defensive options against high kleptoparasite loads, and this cost may be higher if the number of kleptoparasites per web is greater in larger colonies. For example, *Nephila edulis* builds webs in aggregations, and webs in aggregations have higher kleptoparasite loads and infestation rates than those found alone (Elgar, 1989). Re-locating a web away from an aggregation may reduce kleptoparasite load, but the host subsequently does not benefit from the foraging and predator defense advantages of living within an aggregation (e.g. see Uetz, 1988). Moving web sites to reduce kleptoparasite load may not be possible for some social spiders, such as *Anelosimus* that build substantial, permanent webs. Indeed, high kleptoparasite loads are apparently responsible for the demise of some *Anelosimus* colonies (Cangialosi, 1990b) but not others (Vollrath, 1982).

Like their hosts, individual kleptoparasites may also react to variation in prey capture rates. The feeding rates of kleptoparasites are likely to be influenced by both the prey capture rate of the host and the number of other kleptoparasites on the web. Host web capture rates may vary according to both the location and the size of the web. The number of kleptoparasites increases with the web size of several host species (e.g. Elgar, 1989; Cangliosi, 1990a), possibly because larger webs have higher web capture rates that can support more kleptoparasites. Web-building spiders relocate their webs according to prey capture rates (e.g. Gillespie and Caraco, 1987), and *Argyrodes* may behave similarly by moving to different webs (but see Larcher and Wise, 1985). It would be interesting to establish experimentally whether the emigration rate of individual *Argyrodes* increases as a result of lower web capture rates or increased numbers of conspecifics. If the latter, it is possible that the distribution of *Argyrodes* within a population of hosts, particularly those hosts that aggregate, could be predicted by the ideal free distribution (see Milinski and Parker, 1991).

A possible option for kleptoparasites that experience a low feeding rate is to capture and consume the host before moving to the web of another host (e.g. Tanaka, 1984). Some species of *Argyrodes* are either obligate or facultative predators of their hosts (see Table 1). Predatory *Argyrodes* can capture the host through mimicking a prey item (e.g. Whitehouse, 1986) or simply advancing toward the host and attacking it. Such a specialised form of predation is not uncommon in spiders, and has been recorded in several families (e.g. Jackson, 1987; Jackson and Blest, 1982; Jackson and Brassington, 1987; Jarman

TABLE 1: Spiders that are presumed to be kleptoparasites of web-building spiders. * Two categories of relationship ('Assoc') are defined: 'K' is Kleptoparasite only, and 'KP' means that the guest may also capture the host. Some species of *Argyrodes* may be incorrectly categorised as 'Kleptoparasite only' because their predatory behaviour has not yet been observed.

** Taxonomy of *Argyrodes* follows Levi and Exline (1962) and thus *Argyrodes*, *Ariamnes* and *Rhomphaea* are not distinguished.

and Jackson, 1986; Jackson and Hallas, 1990). A potential cost of this foraging strategy is that the kleptoparasite may become prey to the host. At least one host species has a relatively effective defensive behaviour: when the predatory *Argyrodes* is detected, the host simply cuts the web thereby collapsing it and ensuring that the predator cannot proceed further (e.g. Eberhard, 1979b). Suter *et al.* (1989) report that female *F. pyramitela* can discriminate between conspecific males, prey items and predatory *A. trigonum*, apparently using chemical cues, and respond accordingly.

Comparative Patterns Within *Argyrodes*

What evolutionary sequences are responsible for the diversity of predatory specialisations in *Argyrodes*? Smith Trail (1980) stresses the importance of the kleptoparasites' ability to identify the vibratory signals generated by the host, thus allowing them to stalk and safely capture the host. However, kleptoparasites that also attempt to capture their hosts risk being captured themselves. Consequently they may be more likely to attempt to capture vulnerable hosts, such as those that are smaller (e.g. Smith Trail, 1980; Larcher and Wise, 1985), moulting (e.g. Vollrath, 1984), or even the spiderlings of the host (e.g. Whitehouse, 1986).

If relative body size is important in determining the outcome of attacking the host, then predatory species of *Argyrodes* may be larger than primarily kleptoparasitic species, or the former may tend to specialise on smaller hosts. These predictions are supported by comparative data of body length measures for 20 species of *Argyrodes* (see Table 1). Species of *Argyrodes* were divided into two groups, according to whether they preyed on their hosts: females of *Argyrodes* that are only kleptoparasitic are significantly smaller than those that also prey on their hosts (Table 2). However, males of these two groups of species are not significantly different in body size (Table 2). *Argyrodes* that prey on their hosts also specialise on smaller hosts, compared with the size of the hosts of those species of *Argyrodes* that are only kleptoparasites (Table 2). These comparative data show that, as predicted, the difference in size between *Argyrodes* and its host is greater for those species that are primarily kleptoparasitic compared with those that are also predatory. These comparative data suggest that selection has either favoured larger body size for species that are both kleptoparasitic and prey on their hosts, or it has favoured a further reduction in body size in those species that are primarily kleptoparasitic. The latter argument is consistent with the view that kleptoparasitism is a specialised foraging strategy that evolved from a more general kleptoparasitic and predatory lifestyle (Vollrath, 1984).

The evolutionary sequence leading to the divergence of these two foraging strategies within *Argyrodes* is not known; one may have evolved from the other, or both may have diverged from a common web-building ancestor (see Whitehouse, 1986). Thus, it is not possible, without an accurate phylogeny, to establish whether selection has favoured an increase in body size with the predatory lifestyle, or a decrease in body size is associated with a kleptoparasitic lifestyle. Indeed, the species placed within the single genus *Argyrodes* by Exline and Levi (1962) have been placed by others into three genera; the *Ariamnes*, the *Rhomphaea*, and the *Argyrodes*. In this classification, the *Ariamnes* and *Rhomphaea* groups are primarily host-predators and the *Argyrodes* group are kleptoparasites (Whitehouse, 1987). Thus, the differences described above may be confounded by taxonomic associations (see below). Resolving some of these issues is most likely achieved by experimental manipulation of individuals within a species that shows both kleptoparasitic and predatory behaviour.

An additional pattern revealed by comparative analysis also deserves experimental investigation. The degree of sexual size dimorphism (male length/female length) covaries significantly with the foraging strategies of *Argyrodes*. Males are smaller than females in those species that prey on their host, consistent with patterns of size dimorphism in almost all other spiders (e.g. Elgar *et al.*, 1990; Elgar, 1991, 1992; Vollrath and Parker, 1992). However, males of those species of *Ar-*

TABLE 3: Summary of taxonomic distribution of spiders that are host of kleptoparasites (see Table 1 for further details). KP= Kleptoparasites and predators; K=kleptoparasites. * No. species in each genus in parentheses.

gyrodes that are primarily kleptoparasitic are generally larger than their conspecific females (see Table 2). What factors are responsible for this reversal of size dimorphism patterns within this group of spiders? One explanation is that competition between males for access to females may be more intense for kleptoparasitic spiders, and consequently sexual selection has favoured large male size in these species (see also Whitehouse, 1988b).

There is considerable variation in both the number of species that are host to each species of kleptoparasite and the number of kleptoparasite species found on each web-building host species (see also Vollrath, 1984, 1987b). For example, *Argyrodes cancellatus* are found on the webs of at least ten different host species from five families (see Table 3), while the orb-weaver *Nephila clavipes* is host to at least seven species

TABLE 4: Mean host-ranges of *Argyrodes* that are either only primarily kleptoparasitic or they also prey on their host.* refers to *Argyrodes*.

of *Argyrodes*. It is likely that both host-range and parasite-range will expand as more records become available. In contrast, many species appear to be host specific, with one species of kleptoparasite recorded from the web of only one species of host. For example, in certain Peruvian habitats, *Argyrodes ululans* is found only on the webs of the social spider *Anelosimus eximius*, despite considerable effort searching for this kleptoparasite on other potential hosts (Cangialosi, 1990a).

Vollrath (1984) argued that *Argyrodes* can be placed in two general categories; specialists that are host specific but behaviourally versatile, and generalists that invade the webs of many different species but use relatively few techniques to obtain food. Thus, Whitehouse (1988a) considers *Argyrodes antipodianus* a specialist, primarily because its behaviour is versatile, and adults are found primarily on the webs of *Eriophora pustulosa*. Dichotomies like these can be misleading because both host-specificity and behavioural versatility are most likely continuous rather than discrete variables; *A. antipodianus* is found on the webs of several other hosts (Table 1). Furthermore, host-specificity may also vary between populations, depending on the diversity and abundance of potential hosts in different populations. For example, *A. antipodianus* in Whitehouse's (1988a) study may be found primarily on *Eriophora pustulosa* because that is the most common host in her New Zealand population.

The host range of *Argyrodes* may vary according to whether the species is both kleptoparasitic and predatory or whether it is only kleptoparasitic. Purely kleptoparasitic *Argyrodes* may escape host-detection through specialised behaviours, but these behaviours may be effective for relatively few host species. If so, the host ranges of primarily kleptoparasitic *Argyrodes* may be less than for species of *Argyrodes* that are also predatory. The comparative data provide little support for this prediction (Table 4); al-

though the host-range of primarily kleptoparasitic species is less than the range of predatory species, the difference is not statistically significant.

The results of these inter-specific comparative analyses within the genus *Argyrodes* should be interpreted cautiously. These patterns may be confounded by an association between foraging strategy and taxonomic affinity, and thus the differences in body size or host range may be due to other, unknown features that differ between these two groups. This possibility is especially relevant given the ambiguity of the taxonomic arrangement of this genus. Furthermore, some species of *Argyrodes* may be incorrectly assigned to primarily kleptoparasite status simply through lack of observations. Thus, the patterns may change when more data and/or a more accurate phylogeny become available. Nevertheless, the patterns suggest several interesting questions that could be resolved by an experimental approach.

Host Specificity Of Kleptoparasites

Both *Argyrodes* and *Mysmenopsis* belong to web-building families and thus are relatively close phylogenetically (Coddington and Levi, 1991). However, the range and taxonomic affinities of their hosts are substantially different (Table 1). *Argyrodes* have been recorded on the webs of 29 host genera from eight families (Agelenidae, Amaurobiidae, Araneidae, Linyphiidae, Pholcidae, Psechridae, Theridiidae, Uloboridae), and some species have many hosts (see above). In contrast, 11 of the 14 species of *Mysmenopsis* are found on diplurid hosts, with the remaining species found on *Cyrtophora* (Araneidae) and *Pholcus* (Pholcidae). A comparative analysis reveals a significant difference: every species of *Mysmenopsis* has only one host species, while the host range for *Argyrodes* is 2.7 ($\pm$0.7, n=18) species, or 1.6 ($\pm$0.3) host families.

Why is *Mysmenopsis* more host-specific than *Argyrodes*? There are several possible explanations. First, kleptoparasitism may have evolved more recently in *Mysmenopsis* than in *Argyrodes*, and therefore the former kleptoparasite has had less time to expand its host range. Second, the present associations between *Mysmenopsis* and diplurids may have evolved from a common ancestor and subsequently speciated as host/kleptoparasite pairs. Consistent with this is Coyle and Meigs (1989) description of two sister species of kleptoparasites (*Mysmenopsis monticola* and *M. furtiva*) that live on the webs of a pair of undescribed allopatric *Ischnothele* morphs that also appear to be sister species. Third, diplurids may be more sensitive to web invaders than the hosts of *Argyrodes*, and thus the kleptoparasitic behaviours required to avoid detection by one host species are not appropriate for another. In this regard, it is noteworthy that *Argyrodes* are not known to invade diplurid webs, despite the broad taxonomic range of their hosts.

The relatively permanent nature of the host's web is a common characteristic of the hosts of all kleptoparasites (Table 1). Kleptoparasites that live on permanent webs may benefit by spending less time searching for new webs compared with those that are associated with hosts that frequently move their webs. However, it may not be the permanent structure of the web that is important, but rather the tenacity of the web site. For example, the large, nocturnal, Australian orb-weaver *Eriophora transmarina* builds a new web every evening and then destroys it the following dawn. Despite the temporary nature of its web, this spider is also host to many individual *Argyrodes*, probably because it has a high web-site tenacity (M. Herberstein, unpublished data).

MIMICRY BY SPIDERS

Many species of animals, including spiders, resemble other, unrelated species. These resemblances may be visual, chemical, behavioural or acoustic and are usually referred to as mimicry. There are many different types of mimicry, which has precipitated some controversy over its definition (e.g. Endler, 1981; Pasteur, 1982). Two general forms of mimicry are distinguished in this review: defensive mimicry and aggressive mimicry. In the former, the mimetic form is presumed to have evolved because the risk of predation (or parasitism) on the mimic is reduced as a result of its resemblance to the model. The lower mortality occurs because the receiver (the predator) does not usually prey on the model, and fails to distinguish between it and the mimic. Aggressive mimics resemble some feature of their prey species, thereby increasing the chance of capturing the prey model. Both forms of mimicry occur in several families of spiders.

The relationship between mimic, model and receiver is asymmetric; only the mimic benefits and any improvement in the mimic will be favoured rapidly by natural selection. Both the model and the receiver may lose, in defensive mimicry, through increased attack rate and lost

food respectively (see Endler, 1991), and natural selection will favour models that have less resemblance to the mimic (although the strength of this selection will depend on the frequency with which the model is attacked). The degree of resemblance between model and mimic that evolves will depend upon the benefits to the mimic and the costs of mimicry to the model. The costs to the model in aggressive mimicry are more complicated, and depend upon whether the model and the receiver (in this case, the potential prey) is the same individual.

Visual Mimicry: Spiders of Ants

Spiders that resemble ants are an especially intriguing form of mimicry that is poorly understood. Many of these spiders not only have an extraordinary physical resemblence with their ant models, but also exhibit particular behaviours that improves the illusion remarkably. Ant-mimics, represented in at least six families of spiders and mimicking the four major subfamilies of ants (Table 5), fall into two categories: those that appear to have little behavioural interaction with the ants and generally avoid contact with them; and those spiders that specialise on capturing and eating their ant models. There are no clear taxonomic affiliations between the species of spider mimics and the species of ant models; ponerine, myrmecine and formicine ants are models for both clubionid, salticid and other spiders. Nevertheless, certain species of ants appear to be models for spiders more frequently than others. For example, seven species of *Camponotus* are models to spider mimics and one species, *C. femoratus*, is a model for two corinnids (*Myrmecium*) and the salticid *Zuniga*; five species of the ponerine genus *Pachycondyla* are models for five different spiders, and the weaver ant *Oecophylla smaragdina* is a model for three species from Australia and India. It is not obvious why spiders mimic these genera of ants more frequently than others.

Some species of spiders mimic more than one species of ant. For example, the clubionid *Castianeira rica* resembles species of both ponerine and myrmicine ants and the different mimetic forms depend upon developmental changes, colour variation in adult females, and sexual dimorphism (Reiskind, 1970). Male *C. rica* resemble *Atta* and *Odontomachus*, while females resemble moderately large ponerines that are within the spiders' colour range. Furthermore, different instars of these spiders mimic ant models of equivalent size; thus the small, black early instars mimic small myrmicine ants, while the older instars resemble medium sized attine ants. Such a close degree of resemblance at different stages in the spiders' development suggests that the selection pressure favouring mimicry is very strong.

Ant mimicry can provide at least three benefits, depending upon whether the spiders prey on their ant models. These benefits include protection from various predators, improved predatory success on the ant prey, and both. Ant-mimics that apparently do not prey on their models are mostly salticids, corinnids and a few gnaphosids (Table 5). Mimics that prey on their models are mostly represented by thomisids and zodarids, although there are also a few records of theridiids, corinnids and salticids (Table 5). The record for the salticid species *Myrmarachne* (Hingston, 1927) is unusual and unlikely to be typical because other species of this large, ant-mimicking genus do not routinely prey on their model ants (e.g. Edmunds, 1978). Only a few genera of salticids are clearly regular ant-predators (e.g. Jackson and van Olphen, 1991, 1992). The theridiid *Dipoena* resembles the de-capitated head of a dead ant which are found in the refuse heap of the ant nest. Hingston (1927) suggests that mimicry in this species is aggressive because it allows the spider to live in the nest of the ants on whom it may prey. However, predation on these ant hosts by *Dipoena* was not observed.

Perhaps the most vexing question concerning defensive ant mimicry by spiders is establishing the identity of the receiver (i.e. the predator or

TABLE 6: Spiders that specialise on ant prey but are not ant-mimics.Family abbreviations given with Table 1.

parasitoid). Despite widespread reports and descriptions of ant-mimicry by spiders, few studies have addressed this question quantitatively. The visual nature of ant-mimicry suggests that the spiders are gaining protection from visual enemies, including birds (e.g. Belt, 1874; Engelhardt, 1970), wasps (e.g. Edmunds, 1993) and other spiders (e.g. Cutler, 1991). It is unlikely that the visual resemblance to ants provides the spider mimics with protection from either their ant models or other species of ants, because ants perceive the environment primarily by chemical, rather than visual cues (see Hölldobler and Wilson, 1990). Furthermore, many spiders that are either specialist predators of ants (see Table 6) or live in close proximity with ants (Table 7) are not necessarily visual mimics.

Most of the diet of many spiders are other spiders (e.g. Bristowe, 1941, 1958; Reichert and Luczak, 1982; Nentwig, 1987). In contrast, ants are not a common prey item for most spiders, although a few spiders are specialist predators of ants (see Table 6). Thus, ant mimicry may provide some degree of protection from other spiders. Experimental evidence of this possibility is provided by Cutler (1991), who examined whether ant-mimicry in the salticid *Synageles occidentalis*, a mimic of the ant *Myrmica americana*, reduces the risk of predation by two other spiders *Tibellus* (Philodromidae) and *Phidippus* (Salticidae). These spiders do not feed on the ant *M. americana*, but more importantly they were less likely to attempt to capture the mimic *S. occidentalis* than immature *Phidippus* (that are not ant mimics).

Spiders are also prey to a variety of other invertebrates, especially pompilid and sphecid wasps (e.g. Coville, 1987), and acrocerid dipterans (e.g. Schlinger, 1987). These parasitoids are primarily visual hunters and many myrmecophilous arthropods gain protection against these enemies by associating with ants (e.g. Hölldobler and Wilson, 1990). Thus, ant-mimicry may reduce the risk of predation by sphecid and pompilid wasps. Edmunds (1993) provides qualitative data suggesting that ant-mimics *Myrmarachne* are less likely to be taken by the predatory wasp *Pison xanthopus* than might be expected if this wasp was indiscriminate in its choice of prey. Finally, it is interesting to note that no species of lycosid have been reported as ant-mimics (see Table 5), perhaps because these spiders are generally nocturnal foragers and are also seldom victim to sphecid wasps (see Coville, 1987).

Behavioural Mimicry: Courtship Vibrations

Some spiders are renowned for preying exclusively on other spiders. Notable among these

TABLE 7: Spiders that have been found within or adjacent to the nests of ants. Family abbreviations given with Table 1.

are the mimetid or pirate spiders that invade the webs and attack the owners of other species of spiders (e.g. Bristowe, 1941). Many of these spiders are aggressive mimics. For example, the mimetid pirate spiders *Mimetus* and *Ero* wait at the periphery of the web of the social spider *Anelosimus studiosus* (Brach, 1977). The mimetids then pluck on the web thereby attracting a host spider that is then captured and eaten. The salticid *Portia* is also well known for its ability to mimic the struggles of prey ensnared in the web of other spiders. The investigating host is then captured by *Portia* (Jackson and Hallas, 1990).

Some species of *Portia* also mimic the male courtship behaviour of their prey species; a behaviour that increases their chances of capturing the unsuspecting female (Jackson and Hallas, 1986). If prey populations suffer high frequencies of this form of mimicry, then *Portia* may act as a selection pressure favouring improved discriminatory abilities in the prey, thereby establishing an an evolutionarily dynamic 'arms race' (*sensu* Dawkins and Krebs, 1979). Evidence of this form of frequency dependent selection is provided by Jackson and Wilcox (1990, 1993), in their study of the predatory-prey relationship between two Australian salticids, *Portia fimbriata* and *Euryattus* sp.

Euryattus females live in a nest comprising a rolled-up leaf, suspended from rock ledges and tree trunks by silk guylines. *Portia fimbriata* is a versatile predator of many salticids and in a Queensland population, it preys on female *Euryattus* sp. using vibratory displays that apparently mimic the courtship behaviour of *Euryattus* males. This behaviour lures *Euryattus* females from their nest, and they are subsequently attacked by *P. fimbriata*. This specialised form of predation by *P. fimbriata* may be responsible for the improved ability of *Euryattus* to recognise and defend itself from *P. fimbriata*, compared with other salticids. For example, *Euryattus* recognises *P. fimbriata* as a potential predator, unlike another prey species *Jacksonoides queenslandica*. Interestingly, this recognition ability is not present in another population of *Euryattus* in which *P. fimbriata* are absent. Experimental trials reveal that *P. fimbriata* attacks and captures these 'naive' spiders more frequently than spiders from the population that is exposed to *P. fimbriata* (Jackson and Wilcox, 1993). It is still not clear whether the two populations of *Euryattus* are conspecifics or represent two different species. The more distantly related the two populations, the less likely that the differences in behaviour are the result of the presence or absence of *P. fimbriata*. Nevertheless, it appears to be a fascinating example of how the foraging behaviour of a predator has apparently acted as a selection pressure influencing the defensive behaviour of its prey.

Chemical Mimicry: Moths and Ants

Spiders produce a variety of chemicals that function to attract conspecifics. Female spiders from many different families produce pheromones that attract members of the opposite sex (e.g. Lopez, 1987; Pollard *et al.*, 1987), and Evans and Main (1993) show experimentally that pheromones may be important for maintaining social cohesion in social spiders. Several taxa of spiders are capable of inter-specific chemical communication, of which the most familiar is the remarkable form of chemical mimicry by bolas spiders (see Stowe, 1986, 1988 for extensive reviews). Bolas spiders, comprising several genera within the Araneidae, do not construct

orb-webs but instead swing at their prey a bolas (a droplet of adhesive) attached to the end of a silk thread. Bolas spiders are aggressive mimics and prey exclusively on male moths; the spiders produce a chemical substance that mimics the sex pheromone of its moth prey species (see Eberhard, 1977, 1980; Yeargan, 1988; Stowe, 1986, 1988; Stowe *et al.*, 1987). The exact source of the prey attractant compounds is not known, but is likely to be emitted from the spider (Stowe *et al.*, 1987). The evolution of this specialised foraging technique is particularly intriguing because it involves two phases; the first comprises the production of moth-attracting chemicals (see also Horton, 1979), and the second is the adoption of a specialised use of silk together with the loss of the orb-web. Interestingly, anecdotal observations suggest that the spider swings the bolas in response to vibratory signals generated by the flying moths (Main, 1976).

The mate location mechanism of at least seven families of moths are exploited by bolas spiders, but the range of moth prey species captured by each species of bolas spider varies (Stowe, 1986, 1988; Stowe *et al.*, 1987). Some spiders capture only one species of moth, while *Mastophora cornigera* is capable of capturing at least nineteen moth species (Stowe *et al.*, 1987). There are no obvious taxonomic affinities between the different groups of bolas spider and their moth prey species (Stowe, 1986, 1988). The variation in bolas spider prey-specificity is likely to be related to the bio-geographic distribution of potential moth prey, the chemical compounds produced by the spiders and the chemicals used as moth sex-attractants. Furthermore, some compounds that attract certain species of moth may inhibit attraction of other moths (Stowe *et al.*, 1987).

Since araneid spiders are capable of chemical mimicry of moths, it is not unreasonable to expect that ant-mimicking spiders may be capable of producing chemical compounds that 'appease' ants. Many species of invertebrate myrmecophiles produce chemicals that mimic ant communication chemicals (see Hölldobler and Wilson, 1990). The production of these chemicals can reduce the risk of the ants attacking the myrmecophiles. One group of spiders that are likely to be capable of chemical mimicry are those that live in ant nests (see Table 7). Little is known about these spiders, but some earlier reports may have mistakenly recorded them living in ant nests, rather than adjacent to the nest (see Bristowe, 1941). It is not clear whether these spiders prey on the ant larvae within the ant nest, or simply take advantage of a safe refuge. Whatever the reason, it is unlikely that they could remain in or near ant nests without some chemical protection, because ants rarely tolerate foreign nest intruders. Porter (1985) provided qualitative evidence for the presence of ant recognition pheromones by introducing myrmecophilous spiders *Masoncus* into the nests of different *Pogonomyrmex* ants. *Masoncus* were not attacked if they were re-introduced into their original nests, but the spiders were attacked and killed within minutes if they were placed in the nest of foreign *Pogonomyrmex* or other species of ants. It is not known whether these spiders actively produce the appropriate pheromones, or whether they simply adopt it from the substrate of the nest.

The predatory behaviour of two Australian spiders may also involve chemical mimicry. The Australian basket-web spider *Saccodomus formivorous* (Thomisidae) builds a basket-like web that appears to attract wandering *Iridomyrmex* ants that may venture into the basket web (McKeown, 1952). The spider also taps the ant with its legs, that may further mimic ant communication, and eventually captures the unsuspecting ant. It remains to be seen if *S. formivorous* webs capture only *Iridomyrmex* ants, and whether the ants are actively attracted to the basket-web. The extraordinary predatory relationship between an undescribed theridiid and its weaver ant *Oecophylla smaragdina* prey (see Cooper *et al.*, 1990) may also represent an example of the use of chemical mimicry. This theridiid constructs a web made of several strands of silk suspended between vegetation and additional strands that are anchored to the substrate below. The anchor part is a small white bead of silk that is very attractive to the ants. If the web is complete and an ant bites the silk it is catapulted into the web above, where it is captured by the spider. The bead of silk is often placed near ant 'highways' and can sometimes attract the attention of many individual *O. smaragdina* that all attempt to bite the silk.

MUTUALISTIC ASSOCIATIONS

There are few examples of mutualistic associations between species of spiders or even between spiders and other organisms. This is surprising, given the widespread occurrence of mutualistic associations in other taxa (e.g. Boucher *et al.*, 1982; Smith and Douglas, 1987; Hölldobler and Wilson, 1990), but may reflect the predatory nature of spiders. Tietjen *et al.* (1987) describe an

interesting example of a mutualistic association involving the social spiders *Mallos gregalis*. These spiders do not remove the remains of prey from their nest, and this debris becomes a nutrient base for various yeasts. The odour of these yeasts is apparently attractive to various flies, that settle on the prey carcasses and are then captured by the spiders. The association is likely to be mutualistic because the spiders provide food for the yeast and the yeast's presence attracts food for the spider.

The relationship between spiders that live in ants' nests and their ant hosts may also be mutualistic for some species. For example, Shepard and Gibson (1972) found myrmecophilous salticid spiders of the genus *Cotinusa* in 61% of 50 nests of the dolichoderine ant *Tapinoma melanocephalum*. Interestingly, ant nests with *Cotinusa* had more brood per nest, more workers per nest and more brood per worker than those nests without *Cotinusa*. Unfortunately, these differences were not examined statistically, and the greater numbers of ants and brood in the nests with *Cotinusa* may be due to the larger size of the former nests. Nevertheless, Shepard and Gibson (1972) suggest that the spider uses the ant nest as a foundation for the construction of its web, and in return provides the ants with some protection from predators or parasites.

Psechrus and *Philoponella*

Many species of orb-weaving spiders in the genus *Philoponella* (Uloboridae) build their webs within the barrier webs of other araneid, theridiid, agelenid and psechrid spiders (Struhsaker, 1969; Lubin, 1986). These associations were thought to be commensal; *Philoponella* has a place to build a web, but it was assumed that their presence has little effect on the host spider (e.g. Lubin, 1986).

In Madang Province, Papua New Guinea a species of *Philoponella* builds webs between the threads of the tangle web of a large psechrid *Psechrus argentatus*. Not all *Psechrus* webs have *Philoponella*, but as many as 15 males and females can be found on a single host web. Like many small uloborids, *Philoponella* is a communal spider, with several orb-webs sharing support threads. A theridiid *Argyrodes fissifrons* also patrols the barrier web but is never found on the sheet web of the host spider. The number of both *A. fissifrons* and *Philoponella* on a single host web is positively correlated with the size of the host.

The relationship between *P. argentatus* and *Philoponella* appears to be mutualistic (Elgar, unpublished). The growth rate of *P. argentatus* was significantly reduced following experimental removal of both *A. fissifrons* and *Philoponella* from the barrier-web. The lower growth rate during the ten day experimental period may represent a potential reproductive loss of around 30 eggs (estimated from the weights of egg masses). *P. argentatus* probably benefits by increased capture rates as a result of the increased area of tangle web generated by the webs of *Philoponella*, in a way analogous to the webs of some social spiders (see Struhsaker, 1969; Uetz, 1988). The additional webs may increase the probability of arresting insects that then drop into the sheet web, without being caught in the orb-web of *Philoponella*. It seems unlikely that *P. argentatus* benefits from the presence of *A. fissifrons*. In fact, *A. fissifrons* is more likely to have a negative effect on the host because it feeds on prey items caught in the barrier web and also may prey on *Philoponella*: on two occasions, *A. fissifrons* were seen feeding on *Philoponella*, consistent with other reports of the foraging behaviour of this species (see Table 1).

SOME CONCLUSIONS AND PROSPECTS

The relationship between kleptoparasitic *Argyrodes* and their hosts has been extensively examined, yet the effects of the association on the fitness components of either *Argyrodes* or its host are presently unquantified. Consequently, it may be inappropriate to call these species kleptoparasites because (a) they may not take prey that the host would otherwise feed on and (b) their hosts may not suffer a fitness cost. Of course, many other well documented host-parasite systems similarly fail to quantify the fitness effects of the presumed parasite (see Toft *et al.*, 1991). Nevertheless, circumstantial evidence that the presence of *Argyrodes* has influenced the biology of at least a few host species suggests that kleptoparasitism is an evolutionarily dynamic relationship. Comparative analyses reveal interesting differences in the biology of kleptoparasites that do, or do not, also prey on their host. However, there are no obvious explanations for the evolution of this behaviour.

There are interesting parallels between chemical mimicry by the bolas spider and vibratory mimicry by the salticid *Portia*; both are examples of aggressive mimicry in which the mimic exploits the mate-attracting mechanism of the model. They also illustrate the broad spectrum of sensory mechanisms that are exploited and the range of phylogenetic similarity between model

and mimic. The models are clearly disadvantaged by the mimics, and selection is likely to favour mechanisms that allow the victims to distinguish between their conspecific mates and the spider predators. There is some evidence of this selection for *Euryattus*, the model of *Portia*, but there are no data on the impact of bolas spiders on their model moth populations (but see Yeargan, 1988), nor is it known whether the ability of male moths to discriminate between conspecific female pheromones and bolas spider mimics has changed. One difference between these two mimicry systems is that the victims of *Portia* are female, but the victims of bolas spiders are male. This difference may have implications for the relative strength of selection in these types of aggressive mimicry, and the degree to which the model and mimic have undergone an evolutionary arms race.

Defensive mimicry of ants by spiders is taxonomically widespread but has received little experimental attention, compared with studies of other invertebrate taxa (e.g. McIver, 1987). In almost all cases the receiver is not identified and the fitness cost to the ants, as a result of defensive mimicry by these spiders, has not been quantified. Nevertheless, the degree of visual mimicry in many spiders suggests that there has been strong selection for this form of protection against predators. The inter-specific variation in the degree of resemblance between spider mimics and their ant models suggests an evolutionary process reflecting differences in the discriminatory abilities of the receivers. These differences may also reflect the frequency with which the spiders and ants co-occur, and the kind of substrate on which both are found. Finally, ant mimicry by spiders that also prey on their models begs the question of whether specialisation on ant prey followed ant mimicry, or vice-versa.

Mutualisms involving spiders have received little attention, compared with other inter-specific associations. There are several explanations: the Araneae may be characterised by an absence of mutualisms; these mutualisms simply have not been detected; or non-mutualistic associations may even have been incorrectly inferred. For example, the impetus of my study of *Psechrus*, *Philoponella* and *Argyrodes* was to reveal the fitness costs to the host of what appeared to be a kleptoparasitic relationship. The correct nature of the relationship between the species was only revealed experimentally, and this is likely to be true of many other inter-specific associations described in this review. But irrespective of the true nature of these relationships, inter-specific associations involving spiders provide a rich seam of biological systems that pose a variety of fascinating questions.

ACKNOWLEDGEMENTS

I am very grateful for the critical comments and discussion provided by Rachel Allan, Jonathan Coddington, William Eberhard, Malcolm Edmunds, Theo Evans, Mary Whitehouse and especially Robert Jackson and Fritz Vollrath; not all agree with me, but their advice is appreciated. Thanks also to Rachael Bathgate for helping compile the kleptoparasite data-base; Fritz Vollrath for the Zusammenfassung; Mark Harvey, Bill Humphreys and Barbara York Main for their encouragement; and the W.V. Scott Fund, University of Melbourne and Australian Research Council (grant A19130739) for financial support.

VERTICAL DISTRIBUTION AND ABUNDANCE OF PSEUDOSCORPIONS (ARACHNIDA) IN THE SOIL OF TWO DIFFERENT NEOTROPICAL PRIMARY FORESTS DURING THE DRY AND RAINY SEASONS

JOACHIM ADIS AND VOLKER MAHNERT

Adis, J. and Mahnert, V. 1993 11 11: Vertical distribution and abundance of pseudoscorpions (Arachnida) in the soil of two different neotropical primary forests during the dry and rainy seasons. *Memoirs of the Queensland Museum* **33**(2): 431-440. Brisbane. ISSN 0079-8835.

Pseudoscorpions were extracted from 0-14cm soil depth in two dryland (upland) forests near Manaus, Brazil. In a primary forest on yellow latosol, about 1700 specimens per m^2 were obtained during the dry season and 1135 during the rainy season. They accounted for 10-15% of all arthropods extracted, excluding Acari and Collembola. In a primary forest on white sand soil (campinarana), about 530 specimens per m^2 were obtained during the dry season and 480 during the rainy season. They accounted for only 3-4% of all arthropods extracted, again excluding Acari and Collembola. Significant but different correlations were found in both forest types between the abundance of pseudoscorpions and changing moisture, temperature and pH conditions in relation to soil depth and season. Neither during the dry season nor during the rainy season was the abundance of pseudoscorpions in mineral subsoils higher in response to the changing soil moisture content in organic layers. This was reported for arthropods from forests in the seasonal tropics where periods without precipitation occur. Results are discussed at the species level. They are compared with published data on the vertical distribution and abundance of pseudoscorpion species from the yellow latosol of a secondary dryland forest (dry season and rainy season) from the same region.

In zwei Festlandwäldern in der Umgebung von Manaus wurden Pseudoskorpione aus 0-14cm Bodentiefe extrahiert. In einem Primärwald auf gelbem Latosolboden wurden während der Trockenzeit 1700 und während der Regenzeit 1135 Individuen pro m^2 nachgewiesen. Sie repräsentierten 10-15% aller extrahierten Arthropoden, Acari und Collembola ausgenommen. In einem Primärwald auf Weißsandboden (campinarana) wurden während der Trockenzeit 530 und während der Regenzeit 480 Individuen pro m^2 nachgewiesen. Sie repräsentierten nur 3-4% aller extrahierten Arthropoden, Acari und Collembolen wiederum ausgenommen. Signifikante aber unterschiedliche Korrelationen ergaben sich in beiden Waldtypen zwischen der Abundanz der Pseudoskorpione und der sich ändernden Feuchte, der Temperatur und dem pH in Bezug auf Bodentiefe und Jahreszeit. Weder während der Trockenzeit, noch während der Regenzeit, war die Abundanz der Pseudoskorpione im mineralischen Unterboden als Folge auf die sich ändernde Feuchte im organischen Oberboden höher. Dies wurde für Arthropoden in Wäldern der saisonalen Tropen, die Trockenperioden durchlaufen, nachgewiesen. Die Ergebnisse werden auf Artniveau diskutiert. Sie werden mit publizierten Daten über die Vertikalverteilung und Abundanz von Pseudoskorpionarten aus einem Sekundärwald auf gelbem Latosolboden im gleichen Gebiet verglichen.

□*Pseudoscorpiones, abundance, seasonality, vertical distribution, Neotropics.*

Joachim Adis, Tropical Ecology Working Group, Max-Planck-Institute for Limnology, Postfach 165, D-2320 Ploen, Germany, in cooperation with National Institute for Amazonian Research (INPA), Manaus, AM, Brazil; Volker Mahnert, Muséum d'Histoire naturelle, Case Postale 434, CH-1211 Genève 6, Switzerland; 23 November 1992.

In those wet but markedly seasonal tropics where periods without precipitation occur, terrestrial arthropods are reported to migrate to mineral subsoils in the dry season as a response to changing humidity in organic layers (Beck, 1964; Bullock, 1967; Goffinet, 1976; Lawrence, 1953; Levings and Windsor, 1984; Liebermann and Dock, 1982; Merino and Serafino, 1978; Petersen and Luxton, 1982; Rybalov, 1990; Strickland, 1947; Willis, 1976 and others). Central Amazonian dryland (= non-flooded upland) forests experience a rainy season (December-May; average monthly rainfall 211-300mm) and a 'dry' (= drier) season (June November; average monthly rainfall 42-162mm). Annual precipitation is 2105mm (based on 75 years of records from the meteorological station at Manaus, cf. Ribeiro and Adis, 1984). About 75% of the rainfall (1500mm) is recorded during the rainy season. This had no observable difference in vertical distribution of terrestrial arthropods in primary forests on yellow latosol

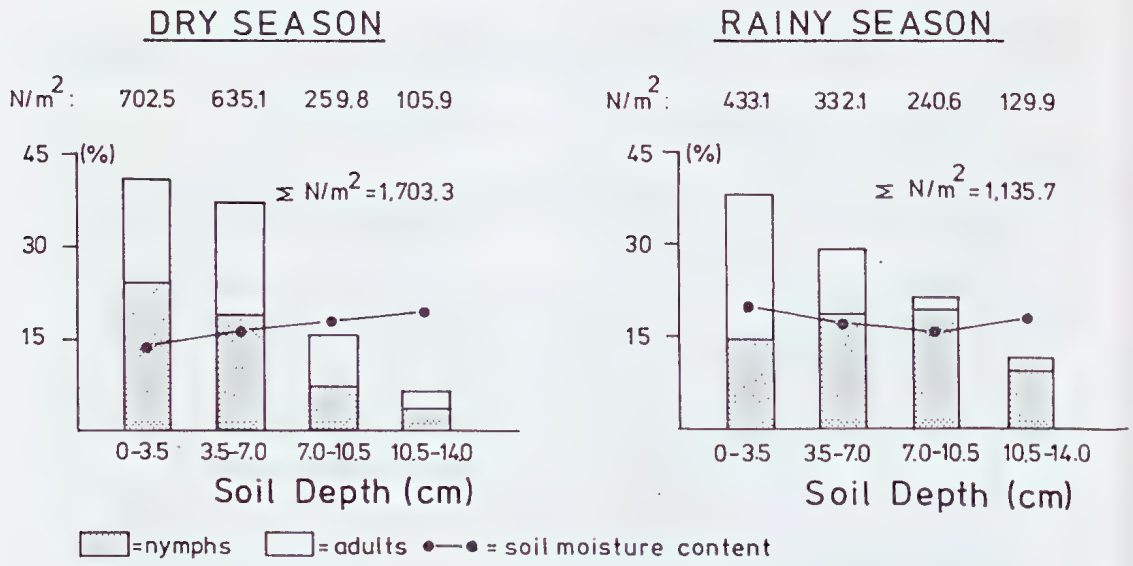

FIG. 1. Distribution of pseudoscorpions in soil and soil moisture content (both in %). Samples taken every 3.5cm to depth of 14cm in dry season and in rainy season in primary dryland forest on yellow latosol near Manaus, Brazil. Total catch each season = 100%. Abundance for each soil layer (N/m^2) and for total catch/ season ($\Sigma N/m^2$).

and on white sand soil (Adis *et al.*, 1989a, b, unpublished data; Morais, 1985). However, results were based mainly on data for orders. Evaluation of sampling data at the species level is now possible for pseudoscorpions, since identification has been completed by the second author.

STUDY AREAS

Primary Forest on Yellow Latosol

Sampling was carried out during the rainy (March) and dry seasons (October) of 1987 in a dryland terra firme forest at the Ducke Forest Reserve (= Reserva Florestal A. Ducke, 2°55'S, 59°59'W) of the National Institute for Amazonian Research (INPA, Manaus), situated on the Manaus-Itacoatiara highway (AM-010; cf. Penny and Arias, 1982). The area sampled was classified as high terra firme forest (Takeuchi, 1961; cf. Brinkmann, 1971) with several species of large, broad-trunked trees (with or without buttresses). The trees reached 44m in height (average height: 22m) and formed a closed canopy. Approximately 235 species, representing 43 families of trees, were recorded in the study area. Most frequent were Leguminosae, Rosaceae, Lauraceae, Sapotaceae and Lecitidaceae. The forest had a patchy understorey and a scanty herb layer. Guillaumet (1987), Lechthaler (1956), Prance (1990), Prance *et al.* (1976) and Rodrigues (1967) provide detailed botanical descriptions of the forest. Microclimatic data are given by Decico *et al.* (1977), Marques *et al.* (1981) and Ribeiro and Nova (1979). The soils near the Ducke Forest Reserve were described by Falesi and Silva (1969) as deep, yellow latosols, strongly weathered, excessively to very strongly acidic, of heavy texture in all profiles (A-C: 0-110cm) and with clay content of the B horizon varying from 50-70%. In the study area, where entomological long-term investigations have previously been undertaken (Adis and Schubart, 1984; Morais, 1985; Penny and Arias, 1982), the soil carried a 1-3cm thick humus layer (A_o), interspersed with fine roots and a thin leaf litter, covering most of the surface. For further details on the study area see Penny and Arias, 1982.

During the 1987 rainy season, 322mm of rain were recorded in March (data from the meteorological station at Ducke Forest Reserve, provided by M. de N.G. Ribeiro at INPA, Manaus). On the day of sampling (March 20, 1987) soil moisture content (= weight difference between wet and dried soil samples in%) was 20.0% at 0-3.5cm (= humus layer), 17.5% at 3.5-7cm, 15.5% at 7-10.5cm and 17.7% at 10.5-14cm soil depth, respectively (= mineral subsoil) (Fig. 1). Soil temperature at 10 a.m. decreased from 25.2°C in the top 3.5cm to 24.5°C at a soil

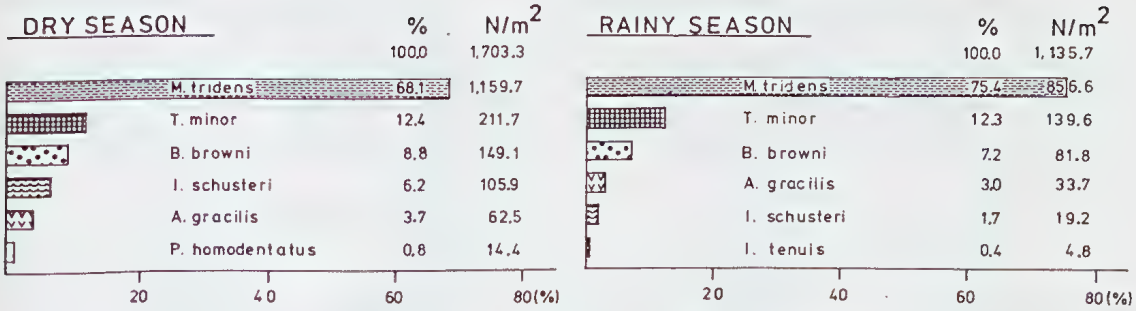

FIG. 2. Dominance (%)and abundance (N/m^2) of species of pseudoscorpions extracted from 1m^2 of soil (0-14cm depth) during dry season (October 1987) and rainy season (March 1987) in primary dryland forest on yellow latosol near Manaus, Brazil. Total catch of each season = 100%. (See text for further explanation).

depth of 14cm. The soil pH increased from 3.3 in the top 3.5cm to 3.8 in the lower layers (3.5.-14cm). During the 1987 dry season, 139mm of rain were recorded in October (data from the meteorological station at Ducke Forest Reserve). On the day of sampling (October 14, 1987) soil moisture content increased from 13.6% in the top 3.5cm to 19.1% at a soil depth of 14cm (Fig. 1) and the soil pH increased from 3.3 to 3.8. Soil temperature at 11 a.m. varied slightly (24.6-24.7°C) from the surface to 14cm.

Primary Forest on White Sand Soil

Sampling was carried out during the rainy season (March) and the dry season (August) of 1988 in a dryland campinarana forest of the Biological Reserve INPA/SUFRAMA (approx. 2°30'S, 60°10'W), at km 45 (formerly km 62) on the Manaus Boa Vista highway (BR -174). Campinarana (= caatinga arbórea) was classified as a low, relatively light forest on white sand soil with thin-stemmed trees 10-20m high, with occasional large, broad-trunked individuals, with or without buttresses, a patchy understorey and no herb layer (Guillaumet, 1987; Anderson, 1981; Lisbõa, 1975). Data on geomorphology and soil genesis are found in Chauvel *et al.* (1987). Floral inventories have been given by Lisbõa (1975), Braga (1979), Anderson *et al.* (1975), Anderson (1981) and Guillaumet (1987), while the microclimatic data were provided by Ribeiro and Santos (1975). In the study area, the white sand soil carried a humus layer that was 10-11cm thick (A_o), penetrated by a matting of roots and a thin, surface-covering leaf litter.

During the 1988 rainy season, 293mm of rain were recorded in February and 280mm in March (data from the meteorological station of EMBRAPA/UEPAE, km 54). On the day of sampling (March 18, 1988) soil moisture content (= weight difference between wet and dried soil samples in %) increased from 20.1% in the top 3.5cm to 26.2% at 10.5cm depth (= humus layer) and dropped to 9.9% at 10.5-14cm (= white sand soil) (Fig. 4). Soil temperature at 11 a.m. decreased from 24.7°C in the top 3.5cm to 24.5°C at a soil depth of 14cm. The pH of the soil was 3.2 (0-3.5cm), 3.3 (3.5-7cm), 3.6 (7-10.5cm) and 3.7 (10.5-14cm), respectively. During the 1988 dry season, 77mm of rainfall were recorded in August (data from the meteorological station of EMBRAPA/UEPAE, km 54). On the day of sampling (August 05, 1988) soil moisture content decreased from 21.9% in the top 3.5cm to 9.5% at 10.5cm depth (= humus layer) and to 9.3% at 10.5-14cm (= white sand soil; Fig. 4). Soil temperature at 3 p.m. decreased from 27.1°C in the top 3.5cm to 25.5°C at a soil depth of 14cm. The pH of the soil was 3.6 (0-3.5cm), 3.5 (3.5-7cm), 3.5 (7-10.5cm) and 3.6 (10.5-14cm), respectively. The relative light intensity on the forest floor was about 2.1% (210 lx; comparative value in the open air at 3 p.m., 10.000 lx (overcast sky); cf. Brinkmann, 1970, 1971).

METHODOLOGY

In both study areas, six soil samples were taken along a transect at random intervals with a split corer (a steel cylinder with lateral hinges; diameter 21cm, length 33cm) which was driven into the soil with a mallet. Each sample was taken to a depth of 14cm and was then divided into four subsamples of 3.5cm each. Animals were extracted from subsamples following a modified method of Kempson (Adis, 1987). All pseudoscorpions were separated by species [adults (males and females), nymphal instars] and their

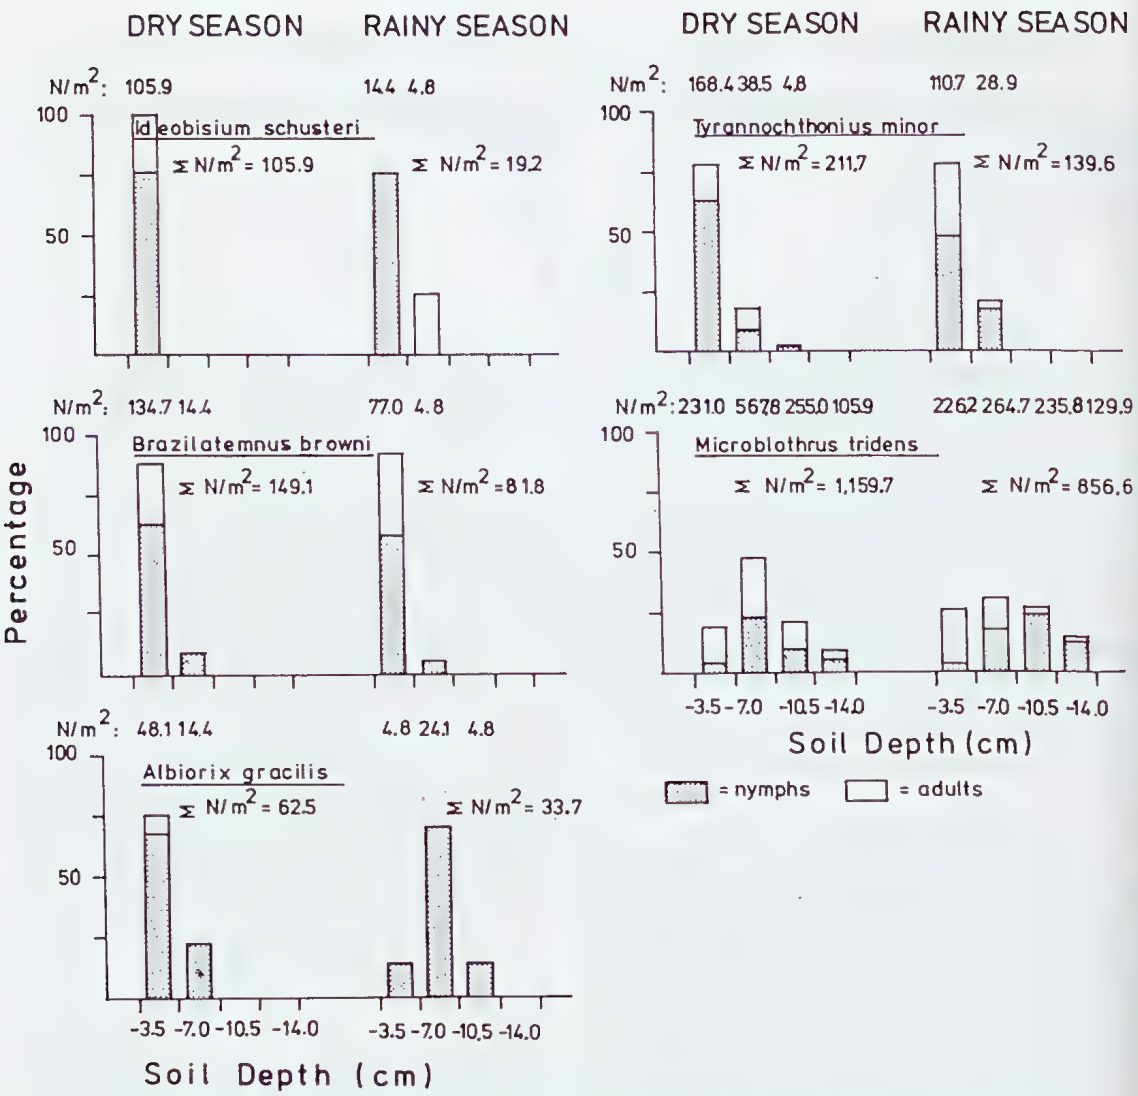

FIG. 3. Vertical distribution of five species of pseudoscorpions in soil (%). Samples taken every 3.5cm to depth of 14cm during dry season and rainy season in primary dryland forest on yellow latosol near Manaus, Brazil. Total catch each season = 100%. Abundance for each layer (N/m^2) and total catch per season (Σ N/m^2).

abundance was calculated for 1 m^2. Vertical distribution of adults and nymphs in relation to changing conditions of soil moisture content, temperature and pH was statistically evaluated with the linear correlation test (Cavalli-Sforza, 1972), using the original field data.

RESULTS

Primary Forest on Yellow Latosol

Pseudoscorpions accounted for 10-15% of all arthropods extracted from 1m^2 soil of 14cm depth (10,000-12,000 ind./m^2, Acari and Collembola disregarded) in the study area (Adis *et al.*, unpublished data). During the dry season, about 41% of all 1,700 ($\pm$71) pseudoscorpions were collected from the top 3.5.cm, 37% from below the humus layer (3.5-7cm) and 22% at 7-14cm depth. About 54% of all specimens collected represented juvenile stages (Fig. 1: nymphs). Decreasing abundance of pseudoscorpions at greater soil depths was significantly correlated with increasing soil moisture content (adults and nymphs: $P<0.01$, $r = -0.998$, nymphs only: $P<0.05$, $r = -0.956$; $n = 4$). During the rainy season, vertical distribution was similar (Fig. 1):

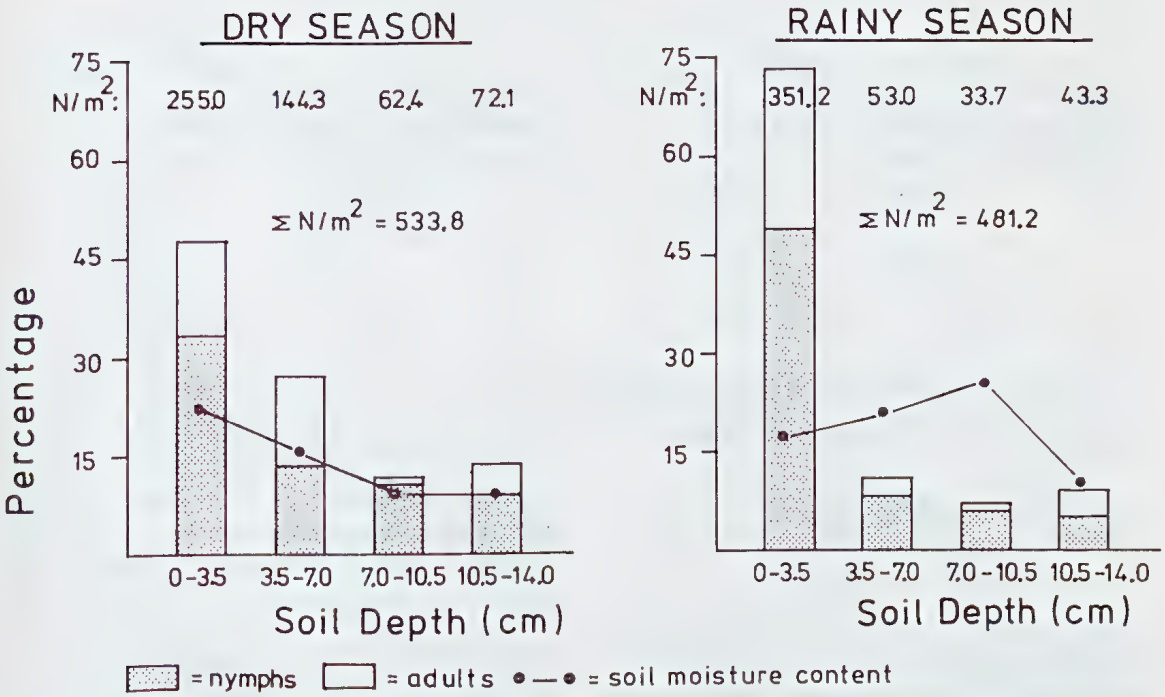

FIG. 4. Distribution of pseudoscorpions in soil and soil moisture content (both in %). Samples taken every 3.5cm to depth of 14cm during dry season and rainy season in primary dryland forest on white sand soil near Manaus, Brazil. Total catch each season = 100%. Abundance for each soil layer (N/m^2) and total catch / season ($\Sigma N/m^2$).

38% of the 1,100 (±46) pseudoscorpions were recovered from the top 3.5 cm, 29% from 3.5-7cm and 33% from 7-14cm soil depth. About 61% of the total catch were nymphs. Decreasing abundance of pseudoscorpions at greater soil depths was significantly correlated with decreasing soil temperature (adults and nymphs: $P<0.01$, $r = +0.993$, nymphs only: $P<0.05$, $r = +0.956$; $n = 4$).

Six species of pseudoscorpions were collected in both seasons (Fig. 2). All were previously reported from soils of Amazonian dryland forests (Mahnert and Adis, 1985). Syarinidae were most abundant, with *Microblothrus tridens* Mahnert (dry season: 1160±55 ind./m^2, rainy season: 860±24 ind./m^2), *Ideobisium schusteri* Mahnert and *Ideoblothrus tenuis* Mahnert accounting for 74-78% of the total catch (Fig. 2). Chthoniidae was the next most abundant family, with *Tyrannochthonius (T.) minor* Mahnert (= *Lagynochthonius minor* (Mahnert)); dry season: 212±17.4 ind./m^2, rainy season: 140±14 ind./m^2) and (dry season only) *Pseudochthonius homodentatus* Chamberlin representing 12-13% of the total catch. Less abundant (>10%) were Miratemnidae (*Brazilatemnus browni* Muchmore[1]; dry season: 149±20 ind./m^2, rainy season: 82±13 ind./m^2) and Ideoroncidae (*Albiorix gracilis* Mahnert). Few differences in dominance were found for species captured during both seasons, however their abundance varied (Fig. 2).

Except for *A. gracilis*, vertical distribution of pseudoscorpions in the soil differed between species but not within species when comparing different seasons (Fig. 3). *I. schusteri* and *B. browni* were only found at 0-7cm soil depth, with abundances being greatest in the top 3.5cm. This is also true for *T. minor* which lived, like *A. gracilis*, to a soil depth of 10.5cm. However, occurrence was restricted to the upper 7cm in *T. minor* during the rainy season and in *A. gracilis* during the dry season (Fig. 3). *I. tenuis* was found only at a soil depth of 3.5-7cm (= below the humus layer) during both seasons, whereas *M. tridens* occurred in all soil layers (0-14cm). During the dry season, significant correlation was observed between decreasing abundance of *T. minor* and greater soil depths (Fig. 3) and the

[1] At this locality, *B. browni* is apparently smaller. It may have adapted to its environment, thus representing an eco-species.

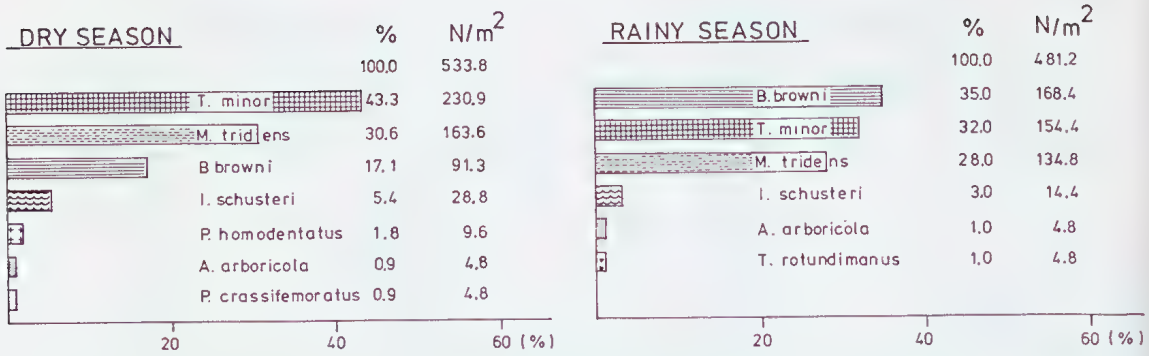

FIG. 5. Dominance (%) and abundance (N/m^2) of species of pseudo scorpions extracted from 1m^2 soil (0-14cm depth) during dry (August 1988) and rainy (March 1988) seasons in primary dryland forest on white sand soil near Manaus, Brazil. Total catch of each season = 100%. (See text for further explanation).

increased soil moisture content ($P<0.05$; adults and nymphs: $r = -0.959$, adults only: $r = -0.968$; $P<0.10$; $r = -0.936$ for nymphs only; $n=4$, respectively). Similar results were recorded from *A. gracilis* ($P<0.05$; adults and nymphs: $r = -0.969$, nymphs only: $r = +0.974$; $n = 4$). During the rainy season, decreasing abundance of *T. minor* and *B. browni* (Fig. 3) was significantly correlated with increasing pH values at greater soil depths (*T. minor*: $P<0.05$, $r = -0.970$ for adults and nymphs, $r = -0.951$ for nymphs only and $P<0.01$, $r = -0.994$ for adults only; *B. browni*: $P<0.01$, $r = -0.998$ for adults and nymphs and $r = -0.995$ for nymphs only; $n = 4$, respectively). In *M. tridens*, the increasing abundance of nymphs at greater soil depths was significantly correlated with decreasing soil moisture content ($P<0.05$, $r = -0.977$; $n = 4$). The decrease in abundance of adults, however, was significantly correlated with the decrease of the soil temperature at greater soil depths ($P<0.05$, $r = +0.962$; $n = 4$). This was also observed for nymphs of *T. minor* ($P<0.05$, $r = +0.951$; $n = 4$). Neoteny and potential parthenogenesis were confirmed for *M. tridens*, with sexually mature tritonymphs (= males) being absent (cf. Adis and Mahnert, 1990a; Mahnert, 1985).

Primary Forest on White Sand Soil

Pseudoscorpions accounted for 3-4% of all arthropods extracted from 1m^2 soil of 14cm depth (14,000-15,000 ind./m^2, Acari and Collembola disregarded) in the study area (Adis *et al.*, 1989a, b). During the dry season, about 48% of the total 530 (± 22) pseudoscorpions were collected from the top 3.5cm, 27% from 3.5-7cm, 12% from 7-10.5cm (= humus layer) and 13% from the white sand soil layer (10.5-14cm). About 66% of all specimens collected represented juvenile stages (Fig. 4: nymphs). Decreasing abundance of pseudoscorpions at greater soil depths was significantly correlated with decreasing soil moisture content ($P<0.05$; adults and nymphs: $r = +0.965$, adults only: $r = +0.952$; $n=4$) and decreasing soil temperature ($P<0.05$; adults and nymphs: $r = +0.967$; $n=4$). During the rainy season, vertical distribution was similar but more pronounced (Fig. 4): 73% of the 480 (± 27) pseudoscorpions were taken from the top 3.5cm, 11% from 3.5-7cm, 7% from 7-10.5cm and 9% from the white sand soil layer (10.5-14cm). About 68% of the total catch were nymphs. No significant correlation was found between the vertical distribution of pseudoscorpions and changing conditions of soil moisture content, soil temperature and pH.

Seven species of pseudoscorpions were obtained during the dry and six species during the rainy season (Fig. 5). All were previously reported from soils of Amazonian dryland forests (Mahnert and Adis, 1985). Chthoniidae were most abundant, with *Tyrannochthonius (T.) minor* Mahnert (dry season: 231 ± 13 ind./m^2, rainy season: 154 ± 15 ind./m^2), *T. (T.) rotundimanus* Mahnert and *Pseudochthonius homodentatus* Chamberlin accounting for 33-45% of the total catch (Fig. 5). Syarinidae was the next most abundant family with *Microblothrus tridens* Mahnert (dry season: 164 ± 10 ind./m^2, rainy season: 135 ± 8 ind./m^2) and *Ideobisium schusteri* Mahnert (dry season: 29 ± 3 ind./m^2, rainy season 14 ± 4 ind./m^2) accounting for 31-36% of the total catch. The Miratemnidae were represented by *Brazilatemnus browni* Muchmore (17-35%; dry season: 91 ± 6 ind./m^2, rainy season: 168 ± 16 ind./m^2). Less abundant ($\leq 1\%$)

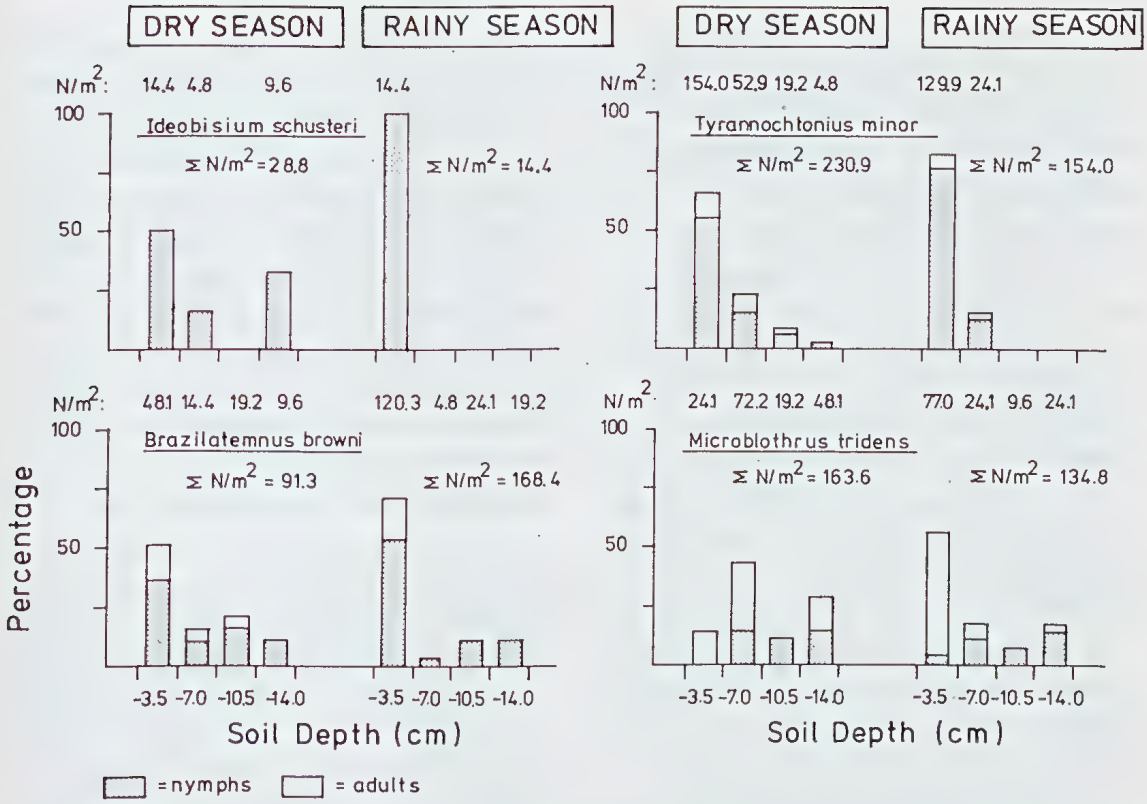

FIG. 6. Vertical distribution of four species of pseudoscorpions in soil (%). Samples taken every 3.5cm to depth of 14cm during dry and rainy seasons in primary dryland forest on white sand soil near Manaus, Brazil. Total catch of each season = 100%. Abundance given for each soil layer (N/m^2) and for total catch per season ($\Sigma N/m^2$).

were Ideoroncidae (*Albiorix gracilis* Mahnert) and Chernetidae (*Pseudopilanus crassifemoratus* Mahnert). The same four species (*T. minor*, *B. browni*, *M. tridens* and *I. schusteri*) were the most abundant in both seasons, however, their dominance in the total catch per season varied (Fig. 5). In two species, vertical distribution differed with the seasons. During the rainy season, *T. minor* and *I. schusteri* were found only from 0-7cm and in the top 3.5cm of soil, respectively. Both species were found throughout the 0-14cm soil sample during the dry season (Fig. 6). Their abundance was greatest in the top 3.5cm, independent of seasons. This is also true for *B. browni* which, together with *M. tridens*, occurred throughout the 0-14cm soil sample during the dry season as well as the rainy season. Adults of *M. tridens* were somewhat more abundant in the top 7cm, whereas no adults of *I. schusteri* were collected, probably due to low catch numbers. *A. arboricola* was restricted to the top 3.5cm. During the dry season, significant correlation between abundance and soil conditions was observed in *T. minor*: its abundance decreased at greater soil depths as the soil moisture content ($P<0.05$, $r = +0.979$ only for adults; $P<0.10$, $r = +0.935$ for adults and nymphs, $r = +0.900$ for nymphs only; $n = 4$, respectively) and the soil temperature decreased ($P<0.05$, $r = +0.967$ for adults and nymphs, $r = +0.972$ for adults; $P<0.10$, $r = +0.939$ for nymphs only; $n = 4$, respectively). No significant correlation was found during the rainy season between the vertical distribution of species and the abiotic factors investigated. In *M. tridens* sexually mature tritonymphs (= males) were absent, which confirms neoteny and potential parthenogenesis in this species (cf. 4.1.).

DISCUSSION

In Central Amazonia the abundance of pseudoscorpions in primary and secondary dryland forests on yellow latosol accounted (independently of seasons) for 3-5% of all arthropods

extracted from $1m^2$ soil of 14cm depth and for 10-15% when Acari and Collembola were excluded (cf. Adis *et al.*, 1987a, b, unpublished data). In the primary forest on white sand soil, their abundance was only 0.7-0.9% and 3-4%, respectively, due to large numbers of Pauropoda and Diplura (cf. Adis *et al.*, 1989a, b). About two-thirds of all pseudoscorpions recovered from the soil of the primary and secondary forest on yellow latosol (61-67% of the total catch) and about three-quarters of the primary white sand forest (75-84%) inhabited the top 7cm. No species were found to occur exclusively in the lower, mineral subsoil (e.g. in 10.5-14cm soil depth). Two species (*T. minor*, *B. browni*) were more abundant in the upper, organic layer in the three forests which were investigated (Figs 3, 6; fig. 3 in Adis and Mahnert, 1990a). *M. tridens*, *T. minor* and *B. browni* were the most abundant species, representing 89-95% of the total catch in the primary forests on yellow latosol and on white sand soil. They represented 58-74% of the total catch in the secondary forest on yellow latosol, where *I. tenuis* and *A. gracilis* were frequent as well (22-33% of the total catch; cf. Adis and Mahnert, 1990a). The similar spectrum of pseudoscorpion species in forests on yellow latosol and on white sand soil and especially the lack of endemic species in the latter forest type, confirm the geological results of Chauvel *et al.* (1987). They reported that the white sand area investigated represents the final stage of podzolisation, i.e. the transformation of clayey latosols to white sandy podzols by (long-term) weathering and leaching processes. If the white sand area were a large dried-up old riverbed, species composition would be different from the yellow latosol area (cf. Adis and Mahnert, 1990b).

Neither during the dry nor the rainy season was the abundance of pseudoscorpions in mineral subsoils higher in response to the changing moisture content in organic layers. This phenomenon has been reported in arthropods in the seasonally-dry tropical forests, where periods without precipitation occur [cf. climate diagrams for Central America (Walter and Lieth, 1960-67) and for Manaus (Worbes, 1986)]. Higher or lower abundance of (at least some) species at a distinct soil depth seems to be related to different abiotic factors. For example, the decreasing abundance of *T. minor* with soil depth during the dry season was correlated with soil moisture content in two forest types: negatively with increasing moisture content values in the primary forest on yellow latosol and positively with decreasing soil moisture in the primary forest on white sand soil (cf. 4.1, 4.2.). In addition, decreasing abundance with depth was also related to somewhat lower temperatures recorded from the lower levels of soil in the white sand forest. During the rainy season, no correlation was found between species abundance and soil moisture content in these two forest types. However, in the forest on yellow latosol there was positive correlation between decreased abundance of nymphs and lower soil temperatures and negative correlation between decreased abundance of nymphs, nymphs and adults ($P<0.05$) and increased soil pH. At greater soil depths there was an even higher statistical probability ($P<0.01$) of negative correlation between decreased abundance of adults and increased pH. Correlation between abundance and soil moisture content has not yet been reported for *T. minor* from the secondary forest on yellow latosol (Adis and Mahnert, 1990a). The more homogeneous occurrence of *M. tridens* in 0-14cm soil depth (Figs 3, 6; fig. 3 in Adis and Mahnert, 1990a) was correlated with soil moisture content as well: there was positive correlation between decreasing numbers of nymphs and soil moisture in the primary forest on yellow latosol during the rainy season and, correspondingly, negative correlation between increasing abundance of nymphs and decreasing soil moisture content at greater soil depths in the secondary forest on yellow latosol (cf. Adis and Mahnert, 1990a). In adults, however, there was a positive correlation between decreased abundance and soil moisture content (secondary forest) and between decreased abundance and lower temperatures at greater soil depths (primary forest).

These data all suggest that factors other than soil moisture content (abiotic and/or biotic ones) may as well cause the different distribution of pseudoscorpion species in the soil. A significant correlation, for example, was found between the abundance of pseudoscorpions and Collembola in the secondary forest on yellow latosol ($P<0.05$; dry season: $r = +0.969$, rainy season: $r = +0.989$; $n = 4$) and in the primary forest on white sand soil (dry season: $P<0.01$, $r = +0.991$, rainy season: $P<0.05$, $r = +0.967$; $n = 4$). This relationship has to be investigated in more detail, as springtails represent a potential food source for pseudoscorpions (cf. Jones, 1975; Ressl and Beier, 1958; Weygoldt, 1969). Thus, complementary studies should be carried out on reproduction patterns, food availability and trophic structure over a one-year period (cf. Adis *et al.*, 1988). Data also show that the number of samples taken per soil

layer (n= 6) was sufficient for a species dominance of 5% of the total catch, as standard deviation did not exceed 20%. Results indicate that terricole pseudoscorpions of primary dryland forests on white sand soil and of secondary dryland forests on yellow latosol represent the terricole species spectrum of a primary dryland forest on yellow latosol, which has been altered either by geomorphological/geochemical processes or human impact (cf. Morais, 1985; Rodrigues, 1986). Habitat preference in pseudoscorpions and the many habitat types existing in Amazonia are considered to be major reasons for the high species diversity found in neotropical pseudoscorpions (cf. Adis and Mahnert, 1985, 1990b).

ACKNOWLEDGEMENTS

The pseudoscorpion material was obtained during the post-graduate courses 'Entomological Field Ecology' of INPA/University Amazonas at Manaus (Brazil) in August 1988 and 'Eco-entomological course on neotropical arthropods' of the Christian-Albrechts-University at Kiel (Germany) in October 1990. All participants are thanked for their valuable collaboration. Inge Schmidt-Brockmann kindly typed the manuscript, Susanne Hamann (both at MPI in Plön) made the drawings and Nancy Weider corrected the English draft.

NEST ASSOCIATES OF *CLUBIONA ROBUSTA* L. KOCH (ARANEAE: CLUBIONIDAE) IN AUSTRALIA

A.D. AUSTIN

Austin, A.D. 1993 11 11: Nest associates of *Clubiona robusta* L. Koch (Araneae: Clubionidae) in Australia. *Memoirs of the Queensland Museum* **33**(2): 441-446. Brisbane. ISSN 0079-8835.

The nests of *Clubiona robusta*, whether or not they contain a resident female spider, are usually inhabited by other invertebrates, here termed nest associates. The abundance and diversity of nest associates for *C. robusta* are described from sampled nests. Associates recorded were: other spiders, Acarina, Mollusca and insects of the orders Collembola, Coleoptera, Heteroptera, Hymenoptera, Lepidoptera, Neuroptera, Psocoptera and Thysanoptera. The presence of a resident female was a factor which affects the abundance and diversity of associates. Biological notes on each group of nest associates are given. Results for *C. robusta* are compared with data on other spiders in the same habitat, and other categories of nest associates used in other studies.□*Araneae, Clubionidae, parasitoid, predator, eggs, spider nest.*

A.D. Austin, Department of Crop Protection, Waite Campus, University of Adelaide, P.O. Glen Osmond, South Australia 5064, Australia; 18 August, 1992.

Most vagabond spiders build a silken retreat in which they moult, mate, lay eggs and protect themselves and their eggs from predators and extreme environmental conditions (Jackson, 1979; Jackson and Griswold, 1979; Pollard and Jackson, 1982; Austin, 1984a, 1988; Wolf, 1990). Different species construct a great variety of retreats which vary in size, structural complexity and the location in which they are placed. For *Clubiona robusta* L. Koch, a moderate-sized clubionid (body length about 15 mm) which inhabits the corticating (shedding) bark of eucalypt trees in south-eastern Australia, two types of retreats have been recognized: flimsy, thin, silk-walled moulting chambers constructed by juveniles, and thicker walled nests constructed by mature females for egg laying (Austin, 1984a).

Whatever the structure of spider retreats, they often attract an array of other invertebrates (termed 'nest associates') which utilize them in a variety of ways (Auten, 1925; Jackson and Griswold, 1979; Griswold, 1986). This aspect of spider retreats has been examined only rarely. A study of the nest associates of the salticid *Phidippus johnsoni* Peckham and Peckham in the U.S.A. by Jackson and Griswold (1979) is the only known detailed work. Jackson and Griswold (1979) divided nest associates into eight categories, following the three described by Auten (1925), based on their biological relationship with the resident spider, its eggs or the nest itself (see Table 1). Most of these biological categories have also been recognized for two eresid species in South Africa (Griswold, 1986).

During a study of the biology of *C. robusta* in South Australia (Austin, 1984a, 1988), incidental observations showed that 1) most nests contained at least some associates, 2) associates inhabited both vacant and occupied nests, and 3) the size range of associates appeared to differ between vacant and occupied nests. This study then sets out to detail the diversity and abundance of nest associates found in *C. robusta* nests, and the factors that might determine their number and size.

MATERIALS AND METHODS

Nests of *C. robusta* were collected from under the bark of eucalypt trees with large plates of corticating bark at their bases (i.e. *Eucalyptus camaldulensis*, *E. cladocalyx*, *E. leucoxylon* and *E. viminalis*) in the Mylor area of the Adelaide Hills, South Australia (see Austin, 1984a). Nests were collected at random in the summer (December-February) over three years (1979-1981). Nests constructed only in that summer were included in samples. The whiter, fresher colour of the silk was used to distinguish them from nests built in previous seasons. Samples included vacant nests, nests containing a resident spider, and nests containing a resident spider and egg-mass or hatched juveniles. In the field, after bark plates were removed from trees, nests were gently teased away and placed in screw-top plastic vials (40 mm dia.). A large white dish prevented accidental loss of any associates or resident spiders. In the laboratory, when nest associates were en-

Category	Description
1a	Endoparasitoids of spiders that seek out and/or emerge from their hosts inside nests
1b	Ectoparasites and ectoparasitoids of spiders that seek out and/or emerge from their hosts inside nests
2	Endoparasitoids of eggs in nests
3a	Predators of eggs in nests (including 'ectoparasitoids')
3b	Predators of spiders in nests
4	Scavengers feeding on dead spiders or other material in nests
5	Predatory spiders that adopt nests as a predatory device
6	Spiders that adopt the nests of other spiders as a refuge or substitute for constructing their own nests
7	Organisms (other than spiders) that adopt nests as a refuge or pupation site
8	Accidental inhabitants
9	Conspecific males

TABLE 1. Categories of nest associates, modified after Jackson and Griswold (1979) (see text for further information).

countered, details of the nest were recorded along with any relevant biological information for the associate, and they were then preserved in 70% alcohol for identification. Parasitized spider eggs and the larvae and pupae of mantispids, pompilids, Diptera and Lepidoptera were left to emerge prior to preservation. As in Jackson and Griswold (1979), nest associates only within the nest, within the silk matrix of the nest wall, or under the nest were collected, not those completely outside or near the nest. To compare differences in the diversity, size and abundance of associates between vacant nests and those occupied by a resident female, 30 nests of each type were collected at random in the field during January 1980 and examined.

Voucher specimens of each nest associate were lodged in the Department of Crop Protection insect collection, Waite Campus, University of Adelaide, South Australia.

RESULTS

Over 400 nests sampled during the summers of 1979 to 1981, yielded over 40 species of nest associates including Acarina, Araneae, Collembola, Coleoptera, Diptera, Heteroptera, Hymenoptera, Lepidoptera, Neuroptera, Psocoptera, Thysanoptera and Mollusca (Table 2). The biological association of each associate with *C. robusta* (categories listed in Table 1), whether determined by direct observation or only assumed, is also given for each species in Table 2. The exact category of individual associates could be assigned only for those species whose biology was observed directly (e.g., parasitoids or predators of eggs or adult *C. robusta*–?*Ogcodes* sp., *Ceratobaeus masneri* Austin), or for those species whose biology was well enough known to rule out all categories except one (e.g., Lepidoptera pupating in nests or Hymenoptera which specifically parasitize other spiders). For other associates, multiple categories are listed to indicate the range of biological associations that might exist. For many species it was impossible to determine whether nests were being used as a specific refuge or the species was there by accident (categories 7/8). For others, their association with *C. robusta* appeared to vary. Gnaphosid and segestriid spiders were observed in the field preying on subadult *C. robusta* (category 3b, see below), as well as constructing their own nests inside those of the host spider (category 6).

Nest associates seemed to occur both in vacant nests and those occupied by a female spider, there appearing to be fewer and smaller associates in the latter. To test these hypotheses, i.e. that occupied nests had fewer and smaller associates, the fauna from 30 occupied nests and 30 vacant nests were compared (Table 3). Of the 40 recognized taxa that were collected during the 1979-81 survey, 28 were found in the 60 sampled nests, with Diptera and Neuroptera being the ordinal taxa not recorded. The 30 occupied nests had substantially fewer nest associates (total 147) compared with vacant nests (227) (see Table 3). Using a Wilcoxin test (Zar, 1984) occupied nests contained significantly fewer associates per nest than vacant nests ($Z = 2.36$, $P < 0.02$), and significantly fewer associates larger than 2.5 mm in length ($Z = -4.38$, $P < 0.0001$). The two major groups of associates that seemed to differ most notably between vacant and occupied nests were other species of spiders and Coleoptera, which were both mostly represented by individuals much greater than 2.5 mm long. This specific size was chosen to test for differences in size of nest associates because previous work on *C. robusta* has shown that this is about the minimum size for potential prey that females spiders can physically handle (Austin, 1988). Hence, one suggested cause for fewer large associates in occupied nests is that they would be killed or driven away by the resident spider.

Biology of Nest Associates

Assigning nest associates to one or more biological categories first required that those used by Jackson and Griswold (1979) be modified. In particular, endo- and ectoparasitoids have been

TABLE 2. Nest associates in nests of *Clubiona robusta* and category of associate to which they belong (see Table 1 and text). I = associates found at least once (+) in occupied or vacant nests over three-year period (1979-81); II = no. of nests in which each associate occurred in sample of 30 vacant nests (Jan 1980); III = no. of nests in which each associate occurred in sample of 30 nests occupied by ♀ spiders (Jan 1980); * = nest associate represented by more than one species.

distinguished (categories 1a and 1b), and predators of spiders and their eggs divided into separate categories (3a and 3b). The term 'parasitoid' (Askew, 1971) is used for species that kill their host (e.g., scelionid egg parasitoids), and 'parasite' for species that feed from but normally do not kill their host (e.g., mantispid larvae feeding on adult spiders, see below). 'Ectoparasitoids' of eggs, a term used by some authors, are not distinguished from egg predators (Austin, 1985; LaSalle, 1990). Also, a new category has been added; that of conspecific males (category 9, see below).

Notes on the biology of nest associates were made both in the field and on nests and associates kept for short periods in the laboratory, during the three-year survey of nests.

Scavengers, refuge seekers and accidental inhabitants. Most nest associates belong to one of these categories (25/40 taxa), but without detailed biological studies on individual species, it was impossible to determine in which specific category they belonged. The major groups are Acarina, Collembola, Coleoptera, Pentatomidae (Heteroptera), Lepidoptera, Psocoptera (New, 1974), Thysanoptera and Mollusca. In addition, three parasitic wasps can be categorized as either refuge seekers or accidental inhabitants; *Ceratobaeus clubionus* Austin, an egg parasitoid of other clubionid spiders (not *C. robusta* -Austin, 1984b), *Ceratobaeus lamponae* (Hickman), an egg parasitoid of *Lampona* spp. (Hickman, 1967a), and *Trissolcus* sp. and *Gryon* sp., egg

TABLE 3. No. of nest associates for vacant nests and nests occupied by resident ♀ spider.

parasitoids of pentatomid bug eggs (Masner, 1976).

Other spiders that use C. robusta nests. More than 50% of vacated nests were occupied by other spiders, including conspecifics, many of which had constructed moulting retreats or their own nests inside that of *C. robusta* (category 6). Sixteen of 30 vacant nests contained juvenile *Clubiona* which, in most cases, could not be identified to species. Some of these may have come from previously hatched eggmasses in the same nest. However, 11 of 30 occupied nests also contained *Clubiona* juveniles, 8 of which contained gravid female *C. robusta* and no previously hatched eggmasses, indicating that these juveniles had migrated from other nests. Ten out of 60 nests sampled in January 1980 contained conspecific adult males, two cohabitating with mature females and eight found in older, vacated nests. Other spiders were encountered more rarely in the survey and only in vacant nests. All species, except for the hahniid *Scotospilus* sp. and the segestriid *Ariadna* sp., at least once constructed retreats or nests inside nests of *C. robusta*.

Parasitoids and parasites of adult C. robusta. Only on two occasions were such organisms recorded. One acrocerid fly (?*Ogcodes* sp.) was reared from a female *C. robusta* (category 1a) (Schlinger, 1987) and a single mantispid larva (possibly *Austromantispa* sp.) was found attached to the pedicel of a gravid female inside a nest (category 1b). Some mantispids are now known to act as ectoparasites of female spiders as small larvae and then as predators of the eggs as larger larvae (Redborg, 1982; Redborg and Macleod, 1983).

Predators of adult C. robusta. The only potential predators of adult *C. robusta* collected during the study were other large spiders, but no such predation was noted (category 3b). Four cases of predation on subadult *C. robusta* outside of retreats were recorded, two each by *Intruda* sp. and *Ariadna* sp. Also, no spider were noted using *C. robusta* nests as a predatory device (category 5, see Jackson, 1976; Jackson and Griswold, 1979).

Parasitoids and predators of C. robusta eggs. An endoparasitic wasp, *Ce. masneri*, was the most commonly noted species (category 2) and was associated with vacant nests, occupied nests without eggmasses, and occupied nests with eggmasses. This wasp caused the highest level of egg mortality (22-25%, Austin, 1984b, 1988) of all species found feeding on eggs. Four species thought to be specific predators ('ectoparasites' of other authors) were seen feeding on *C. robusta* eggmasses only rarely (category 3a). These included a chloropid fly, *Pseudogaurax* sp., on three occasions (Austin, 1985), a eulophid wasp, *Tetrastichus* sp. (LaSalle, 1990), a pompilid wasp, *Epipompilus* sp. (Pollard, 1982), each on one occasion, and a mantispid, *Austromantispa* sp., on two occasions. The only generalist predator of eggs recorded was the ant *Iridomyrmex* sp. which was observed feeding on eggmasses and hatched eggs several times, but only in vacant nests (Austin, 1988). Other possible predators of eggs include a reduviid, *Empicoris rubromaculatus* Blackburn, and other spiders.

Nest Associates of Other Spiders on Eucalypt Bark

During the 1979-81 survey, while collecting nests of *C. robusta*, nests of three relatively common spiders were also collected and their nest associates examined. Observations on these three species are presented here. Other species were either too rarely encountered to report on here or were not found associated with their nests.

Servaea sp. (Salticidae). This same species (or one very similar) was figured as *Plexippus validus* Urquhart by Hickman (1967b), who described some aspects of its biology in Tasmania. The spider constructs a flattened, circular nest (30-40 mm dia.) of dense, white silk, similar in appearance and density to cotton wool. Twenty-five nests were collected: 20 occupied by female spiders, and 10 contained eggmasses or hatched juveniles. Only six associates were identified from these nests: *Austromantispa* sp. 2 (two nests), *Ogcodes* sp. (one nest), *Pseudogaurax* sp. 2 (seven nests), *Iridomyrmex* sp. (one nest), *Anthrenus* sp. (one nest) and an unidentified carabid beetle (one nest). *Iridomyrmex* sp. was feeding on eggs inside a vacant nest. The *Austromantispa* sp., *Ogcodes* sp. and *Pseudogaurax* sp. in these nests were different from those in *C. robusta* nests. Mites, Collembola and

Psocoptera were seen in some nests but were not extracted and identified. No scelionid wasps were reared from eggmasses.

Breda jovialis (L. Koch) (Salticidae). This easily recognized salticid builds a disc-shaped nest (about 30 mm dia.) with two prominent tubular entrances opposite each other (Hickman, 1967b). The surface of the nest is hardened and parchment-like, but the inside is lined with dense, flocculent, white silk. Seventeen nests were collected: six had resident, gravid females, and five had females with eggmasses. Only two associates were identified, and both were feeding on eggs. These were *Idris* sp. (Scelionidae) and *Pseudogaurax* sp. Another scelionid is known to parasitize *B. jovialis* eggs elsewhere in Australia (Hickman, 1967a; Austin, 1981), but this species was not found in South Australia. As for *Servaea* sp., mites, Collembola and Psocoptera were seen in a few nests but were not extracted and identified.

Ariadna sp. (Segestriidae). This species builds a flattened oval or tubular nest with walls of similar construction and silk density to that of *B. jovialis*. Only nine nests were collected, all contained resident females, and four contained eggmasses. The only nest associates recorded were the larvae of a hymenopteran egg predator in one nest. These failed to develop and thus could not be identified. No mites, Collembola and Psocoptera were seen in the nests of this species.

DISCUSSION

The number of species of nest associates collected from *C. robusta* nests and the major taxa represented were similar to that found in nests of a salticid, *P. johnsoni* (Jackson and Griswold, 1979). However, *C. robusta* differed in that many more contained associates: of the 60 sampled nests 55 (92%) contained at least one associate, whereas only 1.2 % of *P. johnsoni* nests were occupied by associates. No nests of *P. johnsoni* occupied by a resident female spider contained associates, whereas most occupied *C. robusta* nests did (87%). *P. johnsoni* nests also differed in that a much greater proportion of recorded associates were spiders (66%), whereas for *C. robusta*, even excluding Acarina and Collembola, only 26% of associates were spiders. The reason for these differences is unclear, but is probably due to differences between the habitats of the two spiders and the size and nature of potential invertebrate faunas that exist at the two locations. Certainly, the bark of eucalypt trees examined in this study harbour a large and diverse invertebrate fauna that acts as a reservoir for *C. robusta* nests. Also, the apparent high and consistent abundance of this fauna means that there is probably a much greater chance of nests being inhabited, compared with the places *P. johnsoni* constructs nests, i.e., under rocks, pieces of wood, and in hollow reeds (Jackson, 1979).

Occupied nests of *C. robusta* have smaller nest associates compared with vacant nests presumably because resident spiders are known to kill and feed on intruders larger than 2.5mm. Also, females are known to guard their eggmasses and kill even distasteful intruders in nests (Austin, 1988). However, the aggressiveness of resident spiders does not explain why there are fewer small associates (<2.5 mm) in occupied nests (see Table 2). One possible reason for this is that the activity of female spiders in building, repairing and tidying nests, disturbs many small invertebrates and they move away.

The notes on nest associates of other spiders given here pose some questions. Generally the nests of the three species examined have structurally more complex nests than does *C. robusta*, and this is associated with them having far fewer nest associates. In the light of this association, further research on nest associates could profitably examine the structure of nests as a factor regulating the number and types of nest associates, as could differences in the behaviour of resident spiders inside their nests.

Finally, the biological categories proposed by Jackson and Griswold (1979) for the nest associates of *P. johnsoni* were directly applicable to the associates recorded here for *C. robusta* and the other three spiders examined and, thus, probably can be applied to the associates of any nest-building vagabond spider. We have modified their scheme in two points: 1) to distinguish between endo- and ectoparasitoids, because these two types of parasitoids have basically different biologies (Austin, 1985; LaSalle, 1990), and 2) to include conspecific males as a new category, which were found in both occupied and vacant nests.

ACKNOWLEDGEMENTS

I wish to thank the following people for identification of specimens: Val Davies, Mike Gray, Penny Greenslade, Gordon Gross, Mark Harvey, David Lee, Eric Matthews and Tim New. I also thank Mike Keller for assistance with statistical analyses, Sally Collins for assistance with field

work and comments on the manuscript, and Paul Dangerfield for comments on the manuscript and proof-reading.

A TENTATIVE ANALYSIS OF THE SPIDER FAUNA OF SOME TROPICAL OCEANIC ISLANDS

L. BAERT AND R. JOCQUÉ

Baert, L. and Jocqué, R. 1993 11 11: A tentative analysis of the spider fauna of some tropical oceanic islands. *Memoirs of the Queensland Museum* **33**(2): 447-454. Brisbane. ISSN 0079-8835.

The spider fauna of oceanic islands in the Pacific (Galápagos, Juan Fernandez, Easter Island, Marquesas, Hawaii), the Atlantic (Saint Helena) and the Indian Ocean (Comoros, Seychelles) is analysed. Family composition, size frequency distribution, species/area relationship, the origin of the faunas and their qualitative compositions are discussed. The colonization of the islands by spiders appears to be greatly influenced by the accessibility of the island, its habitat diversity and the speciation capacity of particular groups. Most of the fauna is composed of species transported by man. Thorough analysis of island faunas is still hampered by the lack of complete published data sets.

Les faunes aranéologiques des îles océaniques situées dans le Pacifique (Galápagos, Juan Fernandez, Marquises, Hawaii) l'Atlantique (Sainte-Hélène) et l'Océan Indien (Comores, Seychelles) sont analysées. Leur composition au niveau de la famille, la distribution des fréquences de taille, leur origine et leur composition qualitative sont discutées. La colonisation des îles par les araignées semble être fortement influencée par l'accessibilité de ces îles, leur diversité en habitats et la capacité de spéciation de certains groupes. Une grande partie des faunes est composée d'espèces apportées par l'homme. Une analyse complète des îles océaniques est encore impossible à cause du manque de données complètes publiées.
□*Araneae, island zoogeography.*

Leon Baert, Koninklijk Belgisch Instituut voor Natuurwetenschappen, Vautierstraat 29, B-1040 Brussels, Belgium; Rudy Jocqué, Koninklijk Museum voor Midden-Afrika, B-3080 Tervuren, Belgium; 26 October, 1992.

Most studies of island spiders have been confined to the description and enumeration of species. A general explanation of the composition of the araneological fauna of islands has not been tried. The availability of many almost complete species lists of remote oceanic and granitic islands allows us to analyse these spider faunas and try to understand their compositions. Only a few data-sets (those of Galápagos and Saint Helena) are nearly complete and most others are likely to grow considerably. For several islands the species lists included many unidentified species submitted for study to us or present in other collections (e.g. Cocos: Natural History Museum of Los Angeles County). Nevertheless we have tried to find patterns in the composition of the tropical island spider faunas.

MATERIAL AND METHODS

Apart from the spiders of the Galápagos and the Comoros, all data used are from the literature (Table 1). Hence, in the analysis of the size distribution, we had to use the total length, which is a less reliable measure than carapace width or the size of another sclerotised body part.

To compare the family composition, the number of species in each family was expressed as a percentage of the total number of species. The Renkonen-index was used to calculate the percentage of similarity.

RESULTS AND DISCUSSION

Family Similarity

Because the islands are in different zoogeographical provinces, a comparison of their faunas on the species level is not informative.

Similarity on family level was surprisingly high between the Galápagos, the Hawaiian Archipelago (Pacific) and Saint Helena (Atlantic), reaching ca 70% (Fig. 1). A second group (ca 60% similarity) consists of the Seychelles and Cocos Islands. These distinct vegetation belts, as on the main islands of the first group, seems important and induces a similar family composition. These islands were initially covered entirely by forest. The southern pacific Easter Island and Juan Fernandez, now covered by a gramineous, so called pampa-vegetation, have little similarity in family constitution.

Body Length Frequency Distribution

In tropical continental habitats, e.g. savanna

TABLE 1. Summary data (age is approximate) of islands and archipelagos considered.

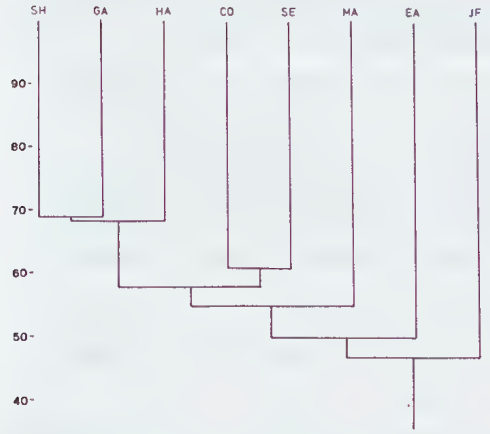

FIG. 1. Dendrogram of the similarities between the islands/archipelagos on family level.

and secondary forest in Ivory coast (Jocqué, 1980), middle-size spiders in the class of 4-6mm dominate (Fig. 2). However, data for Ivory Coast are based entirely on pitfall trap samples. That may bias the size frequency distribution towards higher or lower averages. On the other hand, the collections from islands are clearly biased towards larger spiders. Earlier collectors are more likely to have taken conspicuous large webspiders than small soil dwelling spiders. As for the other analyses it is probably too early to detect relevant differences in size distributions on different islands as compared to the situation on the continent.

Only spiders from Galápagos, Cocos Island and the Seychelles seem on average smaller than those from the collections made with pitfall traps in West Africa (Table 2). As only the difference GA-RCI is significant ($\chi^2 = 23.84$; $P < 0.02$) it seems that the discrepancies are further meaningless. However, complete data from the islands and fully comparable data from the continent might reveal more differences in average size of island and continental spiders. We expect selection to favour small spiders during the colonisation process. Thus, many more small spider species are likely to be present on islands than on the continent. Smaller spiders live in higher densities than bigger ones and the possibility that they reach an island is statistically higher than for larger spiders. Moreover, smaller spiders are usually better aeronauts although young stages of larger spiders have often been observed to balloon as well. The chance that a raft–rafting being an important mean of colonisation–contains a 'propagule' is also likely to be higher for smaller spiders than for larger ones.

However, the possibility for survival of spiders that reach an island is probably better for larger than for smaller ones but the enormous differences in specific ecophysiological characters make it difficult to generalise.

The Seychelles are granitic continental fragments and must have had a well-balanced fauna when they separated from the mainland. Hence, they should have elements of a continental spider fauna. Apparently this is not so. Some unusually large soil-dwelling spiders do exist on the island (see below), but the smallest size class seem more important on that archipelago, just as on the others. The Seychelles are a group of small islands with the largest not exceeding $15km^2$. When ocean levels were higher these islands must have been tiny and the chance for extinction very high. Larger spiders occur in smaller populations. Thus, they are more liable to become extinct hence the otherwise unexpected dominance

TABLE 2. Mean body length (mm), number of species and standard deviation (RCI = Ivory Coast).

	SH	SE	PA	CO	GA	JF	MA	HA	RCI

of smaller spiders on the Seychelles. The spider fauna of Seychelles is probably too little known because the two main expeditions (Benoit 1978, Saaristo 1978) were in the dry season.

Frequency distribution histograms for the smaller Pacific islands (Easter, Juan Fernandez and Cocos) and for the Marquesas archipelago, show very irregular shapes. The distribution seems to have several peaks.

There may be several reasons for this:

1 the fragmentary knowledge of their spider fauna. Few spider species are listed for these islands in the literature. Occasional samples, made by other zoologists during brief visits to Easter Island, yielded important new records of spider species. That is apparently true of our knowledge of the spider fauna of most tropical islands.

2 Cocos and Easter Island are still too young or are so isolated (Easter Island in the centre of the South Pacific Gyre; Juan Fernandez amidst the northerly directed Humboldt Current) that they are difficult to colonise and an equilibrium in their spider communities has not yet been reached.

3 due to their limited size and low habitat diversity these islands cannot support more species and do indeed have several size distribution peaks.

Relation between Island Area and Species Density

Tropical African oceanic islands are far richer in species and their species/area relationship is much higher (0.48-0.81) than for tropical Pacific oceanic islands (Table 3). The very small Cocos Island lying the closest to a continental landmass is exceptional in this respect (0.60). Tropical Pacific archipelagos (0.01-0.04) and the southern pacific islands (0.14-0.18) have relatively low species/area relationships. It is not clear why the African off-shore islands are so much richer than the others. The source areas may be richer but that must be proven by thorough studies of the continental spider faunas. Many more species may have been introduced on the African islands. This is probably true for Saint Helena that has an unusual large proportion (44%) of introduced spiders, mainly from temperate regions. It is doubtful whether that is a sufficient explanation.

There is a relationship between altitude (highest elevation) of the island and the number of species present (Fig. 3.1: $r = 0.677$, $p > 0.01$) and between area of the island and the number of species present (Fig. 3.2: $r = 0.716$, $p > 0.001$). In both cases there is a significant correlation.

Origin of Faunas

As the distance from an island from the mainland increases, its component of continental species decreases.

Very striking is the much lower percentage of continental species on the African islands as compared to those of the Pacific. The same is true for the southern Pacific islands Juan Fernandez and Easter Island. This could be explained by their isolated position. Juan Fernandez lies in the middle of the northerly directed Humboldt Current, whereas Easter Island is situated a long distance from the continent in the centre of the South Pacific Gyre, making the arrival by rafting rather unlikely.

The presence on the Galápagos islands of northern, central (with Antillean elements), as well as southern American elements, could be explained by their special situation astride the equator. The archipelago lies in such a position that it is reached by the warm Niño Current in the rainy season and by the cold Humboldt Current in the dry season. The Californian Current of the Northern Hemisphere runs southwards along the North American coast and reaches the Panama Basin where it is warmed up and turns towards the Galápagos as the Niño Current. The southern Humboldt Current runs northwards along the south American coast and turns westward near the equator towards the Galápagos. Rafts can easily be transported from the north as well as from the south. A floating raft takes about two to four weeks to reach the islands from the South American mainland (Schatz, 1991).

Furthermore, there was a broad connection between the Caribbean region and the eastern Pacific area from 48 my until 3.5 -3 my ago (Woodring, 1959; Jones and Hasson, 1965) with a sea current running from the Atlantic to the Pacific (Petuch,1982). The Panama isthmus was plugged some 3 my ago by the Caribbean Plate which was shoved in between the north and south American plates. At that time the Galápagos islands had already emerged from the sea. It is acceptable that many fauna elements of the Caribbean reached the Galápagos at that time. Nearly 82% of the known spider species of Cocos Island are continental species.

The Marquesas have more species of Pacific origin. This can be expected because of the position of this archipelago at the margin of the Polynesian province (NE end of the south

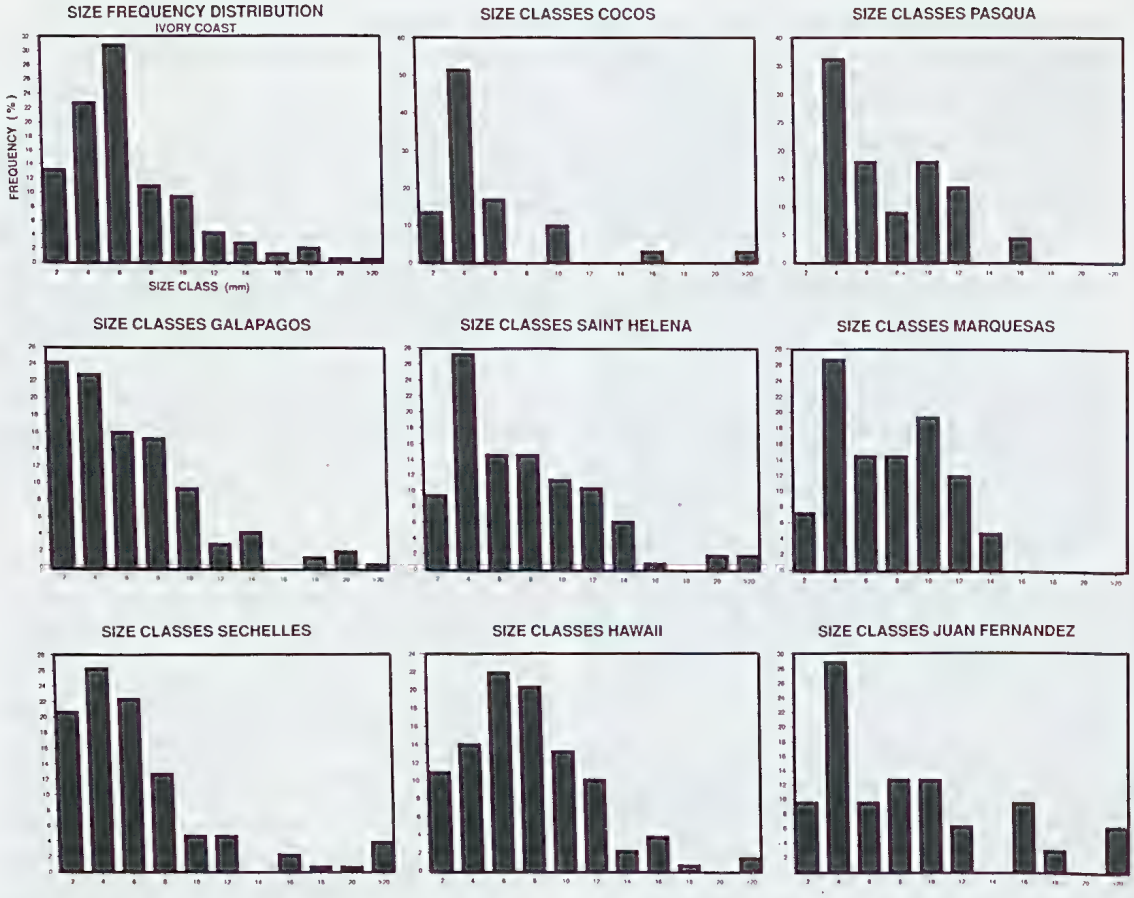

FIG. 2. Frequency distribution histograms of total body length (over 2mm size classes) for each island or archipelago.

equatorial archipelagos chain). In contrast, Hawaii and Galápagos have only a low percentage of Polynesian species as the distances between them and the Polynesian archipelagos are too extensive.

The term 'endemic' must be used now with great care because the continental faunas are far from being well known. This is especially so for the neotropical spider fauna. Many regions have been sampled only superficially or not at all. Few families have been thoroughly revised and new studies will be needed once the 'black holes' have been filled. For instance, the figures in table 2 for Galápagos are based upon 70% of the total of the recognised species. Hence, 46 species have yet to be identified. At this stage in our knowledge one is never sure that the species one describes from an oceanic island really has a dispersion restricted

Island/Archipelago	S	S/area	Continental distribution	Pacific origin	Cosmopolitan species	Endemic
Cocos I. (CO)	30	0.63	82% (A)			18%
Galápagos Arch. (GA)	146	0.02	32% (A)	4%	9%	60%
Hawaii Arch. (HA)	168	0.01	11% (A)	5%	19%	64%
Marquesas Arch. (MA)	48	0.04		31%	20%	50%
Juan Fernandez I. (JF)	32	0.18	17% (A)		17%	70%
Easter I. (PA)	23	0.14	22% (AU)		66%	12%

St Helena I. (SH)	98	0.81	7% (E)	44%	45%	

TABLE 3. The spider fauna of islands and archipelagos. Percentage of species with distribution 1° continental (A=American; E=African; Au=Australian), 2° cosmopolitan and 3° species known only from island or 'Endemic'. Values based only on described species.

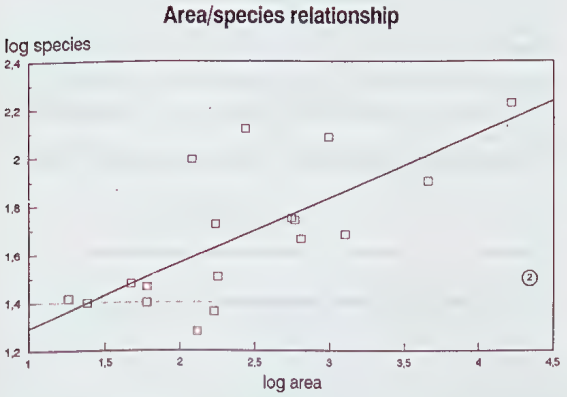

FIG. 3. 1, 2. Relationship between no. of spider species (N) and: 1, altitude (highest elevation) of island or archipelago (logN = -0.6224 log alt.(m)); 2., island/archipelago area (logN = 0.2686 log area + 1.0269).

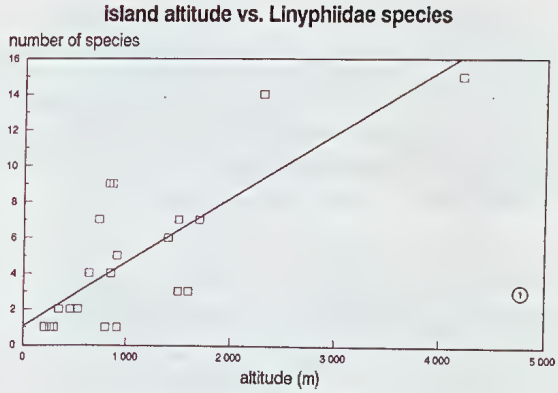

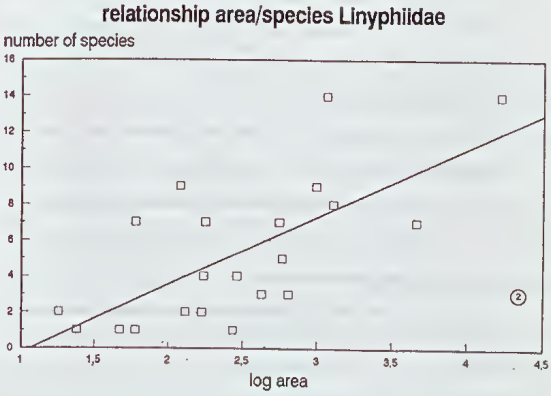

FIG. 4.1, 2. Relationship between no. of linyphiid species (L): 1, and altitude (L = 0.0035 alt(m) + 1.0544; 2., and island/archipelago area (L = 3.7886 log area - 4.0344) (separate islands in archipelagos). (S = no. species).

to that island for it may not yet have been found on the continent. We may therefore seriously question whether we can validly use the proportion of endemics for the analysis of an island fauna. However, we consider that the percentage of endemics we now recognise reflects the rough proportion of real endemics that will eventually be shown to exist.

Cocos Island seems to have few (18%) 'endemic' species. It lies relatively close to the continent. Once the distance to the continent exceeds 900km, we find an 'endemic' proportion in between 50 and 65%. The high percentage of 'endemics' on Hawaii (64%) is probably due to its old age and thus the long period of isolation of the archipelago. The high percentage for the Galápagos islands (60%) may perhaps be due to the fragmentary knowledge of the South American spider fauna (the main reason why one third of the Galápagos spider fauna is not yet identified).

The high percentage (70%) of 'endemics' on Juan Fernandez is very striking. Though close to the mainland, it is a rather isolated island (Humboldt Current) with an environment rendered harsh by the very special climatological conditions.

The proportion of cosmopolitan species on the islands varies between 0 and 20%, with two striking exceptions: Saint Helena with ca 44% and Easter Island with 60% (this figure is based on only 10 species). Most of these species are introduced and restricted to human settlements. This shows the great impact man has had on the spider fauna of Saint Helena.

All the islands considered here do have human settlements, native on Hawaii, Easter Island and Marquesas, but immigrated in historical times on the others. Human settlements invariably result in deforestation for arable land and subsequent introduction of ubiquitous species. Most often this is detrimental to the original fauna. Even more damage can be done with the introduction of

domesticated animals (cattle, dogs, cats, rodents, etc.) and cultivated plants. Accidental introductions can also have serious consequences as for instance the Little Fire Ant (*Wasmannia auropunctata*) on Galápagos. This species haunts large areas, devastating nearly all living animal organisms.

Qualitative Analysis

Qualitative analysis of the distribution of particular groups on islands is perhaps more revealing than quantitative analyses which are still hampered by the incompleteness of many data sets.

Spiders that do not balloon do not seem well adapted to colonise oceanic islands. Good examples are seen in the Zodariidae. Only four species, if we include *Cryptothele*, are present on the islands considered. On the Seychelles we find the endemic *Cryptothele alluaudi* Simon; the Comoros have *Asceua radiosa* Jocqué on Grande Comore and *Diores seiugatus* Jocqué on Mohéli (Jocqué, 1986). *Zodarion trispinosum* Suman is known from Hawaii. The presence of a *Zodarion* on Hawaii, completely outside its main distribution is puzzling, but is probably explained by an introduction as is the presence of *Z. fulvonigrum* (Simon) in North America. The Mygalomorphae are found only on two of these archipelagos. Six species in three families (Benoit, 1978) occur on the Seychelles. Five of these are endemic, the sixth species, *Idioctis intertidalis* (Legendre and Benoit), is also found on Madagascar and Grande Comore, where it occurs together with the endemic *Moggridgea nesiota* Griswold. The presence of these spiders, all but one apparently true endemics, on the Seychelles is explained by its granitic nature, which implies that they have had a fauna from the moment they were separated from the continent. The Comoros are probably more easily colonised than other islands, possibly by rafting, as that archipelago is close to its source area, Madagascar, for which the spider fauna is unfortunately poorly known.

Linyphiidae can be considered excellent colonisers mainly because many frequently balloon. However, linyphiids appear to be able to occupy few habitats. Jocqué (1984, 1985) explained that interference competition in tropical lowland with ants is apparently too important to allow the presence of many linyphiid species. As ants are less common at higher altitude many more linyphiid species tend to be present in highland than at low elevations (e.g. Scharff, 1992). (Since ant diversity and density are linked to climatic conditions, the impression may exist that they are the determining factor.) The presence of an important number of Linyphiidae on high islands was already illustrated for the Comoros (Jocqué, 1985). This is particularly true for islands. There is a significant correlation between the altitude of island and the number of species of Linyphiidae present (Fig. 4.1: $r = 0.780$, $p < 0.001$) and between area of the island and the number of linyphiid species present (Fig. 4.2: $r = 0.688$, $p < 0.001$). There is a third aspect relevant to the colonisation of islands: parapatric speciation on the spot. The Lycosidae are a good example. Wolf spiders might be expected to be good colonisers. Their juvenile stages are active ballooners, and transport by rafting is also a likely means of dispersal if only because lycosids are very common on banks of rivers and in marshes from where rafts are supposed to be derived. However, the number of insular species is quite low compared to the high number of species in continental tropical areas. (Galápagos: 6 species; Hawaii: 11; Cocos: 1; Juan Fernandez: 2; Saint Helena: 7; Seychelles: 2; Comorós: 3). Moreover, almost all species from islands in this study have no continental distribution and must be considered endemics of each island. Only *Bristowiella seychellensis* (Bristowe) is known from both Seychelles and Comorós. Their apparently high speciation rate may be related to this. Of special note, some species at high altitudes on some islands are apparently derived from species at low altitudes. A well documented case is that of *Bristowiella* on the Comoros where two closely related species have clearly differentiated habitats: *Bristowiella seychellensis* living in short grassy vegetation from sea level to about 1500m and *Bristowiella kartalensis* Alderweireldt living in recent lava flows with sparse vegetation from about 600m upwards (Alderweireldt, 1988). Another interesting case is that of the Hawaiian cave dwelling lycosids which have strongly reduced eyes or none and which clearly speciated on the islands themselves (Gertsch, 1973).

On Galápagos, a group of six species apparently derived from the most common one ('Lyc 3'). It occurs over the whole archipelago and occurs mainly in coastal salt marshes. Another species ('Lyc 5') occurs only on the low island Española. The four other species are confined to the high pampa zones of the volcanoes Sierra Negra and Cerro Azul ('Lyc 1') on Isabella, on San Cristóbal ('Lyc 2'), on Santa Cruz ('Lyc 4') and the Alcedo volcano on Isabella ('Lyc 6'). The revision of this remarkable species-group is in preparation.

A fourth example of such segregated parapatric populations is found on Juan Fernandez where 2 *Lycosa* species are found, one living along the coast, the other living in the higher pampa zone.

These statements reveal three important factors influencing the composition of island faunas. In the first place, there is the accessibility of the island, mainly its distance to a source area. In the second place, the diversity of the island's habitats is important. Particular spiders such as mygalomorphs and zodariids are only present on those islands that are easily reached or already had a fauna when they became isolated. Other families, although good colonisers, appear to be restricted by the ecological conditions of the island they can reach. Speciation appears to be the third factor which may be important in the colonisation of habitats that can hardly be reached by the normal ways of dispersal. The effect of niche pressure (Jocqué, 1982) is likely to be an important mechanism in this respect.

CONCLUSION

The faunal composition we now find on many islands is far from being natural. At the same time we know little about the arthropod fauna of most oceanic islands. This makes the analysis and comparison of the faunas very hard. The influence of speciation processes is probably largely overlooked in connection with the compensation of extinction.

THE REPRODUCTIVE ECOLOGY OF *EUSCORPIUS FLAVICAUDIS* IN ENGLAND

T.G. BENTON

Benton, T.G. 1993 11 11: The reproductive ecology of *Euscorpius flavicaudis* in England. *Memoirs of the Queensland Museum* **33**(2): 455-460. Brisbane. ISSN 0079-8835.

The reproductive ecology of the scorpion *Euscorpius flavicaudis* was studied both in the field in England (at a colony dating back 120 yrs), and under semi-natural conditions in the laboratory. Before the mating season males become vagrant to search for females. On encountering a pregnant female or one with young, in her 'burrow', the male may mate-guard her until her period of maternal care ends and she becomes receptive to him. Large males have a higher mating success than small males. Two instars of adult males exist in this population of scorpions: large 7th instars and small 6th instars, and the reasons for this apparently paradoxical situation are explored. □*Euscorpius, mate-guarding, mating, life-history.*

T.G. Benton, Department of Zoology, University of Cambridge, Downing St., Cambridge, CB2 3EJ, United Kingdom; present address: School of Environmental Sciences, University of East Anglia, Norwich, NR4 7TJ, United Kingdom; 7 December, 1992.

Evolutionary and behavioural ecology are relatively young disciplines; and have to date concentrated on using the more 'familiar' animals as subjects: birds, mammals and insects. These disciplines have largely passed arachnids by. Increasingly, however, we are beginning to realise the utility of arachnids as model animals in helping to elucidate general evolutionary principles.

Although there has been considerable increase in behavioural ecological interest in spiders in recent years, scorpions have been largely ignored. This is perhaps because they are difficult animals with which to work – long-lived, inactive, elusive and nocturnal. This paper outlines some of the main findings of a study of scorpion reproductive ecology. It is unfortunately incomplete: posing more questions than it solves; but, I hope that it illustrates the fact that, as in so many areas of their biology, scorpions are idiosyncratic, fascinating and more complex than they may first appear. This study combines the power of controlled laboratory experiments and the ease of laboratory observations with the reality of what is observed in the field; and, by so doing, for the first time the events surrounding the courtship of a scorpion are explored and placed in an ecological context.

THE STUDY ANIMAL

Euscorpius flavicaudis (de Geer), common throughout southern Europe (Birula, 1917), also occurs in England, most probably as a result of introductions. This species is a successful colonising species (Fage, 1928; Wanless, 1977; Lourenco & Vachon, 1981) and is often found associated with buildings (Wanless, 1977). Colonies have been reported from several locations in England, but only one, at Sheerness Docks, Kent (51°26'N, 0°45'E) has lasted many years and is of considerable size. The first record of scorpions at Sheerness is a label on a specimen of *Euscorpius flavicaudis* in the Natural History Museum, London: 'Taken in Sheerness Dockyard, 1870, J.J. Walker' (P.D. Hillyard, *in lit.*).

METHODS

Field Observations

At Sheerness Docks, most present buildings and the perimeter wall date from 1823 (Benton, 1992a). Scorpions are common in areas little frequented by people; and are especially common living in the perimeter wall. This old wall is about 4m high and 66cm thick. It shows the effects of time, with the mortar between the bricks crumbling away, creating 'cracks' which the scorpions readily inhabit. My study area was a 104m length of perimeter wall (bounding ornamental and vegetable gardens). The field study was conducted from January 1988 to July 1989, during which 92 visits were made to Sheerness Docks (totaling 500 hours of observations). Scorpions were observed using a portable ultra-violet light. Benton (1992a) details field methods.

Laboratory Observations

To allow more complete observations and experimentation a laboratory colony of *Euscorpius* was set up, modelled on the habitat at Sheerness. This consisted of a plywood wall (2.44m x 5.79m), covered in sandpaper, with 144 slots (2.5

x 5.1cm) cut into the face. Into these slots were fitted artificial 'cracks' 12 cm long. These were open to the wall and closed at the far end. A layer of soil was placed at the base of the wall. This soil was periodically damped to mimic rain; and each week woodlice (the scorpion's natural food) were released onto it. This colony was kept under a natural photoperiod, and as near natural temperature and humidity as possible. Observations and experiments were conducted at night, when the wall was illuminated by lamps fitted with deep-red filters (invisible to scorpions: Machan, 1968). Unless being used in an experiment, the scorpions (collected at Sheerness) were allowed to move freely around the wall. Benton (1991a) details colony setup.

Experimental Methods

In this study of male contest behaviour for females during the mating season, 11 males were used. On the artificial wall 40 x 40cm enclosures were made around a single crack. A female carrying young was placed in this crack, and later an experimental male was added. Thirty minutes after this male had encountered and entered the crack a second male was added. After encountering the crack the second male would attempt to enter. The males would then meet, assess each other and fight. This procedure was then immediately repeated. The two replicates constituted a 'contest' (and in all cases the results were unambiguous, and identical for each replicate). In total 110 contests were conducted (with each male as 'owner' against every other male as intruder). Contest order was randomly selected. Other methods are detailed in Benton (1992b), and scorpion mensuration in Benton (1991b).

RESULTS

Background

Like most scorpions, *E. flavicaudis* is nocturnal. During the day and over the winter, they are not visible as they have retreated to the back of their cracks in the wall. At night, depending on the season, most scorpions evident are at the entrance to their cracks where they remain immobile, with their claws outstretched and open. The most common prey items are isopods (*Porcellio scaber*) (64%) and then conspecifics (12%) (Benton, 1992a).

Seasons

Scorpion activity at Sheerness is highly seasonal. Over the winter very few (if any) can be seen. The numbers build up during the spring and peak in late summer (Benton, 1992a) before decreasing again to winter levels. As these scorpions live for several years (Benton, 1991b) this pattern reflects varying patterns of behaviour, rather than gross mortality and natality. For most of the year, most scorpions seen are in their crack (for November to June only $8 \pm 11\%$ of all scorpions observed are out of their cracks). However, in summer, on average, $24 \pm 9\%$ of scorpions observed were on the wall surface. Adult males make up most surface-active animals: 3-4x more males are seen on the wall surface than adult females over the summer (Figs 1a, b).

The number of females giving birth or with young peaks when female activity on the wall surface (Fig. 1a) is least. Females with young remain deep within their cracks, and were never observed to venture onto the wall surface. Indeed, females in the last stages of pregnancy also appeared to show a marked reduction in activity.

Most matings at Sheerness (Fig. 1b) are just after the number of females with young peaks (Fig. 1a). Known females with young were found to be unreceptive to males until 2 ± 1.2 days (n=12) after the juveniles had moulted and climbed off her dorsum (Benton, 1992b).

About 3 weeks after male surface-activity begins, the number of matings observed peaks (Fig. 1b). Only at this time can males and females be found together in the same crack. These periods of cohabitation averaged 10 ± 9.9 nights (range 1-30; n=19; data from field). Cohabiting occurred only prior to mating, and whilst the female was either carrying young, or in late pregnancy (Benton, 1992b). Males were associated sometimes with females living in shallow cracks (n=3); in which case the males spent the day in a deep crack nearby and 'commuted' to the female's crack to spend the night sitting at the entrance. The identity of the male mating with a specific female was known for 15 cases of cohabitation: in 14 the male had been recently cohabiting ($P<0.005$) with that female. Females of this species do not appear to assess males, and will mate with any male present when they become receptive (Benton, 1992b). If a male's encounter rate with females is low, and a female's receptivity is predictable, then a male encountering a soon-to-be receptive female may do better waiting for her to become receptive, rather than leaving her and risking trying to find a female nearer receptivity (Grafen and Ridley, 1983); and this seems to be the case with these scorpions (Benton, 1992b). This behaviour can also benefit

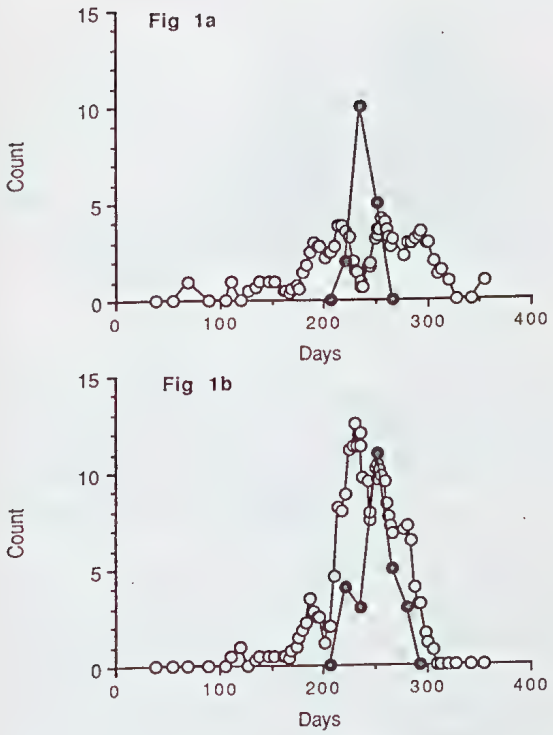

FIG. 1. Reproductive season of *Euscorpius flavicaudis* in England, 1988. (a) Seasonality of adult female surface-activity and no. of births. Female surface-activity is smoothed over two weeks: nightly count shown as average of preceeding and following week's counts. No. of births (for each half-month) estimated from no. of females giving maternal care, and date at which this ended. (b) Seasonality of adult male surface-activity (smoothed over two-weeks), and half-monthly count of no. of matings (observed no. of matings plus no. of spermatophores found). Data originally, in part, in Benton 1992b.

the females for two reasons. Firstly, it ensures that they are mated. Secondly, a major advantage of maternal care in scorpions is to prevent predation of the juveniles (Benton, 1991a), so having a male at the front of the crack prevents entrance by other scorpions which may aid this role.

In all cases of cohabitation, the male stations himself near the entrance, with the female behind him. Males attempting to enter the crack encounter the currently cohabiting males, and each tries to grasp the other's claws. Within a very few seconds one male retreats and flees from the crack. Males therefore fight for 'possession' of a crack occupied by a female in the period before she becomes receptive.

To investigate male mate-guarding contests 110 contests were staged between 11 males (each male as 'owner' against each of the others as 'intruder'). The proportion of contests won correlated very strongly with measures of scorpions size, and most strongly with pedipalpal claw length (r_s=0.97, P<0.001). This is to be expected as *E. flavicaudis* uses its claws as its main offensive weapon. In 80% of contests, the larger-clawed male won; when the smaller-clawed male won (20%), it was the 'owner' in most (91%) contests. Both relative claw-size and ownership status had highly significant effects on contest outcome (two-way ANOVA, size: F=68.5; df 1,36; P<0.0001; status: F=42.7; df 1,36; P<0.0001): large-clawed males usually won contests, but if contestants were closely matched in size then ownership status decided the outcome (giving an advantage equivalent to about 11% longer claws).

Size and Sexual Advantage

In the laboratory, males differed in reproductive success: some males mated twice, some once and some not at all. Larger males mated more often than small males (Fig. 2). This size advantage is for two reasons. Firstly, as described above, larger males are better competitors for female-occupied cracks. Secondly, about 40% of matings are not preceded by mate-guarding. These fall into three broad categories: non-pregnant females at the start of summer, females not found by males before their maternal care has ended and (most rarely) females who have mated already (this is possible as a spermatocleutrum is not secreted in this species). Large males obtain more matings from all three categories than small males. This is because, for each category of mating, females are initially unwilling to court. When a female is mate-guarded prior to her receptivity, she encounters the male frequently, and upon becoming receptive begins courting without aggression. Conversely, when a male encounters a non-pregnant female, or one without young he immediately attempts to court. The male grabs (or attempts to grab) the female's claws and stings her (Benton, 1990). Indeed, the start of a courtship (without mate-guarding) is indistinguishable from a cannibalistic attack. Large males are better at mating with these unwilling females as, unusually for scorpions, large males can be larger than females. In this species, and others (Polis, 1980), size (especially claw-size) is a good predictor of the outcome of cannibalistic contests. At the start of courtship, males

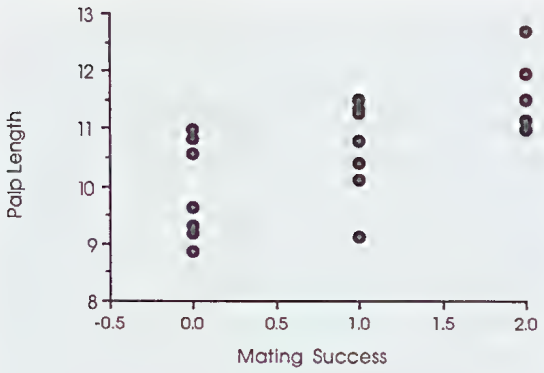

FIG. 2. Relationship between size (claw-length) and mating success in laboratory males free on wall surface (mean ± SD). Difference between groups is significant (Kruskal-Wallis, H=11.4, P=0.003).

sting females, and larger males can eat adult females (and often do: 10 cases observed in the laboratory), therefore, large males essentially give females the choice of being cannibalised or accepting courtship. Small males obtain fewer matings as they have a smaller (or nonexistant) size-advantage over females (Fig. 3) and therefore are more likely to flee from those females who are not immediately willing to court.

Size Dimorphism

Sexually mature adult males are recognised by the secondary sexual characteristic of a notch in the pedipalpal fingers (Fig. 3). Adult males can differ markedly in size, and this is especially noticeable when one considers claw size, which increases allometrically with body size, such that larger males have disproportionately larger claws (Fig. 3). The frequency distribution of adult male claw sizes at Sheerness was dimorphic (Fig. 4). This dimorphism also occurs with other measures of size, such as prosoma length (Benton, 1991b). This dimorphism probaly arises because there are two instars of adult male in the population at Sheerness: 6th and 7th (see also Benton, 1991b).

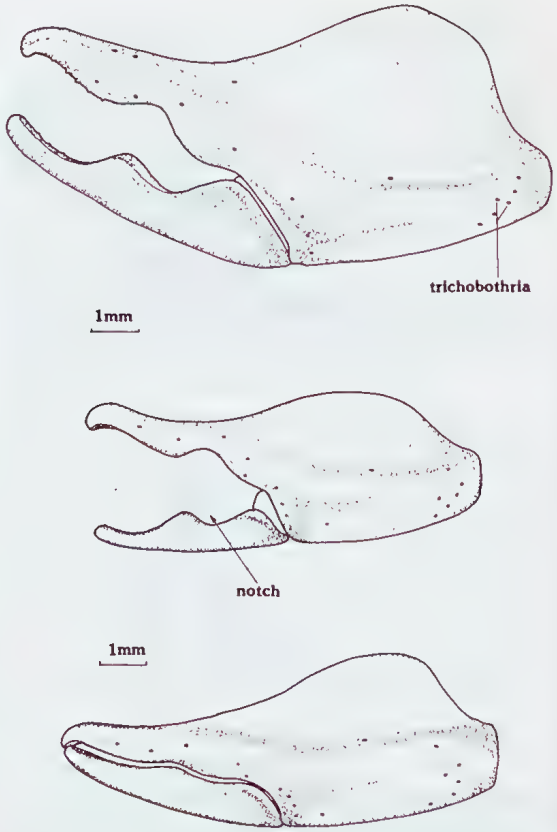

FIG. 3. Claws of two adult ♂ ♂ (a, b) and one adult ♀ (c) same scale. Note secondary sexual characteristic: notch in fingers.

DISCUSSION

Two points are noteworthy. Firstly, the reproductive ecology of *Euscorpius flavicaudis* is much more complex than previously imagined. Naively placing pairs of scorpions together in a laboratory situation to watch the courtship would present a very misleading picture because the most significant behaviours occur before actual courtship. Precopulatory mate-guarding has not been reported in scorpions, but is known to occur in some spiders (e.g. Vollrath, 1980; Watson, 1990) and occurs widely across the animal kingdom (Ridley, 1983). For precopulatory mate-guarding to evolve, males must gain an advantage by staying with a female prior to her becoming receptive rather than searching for a receptive female. Two criteria may determine this situation: firstly, if a male can predict when a female is going to become receptive, and, secondly if receptive females are difficult to find. The former may occur if females become receptive following a moult (e.g. Watson, 1990), or as in the case of these scorpions, after maternal care. The latter criterion may result from female receptivity being very limited in time (e.g., in *Gammarus* female receptivity is limited to a brief period between moulting and the hardening of the amphipod's exoskeleton: Grafen and Ridley, 1983), low population densities (and so low encounter rates) or because of high male mortality

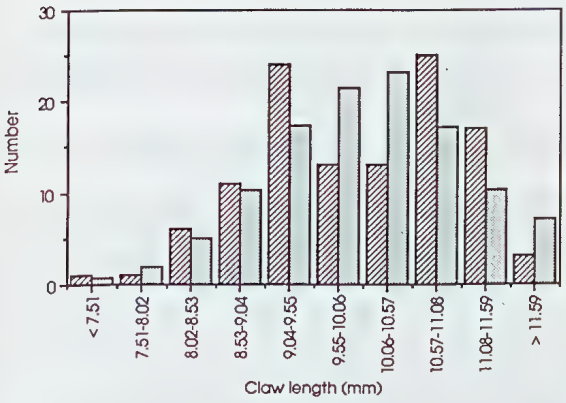

FIG. 4. Distribution of claw-sizes in adult ♂♂ is significantly non-normal. Filled bars are observed distribution; stippled bars are expected normal distribution given mean and standard deviation of data. (χ^2=21.1, P<0.005).

during mate-searching (Vollrath, 1980). The period of female receptivity is reduced where the paternity of a male is ensured by being the first male to mate with a female (so called first-male sperm priority), which may be common in arachnids (e.g. Vollrath, 1980; Watson, 1990). A virgin female is far more valuable to a male than one which is already mated. Thus, *Euscorpius flavicaudis*, first-male sperm-priority and low population densities, coupled with the female's receptivity being predictable, may make it more profitable for a male encountering a female engaged in maternal care to mate-guard her rather than risk searching for another female nearer receptivity.

Secondly, there seems to be a paradox. Adult males exist as two instars in the population. This itself is not a novel finding (see Francke and Jones, 1982). It is surprising that any males mature at the smaller instar since the smaller males seem to be at such a disadvantage in obtaining mates. Natural selection would quickly eliminate any tendency to mature at a disadvantageous size.

The paradox suggests two explanations. First, large males may have an advantage only in a mating season. As large males have more instars, they probably take longer to mature. Although males mate more in the short-term, the younger they mature presumably the more seasons in which to find mates. Perhaps there is a mixed evolutionarily stable strategy (ESS) such that the short-term gains enjoyed by 'large males' are offset by the losses due to having one less season in which to mate, so that, on average, the lifetime reproductive success of 'large' and 'small' males is equal. This ESS could be maintained by frequency dependent selection (Benton, 1992b): large males do relatively better when rare (as they suffer little competition) so their frequency is increased in the population by natural selection. However, when large males are common their gains are reduced, because of increased competition between them, to a point where they are offset by the cost of delaying maturity. Hence, an evolutionary equilibrium is reached between the genes controlling maturation at the 6th and 7th instars.

Secondly, an alternative explanation for this paradox is that there may be phenotypic plasticity in the maturation stage. A gene that can produce a variety of phenotypes depending on the environment is said to exhibit phenotypic plasticity (Lessels, 1991). The 'optimal' time at which to mature may depend on factors such as food availability, and thus growth rate (Stearns and Koella, 1986). For example, if food is plentiful, and an individual is large for its cohort it may be best to mature early. Conversely, if an individual is small for its cohort then it may be better to delay maturity until more food is encountered. This seems to be the case in many spiders (e.g., Deevey, 1947; Vollrath, 1980). This subject will be discussed further elsewhere (Benton, in preparation).

COMPARATIVE POSTEMBRYONIC DEVELOPMENT OF ARACHNIDS

ALAIN CANARD AND ROLAND STOCKMANN

Canard, A. and Stockman, R. 1993 11 11: Comparative postembryonic development of arachnids. *Memoirs of the Queensland Museum* **33**(2): 461-468. Brisbane. ISSN 0079-8835.

A common model is used to describe the growth of various arachnid groups. In these predators there is retardation of development of the first instars, along with greater maternal care for the clutch and even, as far as some groups are concerned, in a viviparous development. Mites, which have very diversified biologies, have developments which have evolved in many different ways.

Les développements des différents groupes d'arachnides sont décrits en suivant une trame commune. Il apparaît ainsi une évolution des groupes de prédateurs qui se traduit par une augmentation du retard de développement des premiers stades, en liaison avec des soins à la ponte croissants, avec même pour certains groupes des développements vivipares. Les Acariens, de biologies très diverses, ont en conséquence des développements qui ont évolué dans des voies très différentes.□*Development, arachnids, growth.*

19 March, 1993.

Analysis of developmental types used in arachnids is very great diverse in the terms used to describe these phenomena. This diversity tends to partially hide some similar points in the developmental process. Authors often use terminology and analyse specific to a single group or species, instead of referring to general concepts relating to all arthropods.

This study compares the developmental processes using the same terms, and we will only use specialised terms if it is absolutely necessary. All developments cannot be discussed in detail here; definitions and more precise descriptions can be found in Canard and Stockmann (1992).

METHODS

Our study is based mainly on literature, enriched with our observations on arachnid growth, particularly on spiders and scorpions.

First, we will evoke the main concepts and definitions used and will then define the different scales of development for each taxon. Taxa which are exclusively predatory are here represented by to the increasing level of care devoted to the clutch. Mites, which have diverse biologies, will be studied separately later.

RESULTS

Concepts and Definitions

POSTEMBRYONIC DEVELOPMENT, HATCHING AND BIRTH

The development, defined as initially embryonic, starts with the first divisions of the egg and continues with the formation of tissues. After hatching or birth, the development is qualified as postembryonic. The postembryonic organism is then covered with an external integument and develops outside of the egg membrane or the female's genital tract. Various organs appear and develop, some will not be functional until late developmental stages (e.g. genital organs). Externally, the development is shown by changes in the cuticle. Reiteration of this concept may seem pointless, but the study of arachnids requires some explanations about hatching and birth.

Hatching, i.e. the opening and release from the egg's membrane, can be a long process. It may take a few days for some spiders, and sometimes some moults can be observed between the beginning of the opening of the egg's membranes and their complete liberation. Hence, the postembryonic period does start with the opening of the egg's membranes. This does not make it necessary to look for a phenomenon before hatching as, for example, Legendre (1958) and Vachon (1958b) did as they chose the 'inversion' to define the beginning of the postembryonic period. Moreover, this proposition has one drawback: it makes the postembryonic development begin at a time when the organism is not covered by a tegument.

Birth appears as a well and easily defined phenomenon, without ambiguity. However, in pseudoscorpions, the organism leaves the female's genital tract and moves into a ventral

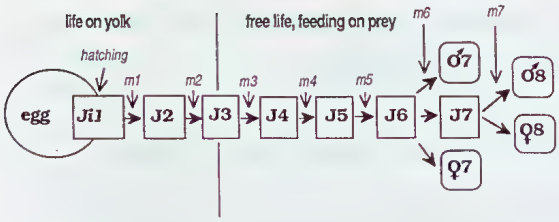

FIG. 1. Stages of postembryonic development of an opilionid, *Liobunum rotundum* (Phalangidae, Palpatores) (after Gueutal, 1943 and Naisse, 1959). (m = moult, **Ji** = incompleted juvenile, **J** = juvenile).

brood pouch, which is like an external extension of the female's genital tract. Once in the pouch, development continues and the organism still receives nutritive fluid from the mother. Therefore, the start of the postembryonic development of pseudoscorpions should be when they leave the pouch, rather than when they leave the female's genital tract, as others have stated.

INSTARS AND STASES

The instar is the organism between two moults. Generally, among arthropods, the external form does not significantly change between these two stages, except for the short periods of pre- and post-exuviation. However, among some mites, the external morphology and biology are modified while the cuticle remains. Hence, Henking (1882) distinguished two forms, called instars ('stade'), one active and the other motionless. Although this use of the term 'instar' was followed only by a few authors to describe the development of few mites, another acarologist (Grandjean, 1938), considered that the term was too indefinite and proposed the term 'stase'. The definition of stase changed later, but this term is the basis for an evolutionary concept (Grandjean, 1954; André and Jocqué, 1986; André, 1989).

We use 'instar' here in its usual definition, which means an organism between two moults (for endocrinal considerations, see Canard and Stockmann, 1992). To keep the general definition, we will discuss the concept of stase later. When the animal presents separate biologies linked with two different aspects during the same instar, we call them 'forms' and give them two different names.

SUCCESSION OF INSTARS

We limit our study to a morpho-biological description of the successive instars. These instars can follow each other in phase (Vachon, 1953) in which all instars are of same kind. These different types are defined in Table 1.

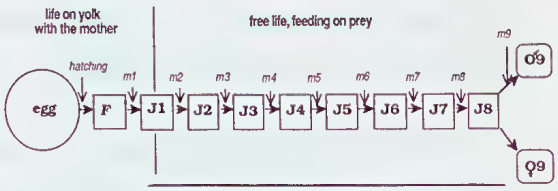

FIG. 2. Postembryonic development scheme of a solpugid, *Eremobates durangonus* (after Muma, 1966).

DIFFERENT DEVELOPMENTAL ROUTES

OPILIONIDS

The eggs are laid isolated from each other and then abandoned. The emergent animal depends on its yolk reserves. It looks like a juvenile harvestman but morphologically differs from following instars by the unpigmented integument and lack of some characteristics, such as unformed chelicerae, unsegmented tarsus, absence of median eyes, etc. Therefore it is an incomplete juvenile: $\mathbf{Ji_1}$ (term taken from Holm, 1940 concerning spiders) (= 'larve' according to Juberthie, 1965). It also has temporary organs (one or two egg teeth located on dorsum of cephalothorax).

After the first moult, the animal differs from the imago only by its size and by sexual characteristics. It is a juvenile, the second of the juvenile phase: $\mathbf{J_2}$ (= 'nymphe' according to Juberthie, 1965). Although active, it still lives on its yolk reserves. After one moult, the juvenile opilionids ($\mathbf{J_3}$) scatter and then feed on prey they catch. Usually, 6-7 juvenile instars occur before it becomes an imago, more rarely there are 5 to 8. The number of moults may vary from with individuals of a species, and according to the developmental conditions; this number is generally the same for both sexes.

On becoming a breeding instar (imagos) the opilionid cease moulting (adults), although some may live for be 5-6 years (Juberthie, 1965).

SOLIFUGIDS

The female isolates herself in burrow but does give care to her eggs.

The animal which hatches is incomplete, motionless and lives on its yolk reserves. It is unpigmented, has no eyes and no racquet organs. Two types may be distinguished. The first is in the Galeodidae (Vachon, 1958a; Junqua, 1966). It does not look like the imago and keeps the aspect it had while under the constraint of the membranes of the egg; it is a foetal instar: **F** (= 'larve' of Vachon, 1958a or Junqua, 1966, = 'post-embryo' of Muma, 1966). The second type is present in some Solpugidae (Lawrence, 1947)

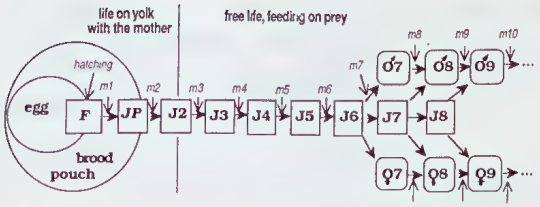

FIG. 3. Scheme of the different stages of the postembryonic development of an amblypygid, *Tarantula marginemaculata* (after Weygoldt, 1970).

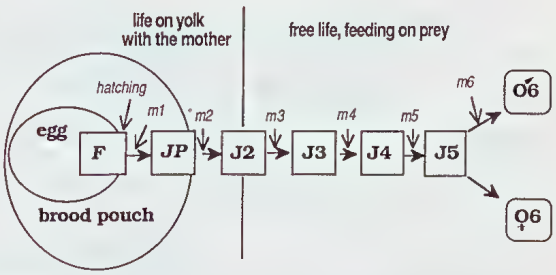

FIG. 4. Scheme of the different stages of the postembryonic development of *Typopeltis stimpsonii* (Thelyphonidae) (after Yoshikura, 1965).

and some Karschiidae (Thaler, 1982). It looks like the imagos (juvenile), but lacks some structures and has temporary organs like thorny continuations of the legs. It is an incomplete juvenile: Ji_1 (= 'primärlarve' of Thaler, 1982).

A further moult results in an animal which has all the adult organs, except those linked with reproduction. This juvenile is, according to the species, the first or the second of the phase (= 'nymphe' of Vachon, 1958a; Junqua, 1966; Muma, 1966). It remains with the female until its integument is hard enough, then it disperses and lives on its own, feeding itself on prey it catches. The number of instars before reaching the status of imago varies according to the individuals. The imagos have a short life expectancy comprising only one instar (adult).

Amblypygids

The female carries the eggs under its abdomen in a brood pouch generated by the genital tract during egg-laying. The incubation period of the clutch may last 3 months (Weygoldt, 1970). Hatching takes place in the brood pouch.

The organism released from the egg's membranes has a foetal aspect with the prosoma bent towards the abdomen and its appendages tight along the body. It is very incomplete (appendages incompletely segmented, absence of setae and of sensory organs, etc.), motionless and lives on its yolk. It is a foetal instar: **F** (= 'deutembryo' of Weygoldt 1970).

After one moult, the animals leave the brood pouch and attach themselves under the females's abdomen. They still live on their yolk, can move, and look like imagos (juvenile), but some structures are lacking and the internal organisation is incomplete (digestive tract, circulatory system, etc.). It is an incomplete juvenile instar which has particular organs on the legs, a dorsal continuation at the distal end of the tibiae (Weygoldt, 1970) and, in some families, an adhesive organ at the tip of the tarsus. It lives on the mother and is adapted to this life, so with reference to Scorpions, we call it the pullus: **JP** (= 'embryon' of Pereyaslawzewa 1901, and 'praenymphe' of Weygoldt 1970).

The pullus moult while on the mother and then leaves her. Through this moult it acquires all the characteristics of the adult (except the reproductive organs). It is a juvenile instar: J_2. After a short gregarious period, the juveniles scatter and live on their own, feeding themselves. The number of juvenile instars may vary between individuals (Weygoldt, 1970) and, after one year, they become an imago.

The imagos of both sexes go on moulting and, under good conditions, the females keep growing after this moult. Therefore, there are no 'adults'.

Uropygids

The female isolates herself in a burrow, and lays her eggs in a newly secreted transparent ventral sac.

Hatching occurs in the brood pouch. It corresponds to a quasi-simultaneous release of the egg's membranes and of the integument of an instar similar to the foetal instar of the Amblypygids: **F** (= 'primärlarve' of Kästner, 1949 and 'prelarva' of Yoshikura, 1965). This instar, which was already formed in the egg, has a very short postembryonic life.

The animal released after hatching and after the first moult, can move and climb upon the mother's back. In general morphology, it looks like the adult (juvenile phase), but lacks some organs (median and lateral eyes are not yet visible, flagellum unsegmented, etc.). It has particular organs linked with its life on the mother, including pad-like organs at the tip of the legs, instead of claws. It is a pullus: **JP** (= 'sekondärlarve' of Kästner, 1949; 'larva' of Yoshikura, 1965). After a 'diapause', there is a moult which releases a juvenile instar: J_2 (=

Forms	Characteristics			Symbols
Non-breeding	different morphology from imagos	motionless instars which do not feed themselves	embryonal aspect unsegmented appendages	foetal instar
			segmented appendages	nymph
		active instar		larva
	same morphology as imagos	several organs which do not function	no temporary organs	incomplete juvenile
			temporary organs linked to life on mother	pullus
		only non-functional genital organs		juvenile
Breeding (= imagos)		with moulting		imago

TABLE 1. Characteristics of different kinds of instars.

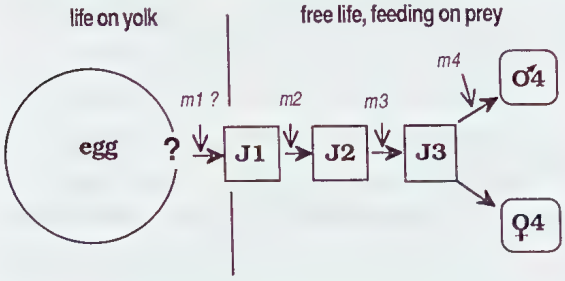

FIG. 5. Scheme of postembryonic development of *Prokoenenia wheeleri* (after Rucker, 1903).

'pullus' of Kästner, 1949; = 'protonymph' of Yoshikura, 1965). They are still gregarious but move around the burrow and begin to feed themselves. After one winter spent together, they then moult and scatter. Subsequent moults usually occur annually, but may be less frequent (Yoshikura, 1965).

Imagos do not seem to moult (adults). Their size of each species does not vary much.

Palpigradids

The sexual biology of palpigradids is almost unknown. Moreover, nobody has ever succeeded in breeding palpigradids. Therefore, knowledge about their postembryonic development is based on observations of natural populations. Under these conditions three immature instars have been determined for many species (Condé, 1984).

The three instars of *Prokoenenia wheeleri* correspond to juvenile instars (Rucker, 1903). Their morphology evolves in a quantitative manner (number of bristles, articulations of the flagellum, evolution of genital parts, etc.).

Spiders

The degree of maternal care given to the clutch varies between species. Some spiders abandon their cocoon (e.g. araneids). Others carry it in their chelicerae or attached to their spinnerets.

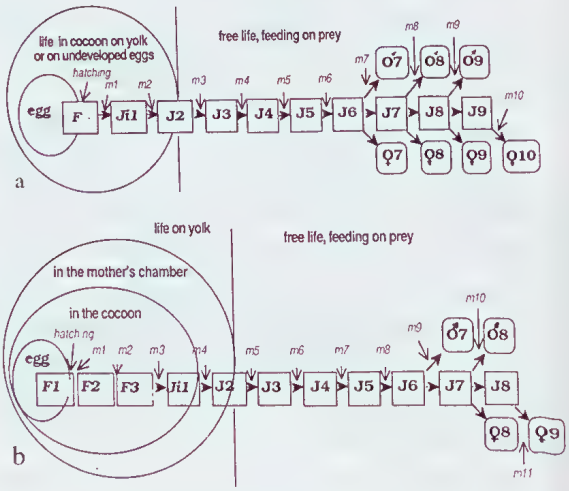

FIG. 6. Postembryonic development in two spider species that (a) abandons its clutch (*Larinioides cornutus*) (after Ysnel, 1992), and (b) cares for young (*Philaeus chrysops*) (after Bonnet, 1933; Canard, 1984).

Others keep their clutch with them in their silk chamber (e.g. salticids).

Hatching occurs in the cocoon and it sometimes takes a few hours before the first instar is released. This instar is generally foetal: **F** (= 'prélarve' of Vachon, 1958b, = 'pullus' of Canard, 1984). Among some orthognathids it remains intrachorional and is therefore not postembryonic. Its very thin cuticle bursts during hatching when the egg membranes open. Among several species which give care to the clutch, there is a series of 2 or 3 instars of this kind: $\mathbf{F}_1$, $\mathbf{F}_2$, $\mathbf{F}_3$ (Canard, 1987). As they cannot move, they stay in the cocoon.

The following instars are mobile and look like a spider (juvenile) but the first one or two still lack some adult characteristics: they are incomplete juvenile (**Ji**) (= 'larves' and 'prénymphes' of Vachon, 1958b). In some cases, the first instar of

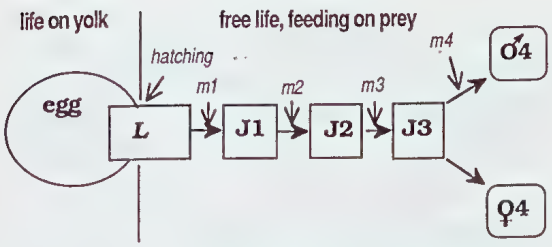

FIG. 7. Scheme of postembryonic development stages of ricinuleid *Crytocellus palaezi* (after Pittard and Mitchell, 1972).

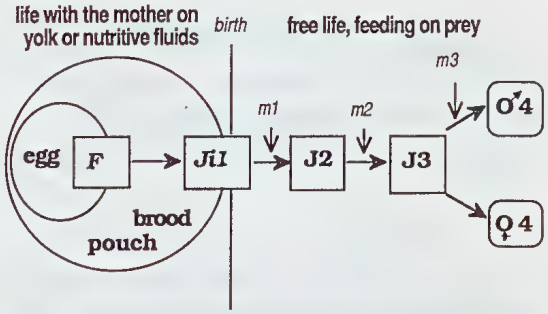

FIG. 8. Postembryonic development of a pseudoscorpion, *Chelifer cancroides* (after Vachon, 1938).

this phase is very incomplete, but in some others, some characters can only be shown absent using an SEM. These first incomplete juvenile instars live on their yolk, but some also feed on undeveloped eggs, which they can pierce with a cheliceral blade. Dispersal takes place after the moult which releases a juvenile equipped with all its organs (**J**). Juveniles then live on prey they catch (= 'nymphes'; Vachon, 1958b). The total number of juvenile instars may vary within a species. Males often become an imago in fewer instars than females.

Female orthognathids and filistatids can still moult. In labidognathids, imagos do not moult any more (adults). In nature, all male spiders die without moulting.

Ricinuleids

Hatching releases an active individual, which catches prey but which has only three pairs of legs and therefore does not present the general arachnid characteristics. It differs from the imago, and is a larva: **L**. The three instars that follow resemble the imago, and possess 4 pairs of legs; however, they lack genitalic structures. They are juveniles instars: J_1, J_2, J_3 (= 'nymphes' of Pittard and Mitchell, 1972). There is only one imaginal instar (adult).

Pseudoscorpions

The eggs are laid in a brood pouch where they feed upon maternal nutrients with the aid of the embryonic membrane. Growth of the embryos bursts the chorion and the external side of the brood pouch to which they remain attached by the buccal region. Their form is not differentiated. Within a few seconds, the mother injects a nutritive fluid which trebles their volume (= 'larves gonflées' of Vachon, 1938; 'deutembryons' of Weygoldt, 1969). Organogenesis continues and a moult occurs which releases an animal which emerges by an anterior cephalothoracic tooth.

The released instar looks like the imago, but retains some non-evolved characteristics (sensorial system, silk glands, digestive tract, etc.). It is an incomplete juvenile: Ji_1 (= 'larve II' and 'protonymphe' of Vachon, 1938; 'protonymph' of Weygoldt, 1969). Some species apparently retain a foetal aspect (Judson, 1990). The first free instar sometimes remains and moults in the chamber constructed by the female (Weygoldt, 1969). The animal lives alone after this moult. The number of following juvenile instars is fixed to two: J_2 (= 'deutonymphe'), J_3 (= 'tritonymphe'). Each instar can be identified through its trichobothriotaxy (Vachon, 1938). Imagos do not moult any more.

Scorpions

Eggs hatch in the female's genital tract (viviparous species) or soonafter laying (ovoviviparous species).

Newly born scorpions climb onto the mother's back and remain there, living on yolk reserves. They resemble an adult (juvenile) but is incomplete (without trichobothria, unpigmented integument, without specific bristles, etc.). It has temporary organs linked to life on the mother's back, such as legs without claws but bearing adhesive organs at their tip. This incomplete juvenile is a pullus: **JP** (= 'larve' of Vachon, 1940).

After one moult on the mother's back, the juveniles periodically move to the ground, where they begin hunting and eating for the first time. They disperse afterwards and live alone. The second instar is a complete one (J_2). The number of juvenile instars may vary according to sex. Mostly there are 6 to 7 instars, but it may vary from 5 (*Orthochirus*) to 10 (*Diplocentrus*) (Polis, 1990). Imagos do not seem to moult, but it may be possible (Stockmann, 1968).

Mites

The Acari have many more developmental

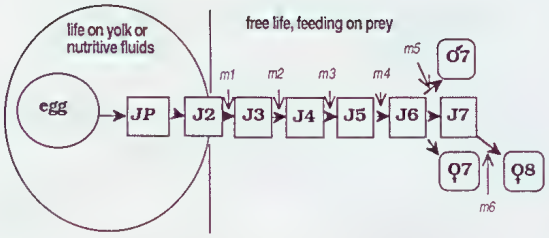

FIG. 9. Postembryonic development stages of a scorpion, *Euscorpius italicus* (after Angermann, 1957).

types than other arachnids. The eggs are often abandoned. There is a first instar which has a foetal aspect, but it remains intrachorionic, except in some cases (Coineau, 1977). This instar can be compared with foetal instars of other arachnids (**F**), but it is not postembryonic.

The first free instar is obviously different from the imago because it usually has only 3 pairs of legs. It moves and can feed itself. It is a larva: **L**.

The following instars are eight-legged and only differ from the imagos by some quantitative or sexual characteristics: they are juveniles (**J**) (= 'nymphes'). The number of instars is often fixed for a species, at 1 or 2, more often a maximum of 3, but up to 4-5 in the Argasidae.

After these immature instars imagos appear, which do not moult anymore (adults) (= 'prosopon' of Reuter, 1909).

In the thrombidiids, there are periods of inactivity between larval and juvenile stages and between juvenile and adult stages. At such times, the animal is covered by the original cuticle, but secretes a new tegument under it, which becomes the tegument of the next instar. In many other cases, motionless instars can be distinguished, sometimes comparable to real nymphs or to specific survival-forms, which allow for dispersal.

DISCUSSION AND CONCLUSIONS

Terminology and Concepts

Most terms used in other arthropods can also be used in arachnids. We have used only the original terms of pullus, foetal instars and incomplete juvenile.

The foetal instar, although it has been defined for arachnids (Canard, 1987), is not specific to this group. It is evident in some insects and myriapods (= 'prolarves', 'prélarves', 'pseudo-foetus', etc.).

The incomplete juvenile instars belong to the juvenile phase of which they form a part (J_{i1} followed by J_2). One can recognize the sys-

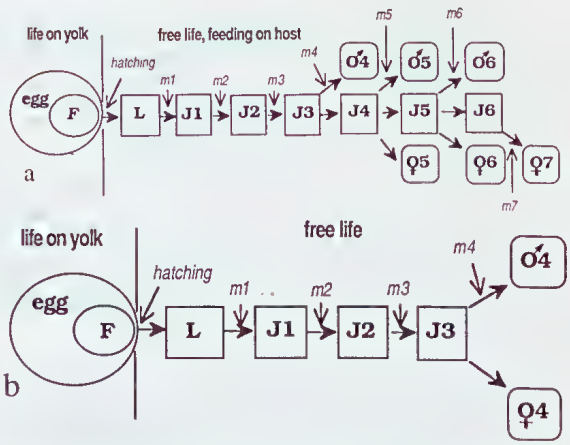

FIG. 10. Succession of stages in postembrional development of mites, (a) Argasidae, *Ornithodoros maritimus* (after Guiguen, 1990); (b) Oribatidae (*Carabodes wilmanni*) (after Bellido, 1983).

tematic group of the imago, therefore they are not larvae, but genital organs and furthermore some other structures are lacking. This 'incomplete' situation is not always easy to observe morphologically. However, biological information is useful, because these instars are nearly always unable to live on their own.

The pullus (Pavlovsky, 1924) is an incomplete juvenile instar with special adaptations to life on the mother, such as pad-like organs on the tip of the legs.

The presence of two morpho-biological forms during the same instar among mites is rare amongst the arthropods (except Diptera), but it does not raise any problems of description and does not require any fundamental vocabulary changes; it simply requires more accurate definitions.

Chronological and Morpho-biological Descriptions

In the development of a systematic group of arachnids, except in ricinuleids, pseudoscorpions and perhaps palpigradids, there is no fixed number of instars. Therefore it would be unwise to base a study on few species and to fix the chronology, because some still unknown developments may modify the established system. Theoretical systems of this kind were proposed by Reuter (1909) for mites and by Vachon (1958b) for spiders. Thus, the constant presence of three post-larval juvenile instars (=nymph) in mites stated by Reuter and often followed (protonymphe, deutonymphe, tritonymphe) does not conform to most species,

in which there are less than 3 juvenile instars and even less to those with 4 to 6 instars (e.g. *Ornithodoros maritimus*).

Developmental analyses based on a fixed number of instars (chronological) establishes common points between instars of different species, in order to envisage evolutionary pathways. But these common points will always remain hypothetical, and moreover, these pathways can be elucidated without this system. Therefore we do not wish to use a method with no decisive advantages and, because of its fixed character, limited development descriptions, because species which do not suit the established system are excluded. In mites, for example, the number of instars is considered fixed to one larval, three juvenile instars and the adult. However, in many species one or more juvenile instars are missing and sometimes there are more than three juvenile instars. For mites there is, depending on the species, a variable number of instars.

Evolutionary Pathways

Immature instars of arthropods are adapted to special lifestyles or environments and sometimes differ from those of imagos. Often these adaptations influence the morphology so deeply that it is difficult to distinguish the imago from the immature forms (larva). Such differences are less marked among the arachnids (larvae absent except in mites and ricinuleids).

A good correlate probably exists between the increased level of care by the mother to its clutch and the increased number of incomplete instars at the start of the development.

Moreover, the biology and morphology of early instars can be observed and explained as adaptations to life in the cocoon or with the mother, e.g., the temporary organs such as distal, pedal pad-like organs of pullus (attaching to the mother) or the cheliceral blade of some incomplete juvenile spiders (feeding on undeveloped eggs). The viviparous cases do depend on the same kind of evolutionary processes.

The evolution of many arachnids has probably been characterized by growing care of the clutch correlated with the increasingly and later development of the first instars. Thus, the instars are both incomplete and regressed, because these adjectives depend on the point of view considered: ontogenetic or evolutionary. This corresponds to the 'deux temps' of Grandjean (1954) and, to a certain extent, to the 'state approach' and the 'stase approach' of André (1989).

Mites present great diversity in their biology and, unlike other arachnids, are not all predators. Therefore, they have followed different evolutionary pathways and sometimes metamorphosis takes place, with larvae and nymphs (similar in these cases to those of holometabolic insects) or with 'survival' instars which enable them to disperse.

This evolution of clutch or juvenile care by the mother does not indicate phylogenetic relations in the different orders, because it is a general phenomenon within the animal world and can appear independently in different groups.

COURTSHIP, MATING AND POST-OVIPOSITION BEHAVIOUR OF *HYPOCHILUS POCOCKI* PLATNICK (ARANEAE, HYPOCHILIDAE)

K. M. CATLEY

Catley, K.M. 1993 11 11: Courtship, mating and post-oviposition behaviour of *Hypochilus pococki* Platnick (Araneae, Hypochilidae). *Memoirs of the Queensland Museum* **33** (2): 469-474. Brisbane. ISSN 0079-8835.

Courtship and mating in *Hypochilus pococki* Platnick is described for the first time for any member of the superfamily Hypochiloidea. Five phases of male behaviour are recognised; pre-courtship, non-contact courtship, contact courtship, copulation and post-copulatory behaviour. Chemotactic stimulation seems to be the prime releaser of male courtship behaviour which involves web-tugging, mutual leg-stroking and female guarding. Post-oviposition behaviour is described and the role of a previously undescribed sheet web, constructed by females after oviposition as well as early instar spiderlings, is discussed in terms of its phylogenetic implications.□*Hypochilus, courtship, phylogenetics, sexual selection, web construction.*

K.M. Catley, Department of Biology, Western Carolina University, Cullowhee, North Carolina 28723, USA; Present address: Department of Entomology, Comstock Hall, Cornell University, Ithaca, New York 14853-0999, USA; 13 October, 1992.

The significance of undertaking ethological studies of spiders in the family Hypochilidae stems from the phylogenetic position of the family as a relic taxon at the base of the Infraorder Araneomorphae (Platnick, 1977; Forster *et al.*, 1987). Diagnosis of behavioural units that are used in such processes as web construction (Coddington, 1986) and courtship (Platnick, 1971; Helversen, 1976; Coyle and O'Shields, 1990) may prove useful in future phylogenetic analysis. This paper describes the courtship and mating behaviour of *Hypochilus pococki* in the laboratory and attempts to recognise potentially informative behavioural sequences. Egg sac construction is also described and attention drawn to a previously undescribed silk construct, a 'veil web' built by post egg-laying females as well as early instar spiderlings. Apart from one incomplete observation by Fergusson (1972) of mating in *Hypochilus thorelli* Hoffman (=*Hypochilus pococki*), this is the first detailed description of reproductive behaviour for any member of the superfamily Hypochiloidea.

The genus *Hypochilus* comprises five species confined to the Southern Appalachian highlands of eastern North America, two species from central and northern California and one from central Colorado. Two additional species, one from New Mexico and the other from the San Bernardino Mountains of southern California will soon be described (Catley in prep.). These haplogyne cribellate spiders build characteristic 'lampshade' webs on rock surfaces often close to running water. All species appear to be allopatric and exhibit an interesting pattern of disjunct endemism (Catley, 1991; Huff and Coyle, 1992). Males moult to maturity later than females, typically appearing in early August. They move extensively (presumably in search of females) and do not associate with penultimate females, suggesting that there is no first male sperm precedence (Eberhard *et al.* in press).

MATERIALS AND METHODS

Despite extensive day and night observation during 1990 and 1991, no courtship or mating behaviour was observed in the field. *Hypochilus* can be very difficult to maintain in the laboratory; they are affected adversely by changes in humidity and only occasionally can they be persuaded to construct a web, making feeding problematical. Following several unsuccessful attempts to establish a mature female in the laboratory, a single specimen collected in July 1990 from Wolf Creek watershed, Cullowhee, Jackson County NC, established a web in a 50x30cm glass tank. The tank was furnished with a sloping wooden framework (45°angle) covered with sandpaper to simulate an overhanging rock ledge. The floor was covered with vermiculite to a depth of 5cm and was kept very moist.

After the female attacked and killed the first male introduced into the arena, she was allowed to feed for a period of one week. The second male was introduced on August 28 1990 and a total of 7 hours 47 mins of male/female encounters were filmed using a Panasonic WV-D5000 video re-

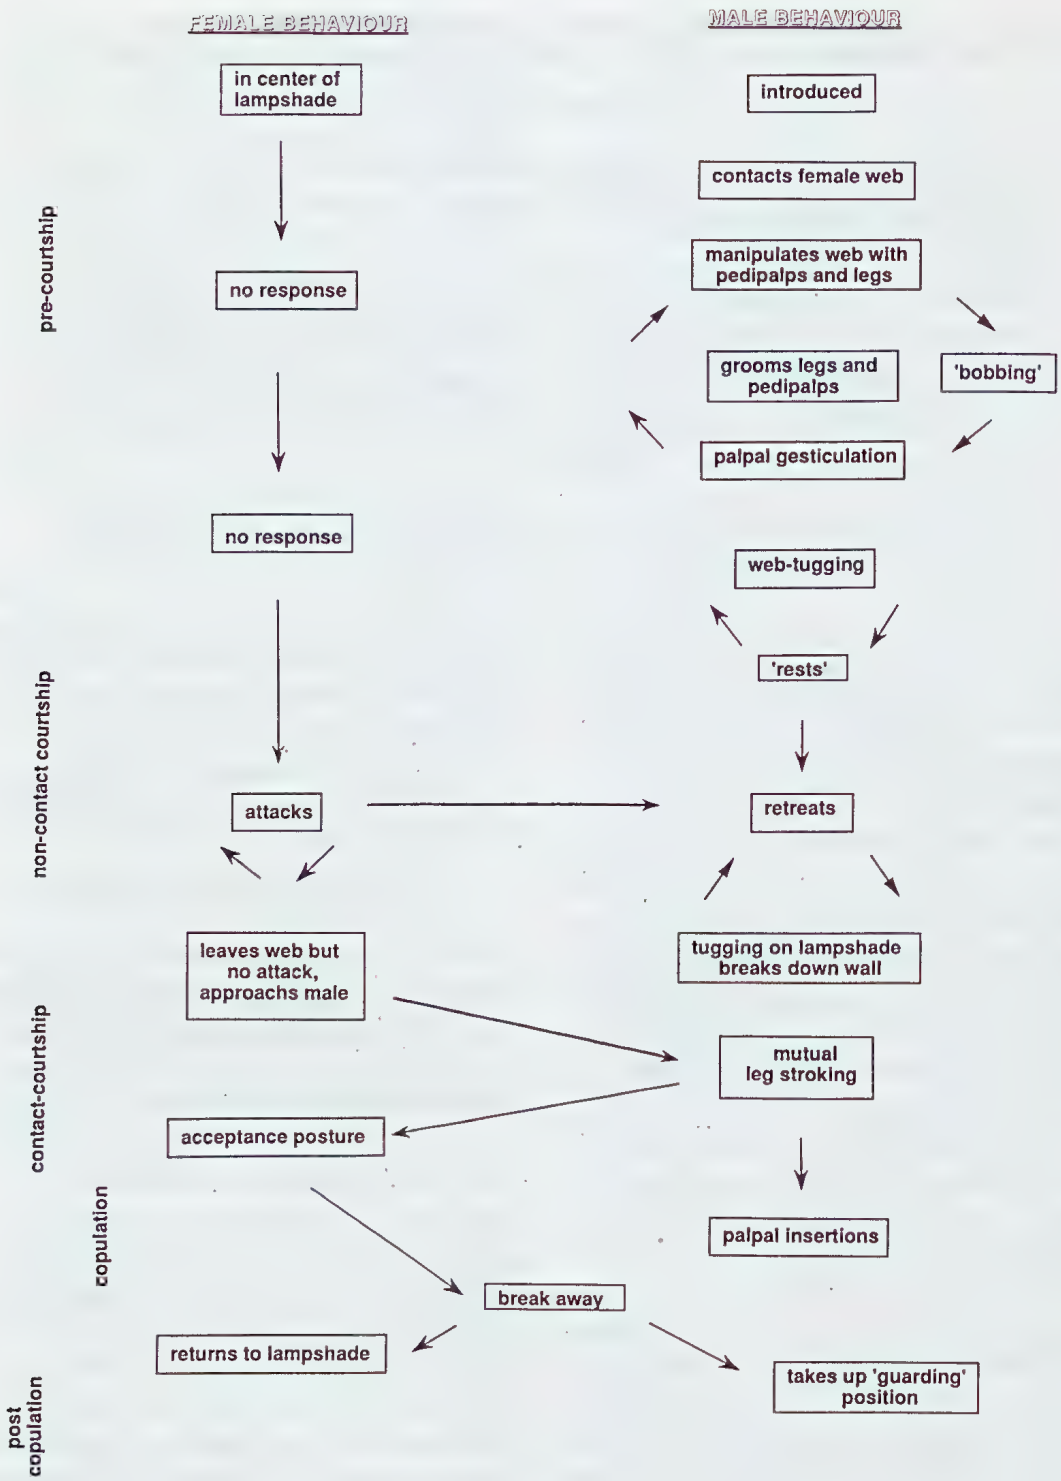

FIG. 1. Sequence of courtship and mating behaviour in *Hypochilus pococki* formulated from encounters in the laboratory involving two males and a single female (see text for explanation).

corder fitted with a Micro-Nikkor 55mm close-up lens. Sessions were annotated by verbal comments recorded through the audio channel of the video camera. Data analysis was achieved using slow motion and freeze frame functions of a VCR.

RESULTS

The description of courtship and mating presented here is a composite derived from laboratory observations of only two males and a single female and therefore may not be representative.

Male courtship behaviour can be divided into five distinct phases: pre-courtship, non-contact courtship, contact courtship, copulation and post-copulation (Fig. 1). The following behavioural units were diagnosed.

Male Behavioural Units

PRE-COURTSHIP

Leg and pedipalpal grooming. Within a few minutes of a male being introduced into the arena, the legs and pedipalps were used to manipulate female silk. A web constructed by the same female but which had been abandoned for several weeks elicited the same response. Rubbing the tarsi and metatarsi of legs 1, 2 and 3 together, as well as drawing them and the pedipalps between the open chelicerae (and presumably the endites) occurred immediately after the first and subsequent encounters with the female web. The pedipalps were rubbed vigorously across the silk for extensive periods, this was followed either by drawing them through the mouthparts, as described above, or by rapid pedipalpal gesticulations.

Bobbing. Flexing of the legs resulted in the whole body moving up and down relative to the substrate. Bobbing is often interspersed between sessions of leg and pedipalp grooming.

NON-CONTACT COURTSHIP

Web-tugging. The male pulled on the cribellate lampshade web of the female with his first pair of legs. Such actions, repeated in bouts lasting 3-7 seconds interspersed with periods of inactivity lasting from 5 secs. to several mins., can result in the side wall of the lampshade being partially destroyed.

CONTACT COURTSHIP

Leg-stroking. The female eventually left the web as a result of male tugging and approached the male, waving her front pair of legs. The male held his ground (unlike previous female approaches which appeared aggressive and from which the male quickly withdrew). A long session of mutual leg-stroking followed, involving mainly legs one and two. The male maintained a constant, very rapid stroking of the female's legs (mainly metatarsi and tibiae) and body as she appeared to become progressively more cataleptic, and eventually assumed the acceptance posture. This stroking session lasted for 3 mins. 12 secs–more than twice the period of copulation itself.

COPULATION

Palpal insertions. Following mutual leg-stroking the female oriented her abdomen at 45° to the substrate and adopted a semi-cataleptic acceptance posture. The male faced the female and advanced, with pedipalps fully extended, to a position where his dorsal cephalothorax was adjacent to the female's sternum (Fig. 2). It was not entirely clear whether or not the male tapped on the female's genital area with his palps prior to insertion as described for some araneids (Robinson and Robinson, 1980). Such apparent tapping may simply be attempts to locate the opening to the bursa copulatrix.

The palps were inserted alternately, the right followed by the left, each insertion lasted 3-10 seconds with the whole insertion sequence lasting 1 min. 22 secs. To achieve insertion from this position requires that the palpal organ be twisted through 90° at the same time as the pedipalp is straightened. The copulatory phase ended abruptly when the female broke away from the male, who was immediately pursued some distance from the web. At no time during courtship or mating was the male observed to lay down silk.

POST-COPULATION

'Guarding' posture. After copulation, the male, after a brief period of palpal grooming, took up a characteristic position close to the female, often touching her. His legs were extended parallel to the substrate, with the first three pair directed anteriorly, and the fourth pair directed posteriorly. The first pair of legs were held in such a position such that the femora were at 30° to the longitudinal axis of the prosoma, while the remaining podites tended to converge distally over the female. This seems to be a characteristic position seen often in the field. It was maintained

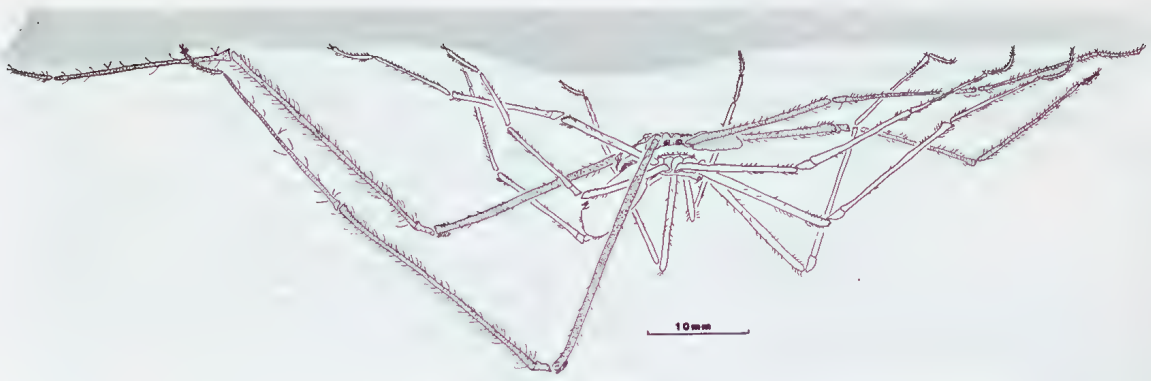

FIG. 2. Mating position of *Hypochilus pococki* (for the sake of clarity not all male appendages are illustrated).

for 2.5 hours after which the female attacked and badly injured the male.

Female Behavioural Units

NON-CONTACT

Attack. The female failed for long periods to show any response to the male's web-tugging but did eventually respond by rushing out of the lampshade and pursuing him. Three attacks appeared in earnest, with the male withdrawing rapidly. The fourth response was instigated more slowly (with reduced speed and vigour); this change in 'intent' appeared to be sensed by the male, who did not retreat. This encounter led directly to contact courtship and copulation (Fig. 2).

CONTACT COURTSHIP

Leg stroking. See male behaviour.

COPULATION

Acceptance posture. A semi-cataleptic position with the abdomen held at 45° to the substrate (Fig. 2) occurring after contact courtship (extensive leg stroking) with the male.

POST-COPULATION

Egg laying ethology. Twenty days after copulation, the female laid eggs and constructed an egg-sac. First a saucer-shaped disc of pink silk was laid down onto which the eggs were deposited. This was then closed up to form a flattened sphere. The pink colour of the silk has been corroborated by several observations in the field, however, when the egg-sac is ready to be covered in cryptic material its colour is off-white. A second egg-sac was produced on October 4, followed by a much smaller egg-sac on October 17, and the final egg-sac was constructed on November 6. Each was suspended from the framelines of the web while particles were incorporated in the outer layer of the egg-sac. This involved the spider descending to the substrate and carrying pieces of vermiculite back to the web in her chelicerae (in the field egg cases are covered with particles of moss or lichen (Fergusson, 1972; pers. obs.).

Two egg-sacs were 'screened in' by a particular type of sheet web not previously described for *Hypochilus*. Observations from the field show that a similar 'veil web' is also constructed by early instar spiderlings (Catley, 1991). The silk is of very different appearance from either framework or cribellate silk and appears as a dense, finely woven sheet. Its purpose, either as a vertical 'veil' in front of egg-sacs (typically those suspended in a fissure in the rock), or as a barrier underneath which a number of very early instar spiderlings build their regular prey catching lampshade webs, may be protective.

DISCUSSION

The function of courtship in spiders may be most simply expressed as: alerting the female to the presence of the male, the possible suppression of female predatory behaviour and stimulation of the female to accept copulation. Variations on this basic theme have been voiced by several authors including Bristowe (1958), Crane (1949) and Platnick (1971); most expand the concept to include elements of species specific recognition, advertisement of sexual availability and the functioning of a releaser system. Other components which may also be important are male behavioural elements designed to ensure his post-copulation survival.

Accounts of courtship and mating in other more primitive spider taxa are scant, but include information on the Mesothelae: Liphistiidae, *Heptathela* (Haupt, 1977); Mygalomorphae: Nemesiidae (Buchli, 1962); Atypidae (Clark, 1969); Dipluridae (Coyle and O'Shields, 1990). Whereas behavioural observations for spiders in the Araneoclada are available from Bristowe (1941, 1958) various families, Crane (1949) for salticids, and Robinson and Robinson (1978, 1980) for araneids, this account of courtship and mating in *Hypochilus* is the first to be published for any lower (non-Araneoclada) araneomorph spider.

The courtship and mating repertoire of *Hypochilus* is relatively underived and given the families' phylogenetic position the behavioural units which comprise it may be hypothesised to represent the plesiomorphic condition of araneomorph reproductive behaviour in general. Given a larger data base within the Araneomorphae, comparison of behavioural characters will allow correct polarity decisions to be made and the resulting data set, combining both morphological and ethological characters, should provide a more stringent test of phylogeny.

Leg and pedipalpal grooming behaviours performed by the male upon contact with the female web may be indicative of the occurrence of female pheromone on the web. Such pre-contact encounters were necessary to release web-tugging behaviour in these observations (n=4) and is consistent with Platnick's (1971) hypothesis that chemotactic stimuli are prime releases of male courtship behaviour in haplogyne spiders. It has been suggested that the longer anterior legs of male *Hypochilus* confer superior mobility when locating females (Fergusson, 1972; Eberhard *et al.* in press). However, such pronounced sexual dimorphism may have had its origin in courtship behaviour. The extreme length of the first legs, by maximising the distance between male and female during web-tugging, should increase the male's chance of surviving female attacks. Such interactions may also provide an opportunity for sexual selection by female choice to occur (Eberhard, 1985), the female testing male 'fitness' by repeated attacks.

Contact courtship was initiated when the female eventually left the lampshade and approached the male. Such behaviour may not however be typical. Fergusson (1972) reported that in the one encounter he observed the male scrambled into the lampshade with the female. The long period of mutual leg-stroking may play a role in placating the female, resulting in her adopting the acceptance posture. It may well be homologous with the 'leg fencing' behaviour seen in some diplurid spiders (Coyle and O'-Shields, 1990).

Copulation was achieved in the mating position (Fig. 2; position 1 of Kaston, 1981). Alternate palpal insertions, as observed in *Hypochilus*, should be considered plesiomorphic when encountered in other araneomorph spiders (using *Hypochilus* as an outgroup) and as apomorphic when palps are inserted simultaneously. Simultaneous palpal insertion has been documented in the following families, Dysderidae, Segestriidae, Oonopidae, Scytodidae and Pholcidae (Bristowe, 1958) but appears not, as Bristowe concluded, to be plesiomorphic for the Araneoclada. Simultaneous insertion may well prove to be a synapomorphy for the higher haplogynes, Dysderoidea plus 'Scytodids' (Coddington and Levi, 1991).

The post-copulatory position taken up by the male is believed to represent a guarding posture. *Hypochilus pococki* males have been shown conclusively not to associate with penultimate females (Eberhard *et al.* in press). Hence, that the numerous occasions when males were found in this position in the field, suggest that they represent in fact, post-mating situations, and that the male was most likely guarding the female and thus his chance of paternity.

The implications of the 'veil' web produced by the female following egg-sac construction require further comment. *Hypochilus* egg-sacs are superbly cryptic and most are not concealed by such a 'veil' web (Shear, 1969; Fergusson, 1972; Catley, 1991). The behaviour of some females in concealing egg-sacs might have primitively represented a selective advantage from vertebrate or hymenopteran predation.

Accepting the cladistic hypothesis of Forster *et al.* (1987) on the relationships of the Hypochiloidea and Austrochiloidea, data on sheet web construction in these taxa suggests that the lampshade web of *Hypochilus* is autapomorphic. *Ectatosticta davidi* (Simon), the sister taxon of *Hypochilus*, constructs a sheet web (Li and Zhu, 1984) as do all known members of Austrochilidae (Forster *et al.*, 1987). Ontogenetic evidence, based on the observation that very early instar spiderlings also construct a sheet web (Catley, 1991), also supports this hypothesis and lends some weight to the suggestion that the plesiomorphic web construct of araneomorph spiders was the sheet web.

ACKNOWLEDGEMENTS

Grateful thanks are due to Dr. Frederick Coyle for the loan of video recording equipment, Rudolf Meier for help with translations and Dr. William Shear for his useful comments on an early draft of the manuscript. I should like to acknowledge financial support from the Organising Committee of the XII International Congress of Arachnology, the Graduate School of Cornell University and the Grace Griswold Fund which allowed me to attend this Congress.

EFFECTS OF SAMPLING METHOD ON COMPOSITION OF A TASMANIAN COASTAL HEATHLAND SPIDER ASSEMBLAGE

TRACEY B. CHURCHILL

Churchill, T.B. 1993 11 11: Effects of sampling method on composition of a Tasmanian coastal heathland spider assemblage. *Memoirs of the Queensland Museum* 33(2:): 475-481. Brisbane. ISSN 0079-8835.

The composition of a spider community in coastal heathlands of north-east Tasmania was derived from a 16 month survey using pitfall traps, sweep net and visual search sampling methods incorporated into a replicated, standardised sampling program. This interpretation of composition is shown to rely on the relative efficiency of the three collecting methods to sample the taxa present. Since mature spiders are required to confirm species identity, the differential selection of age and sex classes by the methods is illustrated. Whilst pitfall traps catch a greater number of taxa (at all taxonomic levels) and adult spiders, certain taxa are not or barely represented by this widely used technique. The subjective nature of the visual search method allows for the potential to target mature spiders. Limits of the sampling methods are emphasised in response to a growing dependence on survey data for the assessment of biodiversity.□*Araneae, methodology, biodiversity, heathland, invertebrates, community.*

Tracey B. Churchill, Division of Environmental Science, Griffith University, Nathan, Queensland 4111, Australia; 6 November, 1992.

Surveys of spider communities in Australia have primarily been motivated by specific taxonomic interests in this relatively unknown faunal group. Whilst this has lead to invaluable improvements in taxonomy, such collections are increasingly being utilised to extract data for the making of critical conservation management decisions. It is therefore necessary that further consideration be given to the factors that can affect the interpretation of survey results.

The primary factor that limits the comparability of data from different locations or times is the method used to sample spiders. Different methods can preferentially sample certain microhabitats and/or particular taxa (Merrett and Snazell, 1983). For example, the commonly used pitfall trap selects ground active species (Duffey, 1974; Merrett and Snazell, 1983; Lowrie, 1985) and the use of this method alone can produce species lists that under-represent more sedentary or foliage inhabiting members of the community.

The effectiveness of different sampling techniques can be influenced by behavioural differences between not only taxa, but also age or sex classes of a given species. For example, males of many species are more readily captured by pitfall traps than females due to their active search for a mate (Merrett, 1967, 1968), which may represent ground activity in an otherwise foliage dwelling taxa. Since mature specimens are usually required to identify species or genera, the ability to catch adults will effect the accuracy of a species list.

By adopting a suite of collecting techniques to target spiders both on the ground and in vegetation, the chances of sampling all taxa present are increased and thus data more useful for community studies are collected (Uetz and Unzicker, 1976). Accordingly, a combination of pitfall trap, sweep net and visual search methods was selected for a 16 month survey of spiders in the north-east coastal corner of Tasmania. The area is largely developed as sheep and cattle grazing properties, although to the seaward side of the remaining coastal *Eucalyptus* and *Casuarina* forests is often a margin of heathland dominated by members of the Proteaceae, Casuarinaceae, Epacridaceae, Papilionoideae and Xanthorrhoeaceae. An increasing impact of recreational and residential development threatens the remaining heathland (Kirkpatrick, 1977). In this paper, the composition of spiders in the heathland community is inferred by the list of spider taxa collected over the survey period. The relative efficiency of the three sampling methods in capturing dominant taxa is then compared to illustrate how the choice of method can influence the final interpretation of community composition or species richness.

MATERIALS AND METHODS

Spiders were collected using pitfall traps, sweep net and by visual searching, each of which

was standardised for effort and replicated. At monthly intervals from October 1986 to January 1988, sampling was carried out during a one week field trip. Two replicate 90m^2 sites were selected at each of two study areas, Waterhouse Point and Eddystone Point. Within each site there were nine 18m^2 plots placed 18m apart in three rows of three. This allowed for three replicate plots per sampling method, allocated initially at random. For the relevant plot the following sampling routine was employed: a) Nine pitfall traps were set 4.5m apart in a 3 x 3 matrix using 9cm diameter traps; b) one sweep sample of 50 sweeps was taken using a 28cm diameter net in a 12 x 3 m area and c) visual searching for 30 minutes was made over a 3 x 3m area. Spiders were preserved in 70% alcohol, identified to species where possible, and lodged with the Queen Victoria Museum, Launceston, Tasmania.

The three sampling methods were considered to be complementary in their selection of taxa occupying different strata. Pitfall traps sample spiders mobile on the ground, in contrast to sweep netting which targets spiders in the foliage. Visual searching can reveal spiders in any microhabitat, but a bias was shown towards those secured within web retreats, as such groups may not be amenable to capture by the previous two methods.

RESULTS AND DISCUSSION

Composition

A total of 8,625 spiders were collected using all three methods over 16 months, and these spiders comprised 130 species of the Araneomorphae in 97 genera and 34 families (see Table 1). Names could not be allocated to 26% of genera and 92% of species, indicating further that many Australian groups need taxonomic revision (Davies, 1985; Raven, 1988). The most diverse families in terms of the number of species were the Salticidae (14 spp.) and Gnaphosidae (11), followed by the Theridiidae (9), Zodariidae (9), Thomisidae (8) and Araneidae (8). The four most abundant species were, in decreasing order Diaea sp. (5.8%), *Badumna vandiemani* (5.3%), *Odo* sp. (4.3%), *Hestimodema* sp. (4.1%).

The number of spiders falling into pitfall traps depends on their activity (Mitchell, 1963;

TABLE 1. List of spiders collected from Tasmanian coastal heathlands. Asterisk indicates the 20 most abundant species.

Greenslade, 1964; Uetz and Unzicker, 1976; Merrett, 1983) and not necessarily on actual abundance in the community (Merrett, 1967; Merrett and Snazell, 1983). Individuals active on foliage presumably experience a higher probability of being knocked into a sweep net and for the visual search method the chance of noticing spiders would be increased by their activity (Curtis, 1980). Therefore it is stressed that references to abundance in this paper relate to numbers caught and not population size.

With respect to the number of individuals, the collections were dominated by the Lycosidae (26% of the total), Zoridae (10%), Thomisidae (9%) and Zodariidae (9%) (Fig. 1). The families Salticidae, Amaurobiidae, Desidae and Gnaphosidae then account for the next 22%. With the exception of the zodariids and zorids, these families are amongst the largest in Australia (Raven, 1988). The Araneidae, which are otherwise the most abundant Australian spider family (Raven, 1988), comprised only a minor component of this collection (1.4%).

The dominance hierarchy (Fig. 1) is determined by the number of adults in each family. However, as it is not standardised as to whether the whole data set (including immatures) or only the adult data are used to describe patterns of family dominance in a given community, a comparison is made to both (Fig. 1). The interpretation of relative abundance of families is affected by which category is used. Given that only adult data are useful for comparisons at the generic or species level, adult data seem the better choice for assessments of biodiversity.

Effects of Sampling Method on Composition

Pitfall traps collected the most individuals (6212), followed by visual searching (1900) and sweep netting (513). However, as the sampling effort of pitfall traps far exceeds that of sweep netting and visual searching, comparisons of taxa between methods are made relative to the total of each method.

Due to a reliance on acquiring mature spiders from surveys to confirm species and generic level identifications, Fig. 2 presents the differential distribution of age and sex classes for each sampling method. Pitfall traps clearly caught the greatest percentage of males (35%) and visual searching, the least (3%). Females are also collected more by pitfall traps, although the difference between methods is not as distinct. Accordingly, the percentage of immature spiders increases from pitfall traps (46%), through sweep net (75%) to visual search (84%) methods. From these results pitfall traps seem to be the most efficient at selecting mature spiders from the coastal heathland community.

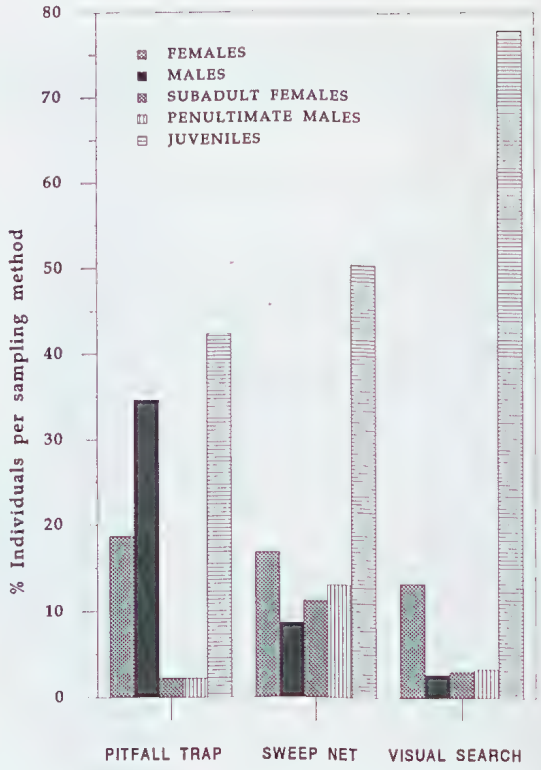

FIG. 2. Percentage of individuals in each sampling method for the different age and sex classes.

The total number of families, genera, and species can be compared to that collected by each sampling method (Table 2). At each taxonomic level, pitfall traps sample the most taxa (between 87-94% of the total), followed by visual searching (41-66%) and sweep netting (25-41%). It is relevant to point out that the results presented here were derived over a 16 month survey period. The likelihood of recording certain taxa using a given sampling method for typically shorter survey periods depends on the relative ease with which they are collected by that method (it also depends on the temporal abundance of taxa, to be discussed elsewhere). The percentage of adult

	Total	Pitfall	Sweep	Visual
Family	34	32	14	23
Genus	97	84	30	45
Species	130	113	33	53

TABLE 2. The number of taxa in total, and for each sampling method at three taxonomic levels.

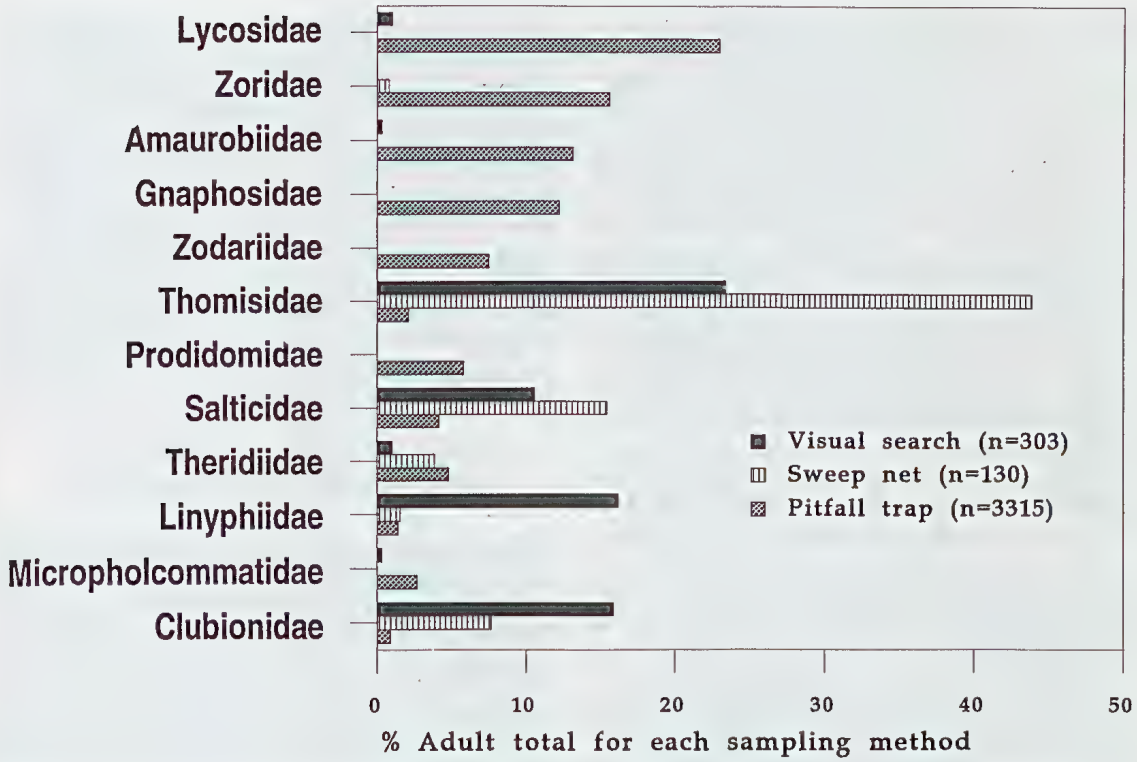

FIG. 3. Percentage of the adult spider total for each sampling method for the 12 dominant spider families.

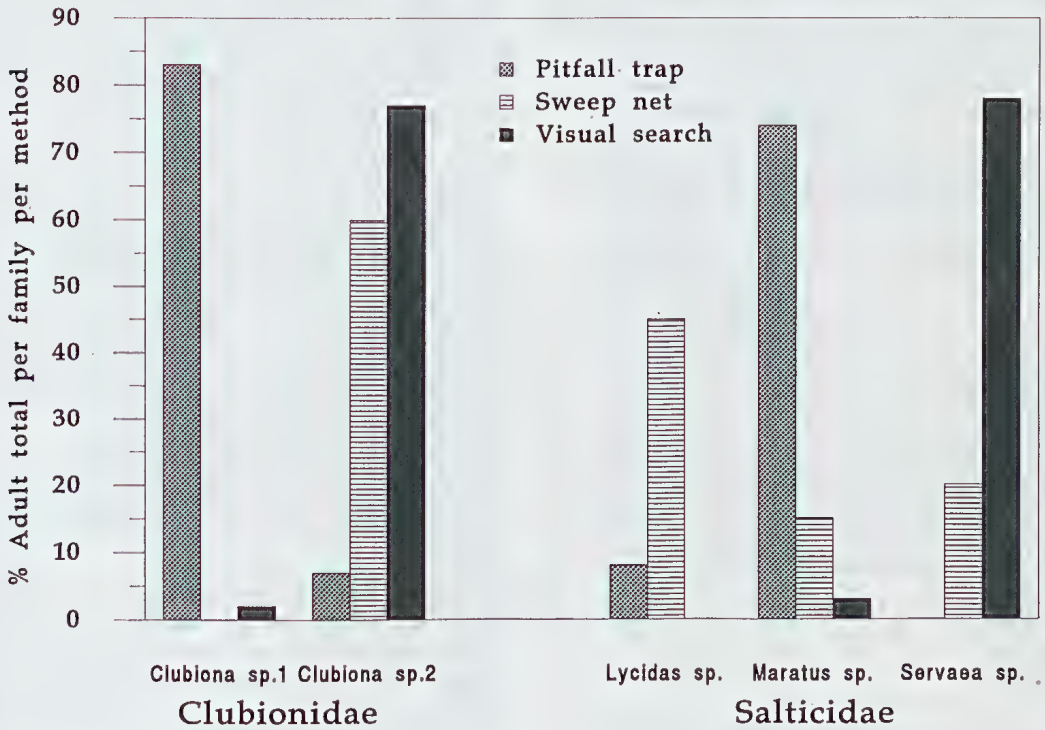

FIG. 4. Percentage of the adult spider total for each sampling method of Clubionidae and Salticidae.

spiders sampled by each method varies over the 12 dominant families (Fig. 3). Ground dwelling spiders such as gnaphosids or zodariids are exclusively caught by pitfall traps. Despite lycosids and zorids being sampled by all methods, there is a reduced chance that they would be represented by sweep net and visual searching over a shorter survey period. If only pitfall traps were used, the probability of representing the families Thomisidae or Salticidae is markedly reduced. Linyphiids, due to their habit of building low webs under the foliage are primarily amenable to capture by visual searching. Consequently, the results show that there is a greater probability of representing some families over others according to the method used.

The number of species in each family are distributed differently across sampling methods (Table 3). Whilst the ground dwelling spiders such as the gnaphosids and zorids have all their species falling into pitfall traps, other families have a pattern of species distribution across methods quite different to the distribution of individuals. For example, thomisids may be best sampled using sweep netting and visual searching (Fig. 3). Yet, these methods inadequately sample all the thomisid species collected (Table 3). The contrast is explained by the two most abundant thomisids, *Diaea* sp. and *Cymbacha* sp. being collected mostly by sweep net and visual search methods. Further examples include all clubionid species being sampled by all three methods (compared to a very unequal distribution of individuals) and a greater number of salticid species being sampled by pitfall traps (compared to this method catching the least number of salticids).

The number of individuals of the dominant species of clubionids and salticids illustrates that the differential selection of taxa by sampling method also operates at the species level (Fig. 4). Within the Clubionidae, despite the two species being collected by all three methods, *Clubiona* sp. 1 was almost exclusively sampled by pitfall traps, whereas *Clubiona* sp.2 was more often taken by a sweep net or visual searching. Similarly, the three dominant salticid species were preferentially sampled by the three different methods. Hence, if one sampling method was favoured over any other, especially for a shorter survey period, many species would be omitted from the final species list.

IMPLICATIONS FOR THE FUTURE SURVEY OF SPIDER COMMUNITIES

There is currently no spider sampling technique that is unbiased. The success of any method is usually related to certain aspects of spider behaviour and therefore generally represents an incomplete range of taxa. Whilst this may be readily acknowledged by arachnologists, the limitations of a given method is not always clarified in the interpretation of community composition. This is particularly important when non-arachnologists utilise the information as representative of the whole community.

Despite the use of three sampling methods in this survey, the species list is not unbiased. In this study, sweep net and visual search methods were carried out during the day and may therefore not select nocturnally active taxa. Visual searching included looking at the ground, but effective sampling of leaf litter was not undertaken, and this micro-habitat can harbour distinctive families (Raven, 1988). The visual search method is also subjective in terms of where the search focus is directed. Attention was paid in this survey to sample spiders in positions (particularly in nests) that were not as vulnerable to the other two collecting methods. Where the objective of the survey is to estimate taxonomic composition of the spider fauna, the efficiency of both the visual search and sweep net methods could be improved by avoiding the collection of distinctly immature spiders.

Also, the equipment design can effect the number of individuals and taxa caught (eg., for pitfall traps see Luff, 1975 and Curtis, 1980). Temporal factors can further influence which taxa are susceptible to capture by a given method and as discussed by Abraham (1983), this can be related to seasonal migration of spiders between vegeta-

tive strata. To enhance the comparability of survey data, there is therefore a need to standardise methodology, equipment design, sampling effort and timing. Yen and Butcher (1992) also make this plea in respect of terrestrial invertebrate surveys for the ultimate goal of conservation. Methodological limitations need to be taken into account during the final interpretation of taxonomic lists for a more useful assessment of the fauna. These aspects are stressed in the light of a rapidly growing reliance on such data sets for conservation and management in Australia, and the need to critically assess invertebrate survey methods for estimating the loss of biodiversity worldwide (Coddington *et al.*, 1991).

ACKNOWLEDGEMENTS

A survey of spiders of the north-east coastal heathland was supported by the Plomley Foundation at the Queen Victoria Museum, Launceston, Tasmania, who also funded curation of half of the spider collection. Specimens were identified and the curation completed with resources kindly provided by the Arachnology section, Queensland Museum (Brisbane) and with taxonomic advice from Mark Harvey (Nicodamidae), Rudy Jocqué (Zodariidae), Rolly Mackay (Lycosidae), Robert Raven (all other taxa) and Marek Zabka (Salticidae). Completion of the project has been possible through an Australian Postgraduate Research Award at Griffith University, Brisbane.

A NEW SPIDER GENUS (ARANEAE: AMAUROBIOIDEA) FROM RAINFORESTS OF QUEENSLAND, AUSTRALIA

VALERIE TODD DAVIES

Davies, V. Todd. 1993 11 11: A new spider genus (Araneae: Amaurobioidea) from rainforests of Queensland, Australia. *Memoirs of the Queensland Museum* **33**(2): 483-489. Brisbane. ISSN 0079-8835.

Malala gen.nov. is described and its relationships discussed; descriptions of two new species, *Malala lubinae* sp.nov. and *Malala gallonae* sp.nov. are given, including their spigot morphology. *Malala* is considered *incertae sedis* within the Amaurobioidea (*sensu* Lehtinen).□*Araneae, Amaurobioidea, new taxa, spigot morphology.*

Valerie Todd Davies, Queensland Museum, PO Box 3300, South Brisbane, Queensland 4101, Australia; 28 October, 1992.

Many amaurobioid spiders in Australia no longer spin a web; they are usually vagrants either in litter or foliage and typically the forelegs have strong ventral spination. Two species of a tree-frequenting genus are described here.

ABBREVIATIONS. Measurements: cephalothorax length (CL) and width (CW), abdomen length (AL) and width (AW). Eyes: anterior median (AME), anterior lateral (ALE), posterior median (PME), posterior lateral (PLE), anterior row (AR), posterior row (PR). Spinnerets: anterior (ALS), median (PMS), posterior (PLS). Collectors: R.J. Raven (RJR), N. Hall (NH), V.E. Davies (VED). *On figures*: **ac** aciniform spigot; **als**, anterior spinneret; **at,** anal tubercle; **c,** conductor; **cp**, protuberance on ♂ chelicera; **cy**, cylindrical spigot; **e**, embolus; **fb**, frontal bristle on ♂ chelicera; **fs,** frontal spur on ♂ chelicera; **Map**, major ampullate spigot; **map**, minor ampullate spigot; **ms**, median sclerite; **n**, nubbin; **pi,** piriform spigot; **pls,** posterior spinneret; **tf**, tegular flange; **to**, tarsal organ. All specimens are lodged in the Queensland Museum.

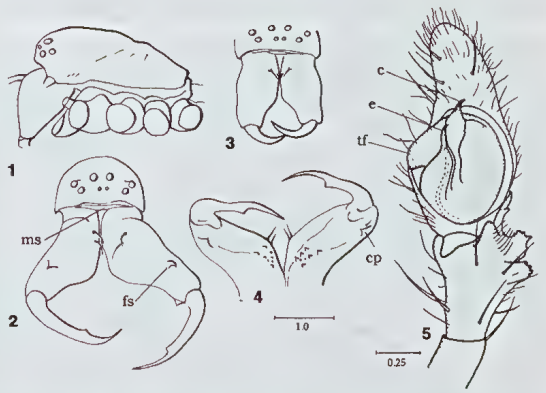
Malala gen. nov.

TYPE SPECIES

Malala lubinae, sp. nov.

DIAGNOSIS

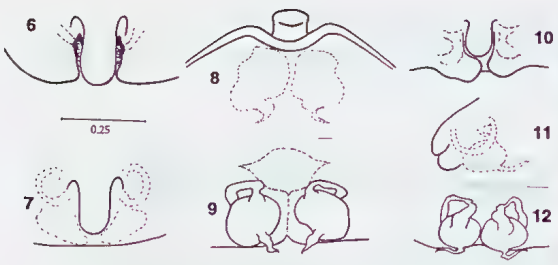
Three-clawed, pale clubionine-like with long spinose legs. Eyes in almost straight rows; AME much smaller than other eyes. Narrow median sclerite above chelicerae. Chelicera with one or two long frontal bristles proximally; pointed frontal spur distally in ♂. ♂ palp without median apophysis; elaborate tibial apophysis with dorso-retrolateral element.



FIGS 1-5. *Malala lubinae*. 1, 3, ♀. 1, cephalothorax (lateral), 3, eyes and chelicerae (frontal), 2, 4, 5, ♂. 2, eyes and chelicerae (frontal), 4, chelicerae (ventral), 5, palp (ventral).

DESCRIPTION

Straw-coloured ecribellate spiders with little or no pattern on abdomen. Carapace rounded dorsally, gradually declining in height behind fovea (Fig. 1). Anterior row of eyes straight, posterior row slightly recurved from above, procurved from front. Canoe-shaped tapetum in indirect eyes. Clypeus x 2 AME; narrow median sclerite above chelicerae (Figs 2,3). Sternum longer than wide, broadly truncate anteriorly, pointed posteriorly. Labium about as wide as long, a little more than half the length of the endite. Four-5 retromarginal cheliceral teeth; proximal ridge leading to 3-5 promarginal teeth, 2 small medial teeth between first and second marginals. Without long retrolateral filamentous setae at base of fang. Legs long (1243), trochanters unnotched. Coxae I longer than IV. Without plumose (ciliate) hairs on body or legs. Numerous strong ventral spines on tibiae and metatarsi I and



FIGS 6-12. *Malala* spp. epigyna. 6-9, *M. lubinae*, ventral, ventral (cleared), posterior, dorsal. 10-12, *M. gallonae*, ventral, lateral, dorsal.

II; metatarsi long, without preening combs; tarsi short. Trichobothria in a single row on metatarsi and tarsi. Bothria grooved, collariform (Fig. 14); tarsal organ with pear-shaped opening (Fig. 13). Superior claws 7-8 teeth, inferior claw 2 teeth; 2 pairs of fringed accessory claw setae present; ♀ palpal claw 2-3 teeth. Colulus. Spinnerets: ALS much larger than PLS; one major ampullate (gland) spigot and nubbin on ALS. Epigynum small with scape-like median structure; anterior gonopores. Male palp with spiniform embolus, membraneous conductor. Tibial apophysis with 3 processes; the anterior process branched or unbranched, the posterior ones 'toothed' and facing each other. Respiratory system with 4 tracheal tubes in abdomen; broad inner tubes branching and rebranching; slender outer tubes simple.

ETYMOLOGY

The generic name is derived from 'malal' an aboriginal word for spider.

Malala lubinae sp. nov.
(Figs 1-9, 13-17, 20-27)

MATERIAL EXAMINED

TYPES. Lamington National Park, southeastern Queensland. Holotype: ♀, Nagarigoon, 8.iv.1976, VED, NH, S20349. Paratypes: Nagarigoon, 1 ♂, 8.iv.1976, VED, NH, S20350; 4 ♀, 2 j, S20351; Binna Burra, 1 ♂, 1 ♀, 27-30.iii.1976, RJR, VED, S20352; 5 ♀, 11-12.ii.1981, Y. FIGS 26-31. *Malala* spp. spinnerets. 26, 27, penultimate ♀ *M. lubinae*. 26, right ALS, 27, major ampullate spigot and nubbin on ALS. 28-31 ♂ *M. gallonae*. 28, spinneret group, 29, right ALS, 30, PMS, 31, left PLS.

palpi, D1-0-1, P1-1-0; I, P2-1-1, V7-6-2, R1-1-1; II, P2-1-1, V5-5-1, R1-2-0. III, P2-1-0, V2-1-2, R2-1-0; IV p1-1-1, V1-1-2, R1-1-1. Metatarsi: I, P2-2-1, V4-3-1, R1-1-1; II P2-1-1, V4-2-3, R1-1-2; III, D2-2-2, P1-0-1, V2-2-1, R1-0-1; IV, D2-2-2, P1-0-1, V2-2-1, R0-1-1. Tarsi: palpi, P2-1-0, V0-0-2. Palpal tarsi swollen distally. Dorsal abdomen with slight foliate pattern. Epigynum very small (Figs 6-9).

Spinnerets: ALS much larger than PLS (Fig. 20). ALS with one large major ampullate spigot (Map), a nubbin (n) and about 30 piriform (pi) spigots arranged in 2 groups (Figs 21, 22, 25). The major ampullate spigot and nubbin are shown more clearly in a penultimate female (Figs 26, 27). PMS (Fig. 23) with large minor ampullate spigot (map), 3 aciniform gland spigots (ac) and one cylindrical gland spigot (cy). PLS (Fig. 24) with one large cylindrical spigot and 10 aciniform spigots.

Other females varied in size: CL 2.9-3.9, CW 2.3-2.9, AL 3.5-4.4, AW 2.3-2.8.

Male: CL 3.1, CW 2.3, AL 3.3, AW 2.0. Ratio of AME:ALE:PME:PLE is 5:9:8:9. Chelicerae divergent; 2 stout setae (fb) crossing over frontally with lesser one above; pointed spur (fs) distal to these. Four teeth on retromargin of chelicera, 4 on promargin; conical protuberance (cp) near base of fang; fang long with marked ventral projection (Figs 2,4,15). Length of coxae I:IV is 1:0.7. Leg measurements are given in Table I.

Notation of spines: Femora: palpi, D0-1-1; I, D1-1-1, P0-0-2, R0-1-1, II, D1-1-1, P0-2-1, R0-1-2; III, D0-1-1, P0-1-1, R0-1-1; IV, D1-1-1, P0-0-1, R0-0-1. Patellae: palpi, D0-0-1. Tibiae: I, P2-1-1, V7-4-1, R1-1-1; II, P2-1-1, V6-4-1, R1-1-1; III, P2-1-0, V2-1-2, R1-1-1; IV, P2-0-1, V1-1-2, R1-1-1. Metatarsi: I, P2-1-1, V4-2-2, R1-1-1; II, P2-1-1, V3-3-2, R1-1-1; III, D0-1-1, P2-0-1, V3-2-2, R1-1-1; IV, D0-1-1, P1-1-1, V2-2-2, R1-1-1.

♂ palp (Figs 5,15): tegulum extended to form anterior prolateral flange; embolus, arising ventrally on tegulum, tapers to a point; conductor membraneous with pointed sclerotized tip; cymbial tip shorter than length of tegulum. Tibia with 3 retrolateral processes, the anterior one branched.

Variation in size: CL 3.1-3.3, CW 2.4-2.5, AL 3.6-3.8, AW 2.1-2.2.

Biology

The spiders were collected from branches or foliage of trees in the rainforest. The egg sac was placed with the spider in a sealed portion of the prickly leaf blade of *Calamus muelleri*, the lawyer vine.

Malala gallonae sp. nov.
(Figs 10-12, 18, 19, 28-31)

Material Examined

TYPES. Holotype: ♀, Bellenden Ker Range, 1054 m, 17.x-24.xi.1981, Earthwatch/ Queensland Museum Expedition, S20357. Paratypes. Same data as holotype; 1 ♂, S20358, 1 ♀, S20359; 1 ♀, S20360. 1 ♂, same locality, 25-31.x.1981, S20361. 1 ♂, Malaan State Forest,, 20-4.iv.1978, RJR, VED, S20362. Upper Boulder Creek, 11km NW Tully, 850-1000m, 1 ♀, 17-18.xi.1984, J. Gallon, VED, S20363; 1 ♀, S20364; 1 ♂, 6.xii.89, G.B. Monteith, S20365. All in northeastern Queensland.

Female: CL 2.7, CW 2.0, AL 3.2, AW 1.9. Ratio of AME:ALE:PME:PLE is 4:8:9:8. Chelicerae with single stout elongate frontal bristles crossing each other. Four retromarginal, 3-4 promarginal teeth on chelicerae. Fang with slight ventral projection. Length of coxae 1:IV is 1:0.8. Leg measurements are given in Table 1.

Notation of spines: Femora: palpi, D0-0-1; I, D1-1-1, P0-2-1, R2-1-2; II, D1-1-1, P0-2-1, R1-2-1; III, D0-1-1, P0-2-1, R0-2-1; IV, D1-1-1, P0-0-1, R0-0-1. Patellae: palpi, D0-0-1. Tibiae: palpi, D1-0-1, P2-1-0; I, P2-1-1, V6-5-1, R2-1-1; II, P2-1-1, V5-5-1, R2-1-1; III, P2-1-0, V0-2-0, R1-2-0; IV P1-1-0, V0-1-0, R1-1-0. Metatarsi: I, P2-1-1, V4-2-3, R1-1-2; II, P2-1-1, V4-2-2, R2-0-1; III, D2-2-2, P1-0-1, V2-2-1, R1-0-1; IV D2-2-2, P1-1-1, V2-2-1, R0-0-1. Epigynum (Figs 10-12).

Variation in size: CL 2.6-2.8, CW 2.0-2.1, AL 3.0-3.4, AW 1.8-2.5.

Male: CL 2.4, CW 1.8, AL 2.9, AW 1.4. Ratio of AME:ALE:PME:PLE is 4:8:9:8. Chelicerae slightly divergent; single enlarged setae crossing over frontally, pointed spur distally; without protuberance near base of fang. Three retromarginal, 4 promarginal teeth. Leg measurements are given in Table 1. Notation of spines is similar to ♂ *M. lubinae*.

♂ palp (Figs 18,19): tegulum without prolateral flange, embolus arising prolaterally. Cymbium tip a little shorter than length of tegulum. Tibia with 3 retrolateral processes, the anterior one with 2 branches.

Spinnerets: ALS (Fig. 29) have a large major ampullate spigot, a nubbin and about 20 piriform spigots. PMS (Fig. 30) have a large minor ampul-

late spigot and 3 aciniform spigots. PLS (Fig. 31) have 10 aciniform spigots.

Variation in size: CL 2.0-2.8, CW 2.0.

DISCUSSION

Malala, a 3-clawed ecribellate, has a single row of tarsal trichobothria of increasing length distally and a single row of metatarsal trichobothria. The ♂ palp has a complex tibial apophysis and no median apophysis. The ♂ chelicerae diverge distally and have a pointed frontal spur distally. The median tracheal trunks are branched. The anterior lateral spinnerets have one major ampullate gland spigot and a nubbin. From these and other characters *Malala* clearly belongs in the amaurobioid/dictynoid complex of families. In his world revision of cribellates, Lehtinen (1967) recognised one major superfamily Amaurobioidea with 6 families. Describing New Zealand spiders, Forster (1970) and Forster and Wilton (1973) defined two groups, Dictynoidea and Amaurobioidea, based on the branching or non-branching respectively of the median tracheal trunks. However, Gray (1983) found that *Forsterina*, an acknowledged close relative of *Badumna* (classified by Forster and Wilton in Desidae: Dictynoidea) has simple median trunks thus invalidating the branching as a synapomorphy for the dictynoids. Gray's evidence suggests that the branching may be important only at the generic level in the same way as the extension of the trunks into the cephalothorax is regarded. In their recent paper on the higher systematics of Araneae, Coddington and Levi (1991) state that 'these superfamilies are among the largest cladistic problems at the family level' and that the difficulty of definition 'partly stems from heterogeneity within families'. I would add that the few Australian genera on which some of these families are based compared with the large number yet to be described, also contributes to this difficulty.

Most Australian rainforest cribellates which range in size from small to very large have a nondescript but recognisable abdominal pattern (see Lehtinen, 1967: 435), a divided cribellar field, a single row of tarsal trichobothria increasing in length distally and a row of metatarsal trichobothria. The ♂ palp has a complex tibial apophysis and a median apophysis is usually present. I am persuaded to return to Lehtinen's classification and regard these Australian spiders as belonging in the Amaurobioidea.

Only one dictynid, *Callevophthalmus* is described from Australia. It is found in grassland and open forest and not, so far as I know, in rainforest. It is a small spider with a distinct abdominal pattern and an entire cribellar field. It has no tarsal trichobothria and a single metatarsal trichobothrium. The ♂ palp has a small tibial apophysis, a large T-shaped conductor extending beyond the edge of the cymbium retrolaterally and has no median apophysis. The ♂ chelicerae are indented prolaterally and have a proximal frontal process; these modifications do not appear to be homologous with those of *Malala*. *Callevophthalmus* is similar to *Arangina* from New Zealand and to *Dictyna*.

This is the first description of spigot morphology in an ecribellate amaurobioid. In general, cursorial spiders use silk only as a drag-line, and for the construction of the cocoon in the ♀. Thus, it is expected they will have fewer kinds of spigots than the web-spinning (cribellate) amaurobioids. *Malala* has 3 aciniform spigots on the PMS and 10 on the PLS. The typical small aciniform spigots which provide silk for swathing prey (Kovoor, 1987) are not present in *Malala*. The lack of these in contrast to their abundance in cribellate amaurobioids and dictynoids (Coddington, 1990b) is probably associated with

Malala's nomadic existence. The presence of one major ampullate gland spigot (Map) and a nubbin on the ALS is found in dictynoids (notably in *Dictyna*) and in the Orbiculariae (Coddington, 1990a) as well as in some other taxa (Platnick *et al.*, 1991). The nubbin (presumably a remnant of a second major ampullate spigot) may be homoplasious in *Malala*.

The fringed accessory claw setae present in *Malala* are probably an adaptation to tree- or foliage-dwelling and are similar to those found in some New Zealand spiders (Forster, 1970; figs 28-31) from a similar habitat. They are unlike the serrate setae which are involved in handling silk in araneoids. The presence of a narrow median sclerite above the chelicerae in *Malala* may be apomorphic. Marples (1962) mentions that a triangular sclerite is present in *Matachia* but not in *Paramatachia*.

At present I am unable to place *Malala* in a family and consider it *incertae sedis* within the Amaurobioidea (*sensu* Lehtinen).

ACKNOWLEDGEMENTS

I am grateful for the support of the Council of the Australian Biological Resources Study for funding the survey of rainforests during which some of this material was collected and for financially supporting Chris Lambkin who did the lay-out for the figures. I acknowledge the help given by Earthwatch and the Center for Field Research, Boston, Mass., U.S.A. for supporting the Queensland Museum's expedition to Mt Bellenden Ker. I thank Don Gowanlock of the Electron Microscopy Centre, University of Queensland for the scanning electron micrographs and staff of the Queensland Museum for their willing help in the preparation of this paper.

AN INVENTORY OF THE SPIDERS IN TWO PRIMARY TROPICAL FORESTS IN SABAH, NORTH BORNEO

CHRISTA L. DEELEMAN-REINHOLD

Deeleman-Reinhold, C.L. 1993 11 11: An inventory of the spiders in two primary tropical forests in Sabah, North Borneo. *Memoirs of the Queensland Museum* 33(2): 491-495. Brisbane. ISSN 0079-8835.

Collecting trips were made to a primary rainforest area at 1500-1900m altitude (Mt Kinabalu National Park) and a primary lowland rainforest (Danum Valley Field Centre) in Sabah, North Borneo. For comparison, a strongly degraded secondary forest in the town Kota Kinabalu was also sampled. All the material, with the exception of the mygalomorphs and salticids, has been identified and compared with collections from Sarawak, Kalimantan and Sumatra. 254 species were distinguished in approximately 120 genera, 35 could be identified as known species, seven of which were clearly synanthropic, the rest are undescribed. 207 species were found in one locality only: 85% of the species from Kinabalu, 70% of the species of Danum and 50% of the species from the town park. Widespread species were found mainly in the Araneidae, Pholcidae, Oonopidae, Clubionidae and Salticidae. A list of the genera and species is given. □*Biodiversity, rainforest, Asia, Araneae.*

Christa L. Deeleman-Reinhold, Sparrenlaan 8, 4641 GA Ossendrecht, The Netherlands; 8 April, 1993.

Tropical rainforests, covering only 6% of the Earth's surface, are believed to harbour more than half of all terrestrial animal species, of which less than 10% are described at present (Stork and Gaston, 1990). Inventorying the spider fauna of rainforests in south-east Asia has given spider taxonomy a new turn, especially so after the introduction of a new sampling method that targets canopy arthropods.

Most rainforests in Asia have now been destroyed or degraded, but the number of undescribed species is still overwhelming. The rapid destruction of our rainforests is an incentive to securing as much data as possible as ... 'an extensive program of inventorying aimed at estimating diversity of species ... is essential for a fuller understanding of the role of biodiversity in ecosystem function' (Coddington *et al.*, 1992).

Records of spiders from Borneo are extremely poor. With more than 30,000 species of spiders described so far, only about 160 named spider species have been described or recorded for the whole of Borneo; 65 of these are salticids. Only 96 spider species were reported from Borneo before World War I. Wanless and Hillyard (1984) present a list of species collected during the arachnological survey of Gunung Mulu National Park, Sarawak; 360 species were collected in all families, 38 of which were identified with known species, another 14 with reserve; 20 identified species are salticids. From Sabah, a mere 20 spider species are known, all published since 1979 (Deeleman-Reinhold, 1980, 1987; Lehtinen, 1979, 1981, 1982; Levi, 1982, 1983; Okuma, 1988; Platnick and Murphy, 1984; Wanless, 1987).

In a privately undertaken program of inventorying spiders of primary and secondary forests in south-east Asia, during the last 14 years I have been engaged, with the help of other, partly autochthonous collectors, in surveying the spider fauna of south-east Asia, mainly Indonesia, Malaysia, Thailand, Sri Lanka and the Philippines. As part of this initiative, I made three collecting trips to Sabah in the north-eastern part of Borneo.

METHODS

In June 1979, July 1980 and April-May 1991, I collected spiders in the primary rainforest of Mount Kinabalu National Park at altitudes of 1500-1900m. In May 1991, 2 days were spent collecting at an altitude of 500m (Poring Hot Springs). In May 1991, spiders were collected in lowland primary forest around the Danum Valley Field Centre in eastern Sabah. For comparison, some time was also spent collecting in the town park in Kota Kinabalu.

The spiders were collected by hand picking, sweeping, litter sieving and pitfall trapping on the ground. All araneomorph spiders, with the exception of the Salticidae have been identified (Tables 1-3). The collected spiders were compared with most specimens of the above mentioned south-east Asia collection. Identification was done as

Table 1. Spiders from Mount Kinabalu, 1500-1900m (Headquarters and Power Station) and 500m (Poring Hot Springs), primary rainforest, 18 collecting days in April-May, June and July. Family order is 'phylogenetic'. List gives no. of undescribed species in parentheses and notes on species.*= only at 500m.

much as possible with the aid of modern revisions but, where these do not exist, I had to rely on the keys in Simon (1892-1903) and the Latin descriptions (without illustrations) of Thorell (1877-1899) and Simon. Many nineteenth century types deposited in Genova, Paris and London were studied. Only species of which adults were collected are considered here.

RESULTS

From the three main prospected localities in Sabah, a total of 254 species from most spiders families (for practical reasons the mygalomorphs and the salticids were excluded) could be distinguished. Of these, 35 species could be identified as described species, seven of which are clearly synanthropic.

On Mt Kinabalu (1500-1900m), 135 species were collected in 18 days (41 species represented by one specimen only); 25 species were collected in two collecting days at Poring Hot Springs, lower down on the mountain slope at 500-600m; four of these were shared with the 1500-1900m site (see Table 1). For six of the 19 described and named species this is the type locality (Deeleman-Reinhold, 1980, 1987; Levi, 1982). 132 species (85%) were collected only in Kinabalu; 24 species were also found elsewhere.

Table 2. Spiders from Danum Valley Field Centre, primary lowland forest, 8 collecting days in May; some species, mostly Thomisidae, in freshly logged area. Family order is 'phylogenetic'. List gives no. of undescribed species in parentheses and notes on species.

Compared to the lowland catches, a predominance of Linyphiidae was found.

In primary lowland forests around Danum Valley Field Centre in East Sabah, 90 species were collected in 9 days (Table 2); 14 species have been previously described. Of these, 67 species (70%) were only found at Danum, and 23 were also found elsewhere. In a freshly logged area, thomisids were particularly diversified.

In the secondary forest of Signal Hill in the township of Kota Kinabalu, 16 species were collected, 7 of which could be identified to species. Eight species were found also elsewhere, and 8 species (50%) were collected only on that site.

DISCUSSION

The main conclusion is that in tropical forests, spider species known from only one locality are enormously preponderant even though all distribution types from cosmotropical to very restricted ranges were encountered.

In a total of 254 species from the three localities (Tables 1-3), 207 were collected at one locality only, 92 of which were 'singletons'. Is this due to the lack of data only, or is a high percentage of endemic species real? This phenomenon occurs much more frequently in some families than in others. Quite often, in adjacent localities a sister species is found. In a long-term inventory of a 1-2 km^2 area on the northern side of the Sibolangit range, on Gunung Leuser in Sumatra (Deeleman-Reinhold, unpublished data), spiders were collected once a week for two years. A similar study was conducted on the other side of the ridge. Less than half of the species were found on both sides of the range! Therefore, endemism in spiders seems characteristic of primary rainforests, even though the real extent of distribution ranges will only be revealed after long and extensive sampling. For example, recent studies on south-east Asian Linyphiidae (Millidge and Russell-Smith, 1992) report 27 species, 26 of which new, described in 11 new and four known genera; all new species were recorded from only one locality (see also Scharff, 1992).

Also, widely distributed species were often found in human-made habitats. In such habitats most species described in the last century were found. In the course of identifying large south-

east Asian collections it appeared that the majority of the species described prior to the early 20th century occur in habitats created by humans rather than in the rainforests. Thus, the spider fauna of the latter is still almost unknown.

A high degree of endemism seems to occur in certain families; other families which include a relatively high number of widely distributed species are Araneidae, Gnaphosidae, Oonopidae, Pholcidae and Salticidae. Occasionally, one or two species in a family are able to disperse considerably, whereas their relatives have remained limited to a restricted area. Among the best dispersers are some of the smallest known litter-dwelling spiders, with a body length of less than 1mm, which independently seem to have developed methods to overcome the vicissitudes of ballooning, e.g. the tiny armoured anapid *Pseudanapis paroculus* Simon is distributed over much of tropical south-east Asia both in primary and secondary forests. The small ochyroceratid *Theotima minutissima* (Petrunkevitch) and the oonopid spider *Ischnothyreus peltifer* (Simon) are distributed over the palaeo- and neotropics, where they live side by side with local congeners. Also larger spiders have been found to be widely distributed in humid forest, such as some *Cyclosa*, *Argiope*, *Acusilas*, *Neoscona* and *Gasteracantha* species, but also the delicate, almost transparent pholcid *Calapnita vermiformis* Simon.

The number of small-range species in both primary and secondary evergreen forests seems to be enormously higher than we are used to in temperate climates. Very few wide-spread species seem to occur naturally on Mount Kinabalu; more were found in lowland forest.

It is premature to estimate the total number of species present. Richest in species probably is the family Salticidae. Also numerous in species are the Theridiidae, Oonopidae, Araneidae, Clubionidae s.l. and Tetragnathidae in that order (see also Wanless and Hillyard, 1984 for Gunung Mulu).

Some genera have been particularly speciose in primary forest. In *Ischnothyreus* I found 11 species in Sabah (10 undescribed); in *Theridion* 11; in *Dipoena* 8; and in *Clubiona* 8 (all undescribed).

One final remark on diversity. Among the strongly represented families, diversity in the following families appears to be higher than average: Pholcidae, Clubionidae *s. lat.*, Tetragnathidae, Araneidae, Linyphiidae.

This study indicates that, when replacing primary forest by secondary plantations, the loss of species diversity of spiders is enormous.

A REVIEW OF FACTORS INFLUENCING THE DISTRIBUTION OF SPIDERS WITH SPECIAL REFERENCE TO BRITAIN

ERIC DUFFEY

Duffey, E. 1993 11 11:. A review of factors influencing the distribution of spiders with special reference to Britain. *Memoirs of the Queensland Museum* 33(2): 497-502. Brisbane. ISSN 0079-8835.

Available data on factors influencing spider distribution are synthesized using mainly British and other European information. The importance of landscape history is stressed, in fragmenting ancient natural habitats and creating new ones. It is postulated that this has reduced the number of specialists and allowed a range expansion of pioneer and euryoecious species. A tentative classification of life strategies is proposed. Habitat diversity and microspatial distribution are discussed with examples. □*Spiders, habitat preferences, geographic distribution, life strategies.*

Eric Duffey, Cergne House, Wadenhoe, Peterborough, PE8 5ST, United Kingdom; 3 November, 1992.

Many attempts have been made to categorise the habitats of spiders according to their preferences for dampness, dryness, shade, light, warm or cool temperatures. In addition, increasing knowledge derived from extensive collections made during the last 50 years in Britain and the rest of Europe have made it possible to draw distribution maps (Locket *et al.*, 1974; Ransy and Baert, 1985, 1987a, 1987b; Janssen and Baert, 1987; Ransy *et al.*, 1990; Alderweireldt and Maelfait, 1990; Canard, 1990), even though their incompleteness is acknowledged. The distribution of some species shows a clear influence of latitude and longitude, with north-south or east-west trends, or an association with major habitat formations. This paper discusses some factors which influence spider distribution, such as landscape history and geographic range, habitat preferences, adaptation to man-made biotopes and small-scale environmental differences, with the object of categorising the occurrence of species according to life strategy.

Islands of modest size such as Britain are poorer in species than adjacent continental areas. For example, the spider fauna of Belgium, a near neighbour, which is only 1/8th the size of Britain and has 75km of coastline compared with Britain's 19 000 km, and a lower landscape diversity, has almost as many recorded species (600) (Keckenbosch *et al.*, 1977) as Britain's 622 (Roberts, 1985-87).

Habitat labels based only on local information may be unsatisfactory, since (in Britain and the rest of Europe) we know that (a) some widespread species are found in different habitats according to where they occur in their geographic range; (b) within a restricted area some species are found only, or mainly, in 2 very different habitats, for example sand-dunes and marshes; (c) some species are so widespread that they are difficult to characterise in terms of habitat preferences; (d) species confined to only one specialised habitat are generally few in number and often rare. Examples are presented in this paper.

Nomenclature follows Roberts (1985-87) for spiders and Anon. (1964-80) for plants.

LANDSCAPE HISTORY AND PATTERN OF SPIDER DISTRIBUTION

Britain was largely forested before human settlement but forests are now much modified scattered remnants. This extensive environmental change will have favoured some species and disadvantaged others. For example, when the surviving rare species associated with major formations in Britain are listed (Table 1) most are recorded for coastal systems which–apart from the more limited mountain tops–are the least modified components of the present-day landscape. Species which are regarded as 'characteristic' of major habitat formations (Ratcliffe, 1977) (Table 2) may also be identified. The high numbers recorded for grassland, dry heaths and coasts probably reflect a great expansion of range by open-ground species after forest clearance.

The extent of habitat modification and disturbance is difficult to quantify because the type and intensity of change varies from place to place. In the case of wetlands, however, there is a common factor in that alteration to the water table has a greater impact on the fauna than other uses made

of these areas by man. In 1969 11 fens in East Anglia were surveyed by a group of arachnologists hand-collecting for a total of 10 hours per site. Each hourly collection was kept separate. The similarity between the faunas of the 11 fens in terms of abundance of each species present was assessed using Mountford's Index of Similarity (Mountford, 1962). Three groupings were derived, of which 2 were more similar than either was to the third group. The 8 fens in groups 1 and 2 had survived with little change to their water regimes at that time, while the third group had suffered falling water tables and hence vegetation changes (Duffey, 1974). The mean numbers of species for groups 1 and 2 were 53.2 and 50.0, respectively, and 34.6 species for group 3. Most of the rarer and more specialised fen species (*Marpissa radiata* (Grube, 1859); *Hygrolycosa rubrofasciata* (Ohlert, 1865); *Neon valentulus* Falconer, 1912; *Carorita paludosus* Duffey, 1971; *Centromerus incultus* Falconer, 1915; *Maso gallicus* Simon, 1894) were recorded in groups 1 and 2.

HABITAT VERSATILITY IN SPIDERS

The ability of many spiders to live successfully in a range of different environments has been little studied. The best known examples are pioneer species that are good aeronauts and the first to colonise newly created habitats. Meijer (1977) discusses this for Dutch polders, and Duffey (1978) for croplands and grasslands. Not all aeronauts behave in this way. *Erigone arctica* (White, 1852) and *E. longipalpis* (Sundevall, 1830) are often abundant on coastal driftlines and saltmarshes but are rare inland. The former is found on mountainsides in Sweden (the late A. Holm, pers. comm.) and both have been recorded on inland saline areas as well as in sewage works.

TABLE 2. Numbers of British spider species assessed as characteristic of various major habitats (compiled by P. Merrett in Ratcliffe, 1977)

Grasslands	74
Dry lowland heaths	63
Coastal formations	53

This provides evidence that they disperse over long distances but survive in only a few places.

Agricultural land has been colonised by species whose natural habitats are sand-dunes and stony open ground, for example *Troxochrus scabriculus* (Westring, 1851) and *Milleriana inerrans* (O.P.-Cambridge, 1884). *Porrhomma convexum* (Westring, 1861) is also frequent on cultivated land but elsewhere occurs in caves, mines, culverts (Locket and Millidge, 1953), and under stones by stream and lake shores (K. Thaler, pers. comm. and Duffey, unpublished).

The stone-filled filter beds of sewage works attract another cave species, *Lessertia dentichelis* (Simon, 1884), together with *Leptorhoptrum robustum* (Westring, 1851), whose natural habitat is freshwater marshes and wet meadows, and also *E. longipalpis* and *P. convexum*. The environment of filter-beds is completely artificial and uniform with stable temperature and high humidity, forming a 'super habitat' in which few species occur but in much higher numbers than found in nature.

The ability of some species to live successfully in two contrasting habitats was first noted by Bristowe (1939) and described as 'diplostenoecism' by Duffey (1974) and 'doppeltes ökologisches Vorkommen' by Schaefer and Tischler (1983). The best-known examples are those species found on coastal dunes and also in marshes–*Synageles venator* (Lucas, 1836), *Tibellus maritimus* (Menge, 1875), *Clubiona juvenis* Simon, 1878, *Hypomma bituberculatum* (Wider, 1834) and *Thanatus striatus* C.L. Koch, 1845. The last is also found in dry grasslands. *Sitticus rupicola* (C.L. Koch, 1837) is widespread on stony mountainsides in central Europe (Prószynski, 1978) but in England occurs only on coastal shingle banks.

Competitive relationships may also influence choice of habitat and hence distribution. *Zelotes electus* (C.L. Koch, 1834) is the characteristic species of this genus on coastal sand-dunes in

Britain whereas *Z. pusillus* (C.L. Koch, 1833) is associated with inland heaths, dry grasslands and open, stony ground. However, *Z. electus* was found (Anon., 1979) to extend only as far north as south-east Scotland and at higher latitudes was replaced on the coastal dunes by *Z. pusillus*.

All these species can adapt to different environmental conditions and emphasise the need to study habitat selection throughout the whole geographic range of a species before its distribution status can be understood.

EFFECTS OF HABITAT FRAGMENTATION

Several distribution maps in Locket *et al.* (1974) show widely scattered records for certain species which may indicate a decline from a former continuous distribution.

Lepthyphantes midas Simon, 1884 is an ancient forest specialist and is associated with loose bark and dead timber or birds' nests made of twigs. It is only known from 4 scattered sites in Britain where ancient forest survives. Similarly, wetlands have suffered serious losses, including the Fen Basin, East Anglia, which was progressively drained from Roman times and lost the remaining large areas of marsh in the mid-19th century. The local lycosid *Hygrolycosa rubrofasciata* (Ohlert, 1865) survives in the two remaining fenland areas and also in numerous small fen relicts around the

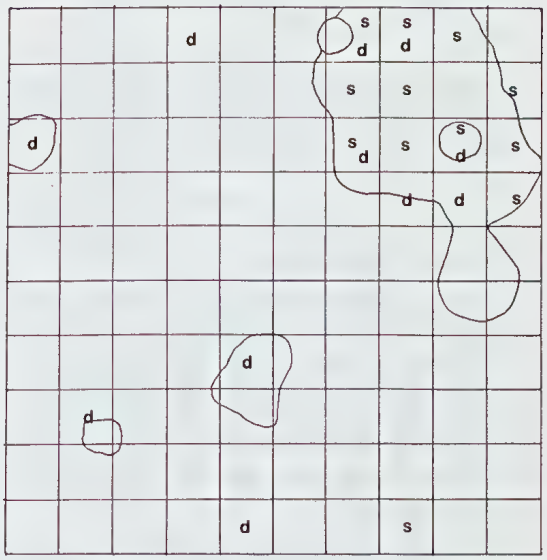

FIG. 1C. Other species preferred cover of heather plant or grass tussocks, e.g. *Scotina gracilipes* (Blackwall, 1859) (s) and *Dipoena prona* (Menge, 1868) (d). Each record refers to a catch of 1-5 individuals.

TABLE 3. Classification of life strategies and adaptability to environmental diversity based on British spiders.

PIONEER SPECIES
Active aeronauts which disperse freely, exploiting newly created open ground where competition is low. Widely distributed in temporary or changing habitats such as agricultural cropland, gardens, urban areas, leys and other types of disturbed ground or vegetation.
GENERALISTS
Common species with a capacity to adapt to a wide range of semi-natural habitats and permanent artefacts in the man-made environment. May be difficult to assign to a particular habitat.
BROAD SPECIALISTS
A. Widespread, euryoecious, or 'characteristic' species (Table 2) associated with major habitats such as deciduous woodland, marshes, heaths or ancient grassland, but may be found in many different variants of the chosen major formations.
B. Diplostenoecious species, mostly widespread and associated with 2 different habitats but usually more common in one than the other. Occasionally much more abundant in man- made habitats than in the natural environment. This grouping grades into species successful in 3 or more different environments.
NARROW SPECIALISTS
Stenoecious species which seem confined to clearly defined habitat. Includes rare species in low numbers and others which may be locally abundant, although confined to a restricted area because the habitat is scarce.

margins of the Fen Basin. Are these relicts of a former more extensive distribution?

Lowland heathland has also suffered severe losses, having been reduced to many small fragments by agricultural reclamation with a consequent loss of biodiversity (Webb, 1990). *Eresus niger* (Petagna, 1787) was formerly more widespread in heaths in southern England but is now known from only one locality where the population is small.

In contrast, some species are able to live in a range of different habitats, and thus overcome the problem of fragmentation. If this characteristic is also combined with active aeronautic dispersal, the chances of finding isolated suitable environments will be further enhanced. For example, *Pardosa palustris* (L., 1758) is the most active aeronaut of the common lycosids found in Britain and northern Europe (Richter, 1970). Few have been recorded in a wide variety of habitats, including marshes, grasslands, heathlands, and agricultural crops, but occasionally is found to be dominant, as in moist hay meadows in river valleys and on some sand-dunes. In a survey of dune systems in Scotland (Anon., 1979) it was the most abundant lycosid, although it was not recorded on all the dune areas which were studied. It seems that the active aeronautic behaviour of *P. palustris* enables it to move about freely and its ability to exploit many different habitats gives it a high ranking as an opportunist. Kessler (1973) also showed that *P. palustris* is able to produce more eggs per unit of body size under field conditions than 7 other *Pardosa* species. This may be an advantage when colonising new areas.

Adaptability to environmental diversity varies from species to species, so that a gradient exists from those which are very widespread (usually many species) to those which appear to be confined to a specialised habitat (relatively few species). The different components of this gradient are outlined in Table 3, and modified from Duffey (1975a).

HABITAT DIVERSITY AND MICROSPATIAL DISTRIBUTION

The structure of the vegetation, the litter layer and physical features of the environment have a strong influence on spider distribution and species composition (Duffey, 1962, 1968, 1974; Edwards *et al.*, 1975; Uetz, 1991). There is evidence that all species, however widespread, are influenced in some way by habitat structure. This was shown by comparing the fauna in different quadrats of a simple vegetation type on a Danish heathland (Duffey, 1974). Fig. 1 shows the differences in species and numbers of spiders between 100 25x25cm quadrats in a block measuring 250x250cm. The vegetation consisted of a heather plant (*Calluna vulgaris* (L.) Hull, 1808) in one corner of the block, and a few scattered grass tussocks of *Deschampsia flexuosa* ((L.) Trin., 1836), while most of the area was covered with mosses, lichens and small stones. The species in Fig. 1 occurred in clearly defined microhabitats. *Trichopterna cito* (O.P.-Cambridge, 1872), which was widespread in the open ground of moss and lichen, avoided the heather, and was also absent from 4 quadrats on the right-hand side of the sampling area which

had been trampled. Similar results are reported by Jocqué (1973), who studied the fauna of different types of woodland litter layers in Belgium. On a heathland ranging from dry to wet areas, Snazell (1982) sampled the spider fauna by pitfall trapping at 154 random points over 12 months. By Principal Components Analysis on the 45 most numerous species he was able to show a wide gradation from specialised to broad habitat preferences, which conform well with the categories in Table 2.

In an experiment in tall grassland in England, faunal changes were recorded in grass litter modified by trampling. Samples of grass litter enclosed in nylon-mesh bags (20x20x8cm) received 3 different treading treatments (5 treads/month, 10 treads/month and an undisturbed control series) (Duffey, 1975b). There were 25 replicates in each case. After 12 months the volume of the litter in the controls had fallen by 50 % due to natural decay, but those having had 10 treads/month had fallen by 81 %. Of the 10 most frequent species, 5 were eliminated by the treading after 12 months, and the total numbers of all species fell by 84 %. Of the 5 remaining species, 3 showed little response to the treading, their numbers falling only marginally. The higher level of treading in this experiment was very light compared with that on a public footpath in a popular area, but the effect on the litter fauna was quite dramatic.

CONCLUSIONS

The modification of the European landscape through many centuries has been the greatest influence determining the distribution of spider species. Natural and near-natural habitats are now rare, as are the specialist species associated with them. Today many species have adapted to man-made environments, whether permanent or temporary, and those preferring open-ground conditions have greatly expanded their range. A gradation of life strategies (or adaptability) from pioneer species to narrow specialists is proposed. Superimposed on these factors are the influences of major climatic zones and the microspatial variations in the abiotic environment. All these features should be considered when defining the distribution and habitat characteristics of a species, drawing on evidence from the whole geographic range.

THE DEVELOPMENT OF THE ASYMMETRICAL WEB OF *NEPHILENGYS CRUENTATA* (FABRICIUS)

JANET EDMUNDS

Edmunds, J. 1993 11 11: The development of the asymmetrical web of *Nephilengys cruentata* (Fabricius). *Memoirs of the Queensland Museum* 33(2): 503-506. Brisbane. ISSN 0079-8835.

In the field, young *Nephilengys cruentata* (Fabricius) remain on the barrier threads of their mother's web for about ten days, before moulting. Some do not initially disperse far, and may even remain on the barrier threads to build their first web. These first webs are complete orbs. As the spiderlings grow the hub of the web is spun approximately three quarters of the way up the web; later there are no spirals above the hub. At this stage some spiders join the hub to the barrier, forming a 'tent' under which the spider rests. The true retreat, of a tube that is closed at the end away from the hub, develops gradually as the spiders grow further.□*Nephilengys, web development, evolution of webs.*

Janet Edmunds, Mill House, Mill Lane, Goosnargh, Preston PR3 2JX, United Kingdom; 12 November, 1992.

Nephilengys cruentata (Fabricius) is common throughout tropical Africa. In Ghana it lives in savanna and forest edge areas. Under natural conditions it attaches its web to trees, but it has frequently adapted to attaching it to dwellings. It was very common at Legon in such situations. The adult female is large but the male is much smaller. The webs of larger spiders are usually a roughly triangular partial orb. The hub is at the upper apex, where there is a cylindrical retreat, closed at the end away from the hub. There is an extensive barrier above and behind the viscid web; the main attachment between the two is at the hub. The hub and retreat are often in the angle between a wall and the ceiling or overhang. This paper presents data on the shape of the web of *N. cruentata* from the earliest instars to adults.

METHODS

Spiders of all ages were observed living on the verandahs of a private dwelling and of the Zoology Department at Legon, but it was not possible to follow individual spiders in the field or captivity. Web size and length of the first leg of each spider were measured, although the relation between spider size and instars was not determined. The vertical asymmetry, lateral asymmetry and shape (circularity) of the web were determined from the ratios of vertical radii, horizontal radii and the two diameters respectively, all measured to the nearest 5mm; N for all figs is given in Table 1.

RESULTS

The cocoon is laid close to the web, often on a wall or ceiling. When the spiderlings emerge, they remain close to where they have emerged in a tight bunch on the barrier web for about ten days, spinning extra irregular threads. After the first post emergence moult, they disperse, but many remain close to the mother's web, some even building their first catching web in the threads of the barrier web.

When the spiders are grouped into different size classes based on leg 1 length, the extent of the web below the hub increases with each succes-

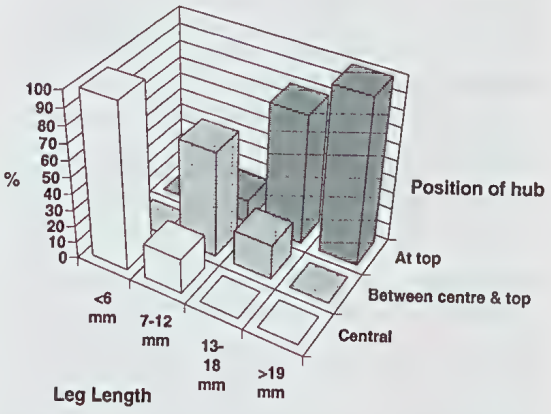

FIG. 1. Changes in vertical asymmetry in webs of *N. cruentata* with different leg lengths. At top: ratio of upper to lower radius = 0; Between centre and top: ratio of upper to lower radius >0 <1; Central: ratio of upper to lower radius = 1 .

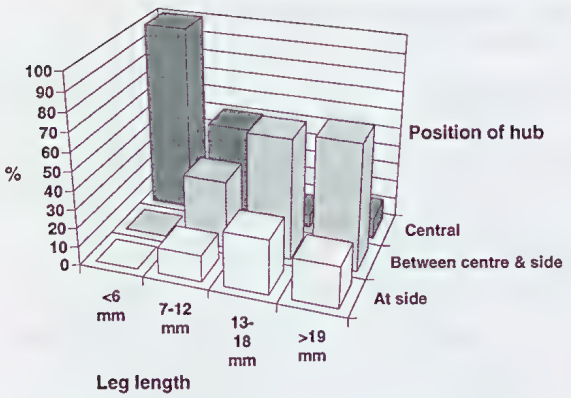

FIG. 2. Changes in lateral asymmetry in webs of *N. cruentata* with different leg lengths. At side: ratio of two horizontal radii = 0; Between centre and side: ratio of two horizontal radii >0 <1; Central: ratio of two horizontal radii = 1.

sive class, while that above the hub increases slightly before decreasing to zero (Table 1).

The vertical asymmetry increases with size (Fig. 1): spiders with leg 1 <6mm spin complete orbs. As they grow, less web is spun above the hub, so that the hub is then about three quarters of the way up the web. Larger spiders, with leg 1 >19mm have no web above the hub. Because of the difficulty in following individual spiders, the time span over which these web changes occurred is not known.

Early webs are symmetrical laterally (Fig. 2), but webs of larger spiders show greater variation and may be markedly asymmetrical laterally; at the extreme the hub is completely to one side. Some early webs are also circular or nearly so (Fig. 3), however very few webs of spiders with leg 1 > 6mm have the vertical and horizontal diameters of the same size.

During these changes in the proportions of the viscid web, the barrier increases (Fig. 4). The very first webs have no barrier or just a few threads, which are attached to the orb at only a few points. But over some days more threads are added, until the barrier is a fairly dense cone shaped tangle behind the orb, and more firmly fixed to the web. Small pellets of detritus, similar in size and shape to the spiderling and of the same pale grey colour, usually occur in the barrier (Edmunds and Edmunds, 1986). These may deflect attacks of potential predators.

The development of the retreat increases with the size of the spider (Fig. 5). Spiders with the hub

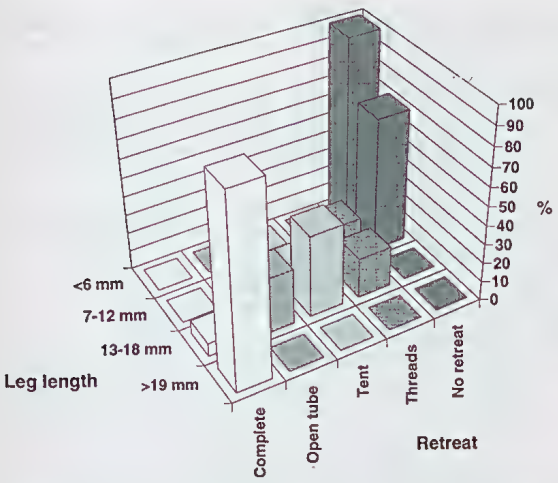

FIG. 5. Development of retreat in webs of *N. cruentata* with different leg lengths.

at the centre or part of the way up the web rest at the web hub and there is no retreat. When the hub is built at or very close to the apex, the first stages of a retreat are formed as a denser group of threads within the barrier close to the hub. As more threads are added, this becomes a roof-like tent between the hub and the barrier, or sometimes an open ended tube. Spiders with leg 1 >19mm normally had a closed tubular retreat, like an adult.

Early webs are very fine, and it is not easy to see the details of the individual threads. However, a complete web appears to be spun in one operation, unlike larger webs which are spun in two or more sections on different days. The temporary spiral does not appear to be left up, though more detailed observations would be needed to confirm this. Larger spiders leave the temporary spiral in the finished web.

DISCUSSION

The webs of most adult female Nephilinae are not typical orbs. Most *Nephila* species build incomplete orbs, with the hub near the top (Robinson and Robinson, 1973, figs 2, 20; pers. obs.). However, unlike *Nephilengys*, there are threads above the hub, including in some instances a few sticky spirals. In *Nephila plumipes* large, probably mature, females were seen in Brisbane, Australia, that had several sticky radii above the hub. However, in at least some individuals, these appeared to have been laid as pendulum turns, rather than complete spirals (pers. obs.). *Nephila* does not build a retreat and the spider rests at the hub. Like *Nephilengys*, there are barrier webs, though on both sides, and often above the orb. These are supportive and probably also defensive (Robinson and Robinson, 1973). *Herennia ornatissima* (Doleschall) constructs a very long web, with almost parallel sides (Robinson and Lubin, 1979). The spider sits in a cup-shaped depression of dense silk that forms the hub. It is towards the top of the web, though there are several sticky spirals above it. The spider has no barrier web, but as it builds very close to tree trunks, it would be difficult to find a place to build one.

Larger juvenile Nephilinae build webs like the adults, and a few observations have been published on the very early webs. The first webs of *Nephila clavipes* (Linnaeus) are circular (Comstock, 1948; Levi and Levi, 1968). Brown and Christenson (1983) give measurements of the webs of *N. clavipes* spiderlings between 2 and 9mm body length. The webs show an increase in vertical asymmetry as they grow. However, unlike *Nephilengys cruentata*, even the instars that spin the first catching webs had the hub approximately two thirds of the way up the web. Both species seem to spin the hub at the top of the web when they reach a similar size. Webs with spirals above the hub are spun by juvenile *Nephila maculata* (Fabricius) (Robinson and Robinson, 1973, figs 5, 6), and possibly by *Nephila senegalensis* (Walckenaer) (Clausen, 1987). The webs of juvenile *Herennia ornatissima* (Robinson and Lubin, 1979) are also more like a complete orb.

The fact that the earliest webs of at least some species of Nephilinae are complete orbs indicates that the orb is a primitive characteristic in them, and that the incomplete orbs of the larger spiders are derived. There are other spiders which have a highly modified orb-web, but build a more complete orb as a juvenile. Spiders of the genus *Scoloderus* build extremely elongated inverted ladder webs, with the hub towards the base. The juveniles of *Scoloderus tuberculifer* O.P.-Cambridge have webs that are far less distorted (Eberhard, 1975). However, even the smallest *S. cordata* (Taczanowski) have elongated ladders (Stowe, 1978). In *Araneus atrihastulus* from New Zealand, which builds a web that is elongated both above and below the hub, some of the proportions of juvenile webs are less extreme (Forster and Forster, 1985). It would be interesting to find the very early webs of other spiders with atypical webs, such as that of the spider that built the ladder web observed by Robinson and

Robinson (1972) in New Guinea, now identified as close to *Tylorida* (Eberhard, 1990b). Other aspects of web construction and use may be more derived in adults than in juveniles, such as the angle of the spring line and resting position of the spider in *Epeirotypus* sp. from Costa Rica (Eberhard, 1986). However, in the west African *Pararaneus cyrtoscapus* (Pocock), the conical horizontal webs of juveniles are more derived than the planar vertical of adult females (Edmunds, 1978).

If it is confirmed that young *Nephilengys cruentata* build webs in one piece and destroy temporary spirals, then the adult behaviour of leaving the temporary spirals in place is presumably also a secondary modification. There are other characteristics of the webs of Nephilinae that are derived. Despite their size, the webs of adults have a finer mesh compared to some other orb weavers (personal observation). Eberhard (1982, 1990a) concludes that some characteristics of the web building behaviour of *Nephila clavipes*, such as the unique method of laying the sticky spiral, are an adaptation to spinning a tightly meshed web, even though other aspects (e.g. frame construction) are primitive. Levi (1986), Eberhard (1990a) and Coddington (1990) classify the Nephilinae with the Metinae and tetragnathids, rather than with *Araneus* and its relatives. The derived nature of the partial orb of the larger Nephilinae would be consistent with this classification.

ACKNOWLEDGEMENTS

I would like to thank Prof D.W. Ewer for the use of facilities while working at the University of Ghana, and Malcolm Edmunds for constructive comments.

DOES MIMICRY OF ANTS REDUCE PREDATION BY WASPS ON SALTICID SPIDERS?

MALCOLM EDMUNDS

Edmunds, M. 1993 11 11: Does mimicry of ants reduce predation by wasps on salticid spiders? *Memoirs of the Queensland Museum* **33**(2): 507-512. Brisbane. ISSN 0079-8835.

A common predator of spiders at Legon, Ghana, is the wasp *Pison xanthopus*, 96% of whose prey were salticids. The data from cells built by 31 wasps containing over 800 spiders are used to examine whether mimicry of ants gives protection against *Pison*. Comparison of salticids in wasp cells with those found on nearby vegetation shows that fewer ant mimics (*Myrmarachne* spp.) are taken than one would expect if wasps were capturing salticids in proportion to their occurrence, but also that some individual wasps specialize in capturing *Myrmarachne*. Implications for the searching image hypothesis are discussed. □*Batesian mimicry, ant-mimicry, Salticidae, predation, search image, Pison, Myrmarachne.*

Malcolm Edmunds, Department of Applied Biology, University of Central Lancashire, Preston PR1 2HE, United Kingdom; 12 November, 1992.

Ant mimicry has evolved in several spider families, e.g. Salticidae, Clubionidae, Thomisidae, Aphantochilidae and Theridiidae (Hingston, 1927; Mathew, 1954; Reiskind and Levi, 1967; Reiskind, 1977; Edmunds, 1974, 1978; Wanless, 1978; Oliveira and Sazima, 1984, 1985; Oliveira, 1988). Some of the most precise morphological and behavioural resemblances to ants occur in the salticid genus *Myrmarachne* which is widespread in both the Old and New Worlds, especially in the tropics (Wanless, 1978). At Legon, Ghana, three species of *Myrmarachne* are common, each one closely resembling one species of ant when it is full grown but a different ant species when it is immature (Edmunds, 1978). This mimicry could have two advantages for the spider:

1. It could deceive the ants and so enable the spider to creep up and prey on them. This is aggressive mimicry as may possibly occur in the thomisid *Amyciaea forticeps* (Mathew, 1954), and is well documented for the aphantochilid *Aphantochilus rogersi* (Oliveira and Sazima, 1984);

2. It could deceive a predator into mistaking it for an ant which that particular predator does not eat. This is batesian mimicry.

Myrmarachne do not normally attack ants, so there is no support for aggressive mimicry (Edmunds, 1978; Wanless, 1978). Indeed whenever an ant comes near they use their acute eyesight and quick reactions to avoid contact. This suggests a danger of being killed if caught by the ants (Edmunds, 1978; Wanless, 1978). Direct evidence supporting batesian mimicry is sparse. Edmunds (1974, 1978) argued that because few insectivorous birds prey on ants, the ant mimics associated with them would also escape predation. He further attempted to show that ant-mimicking spiders are less often taken by the wasp *Pison xanthopus* than are other salticids, but there were rather little data available at that time. More recently, the American ant mimic *Synageles occidentalis* was found being preyed on much less than are non-mimicking salticids by the philodromid *Tibellus oblongus*, and the large salticid *Phidippus clarus* ignored or avoided *Synageles* and ants in exactly the same way, while continuing to attack non-mimicking salticids (Cutler, 1991).

More data on the prey of *Pison xanthopus* are given here to test the theory that ant mimicry gives protection against spider-hunting wasps.

MATERIAL

Mud cells of *Pison xanthopus* were collected from window frames at the University of Ghana, Legon, Ghana between 1969 and 1973. Individual wasps build from 1-6 cells in a row. Each cell is stocked with 5-10 paralysed salticid spiders and an egg is laid on one of these. The spiders were preserved in alcohol and identified, usually to genus or species. They were also classed as either good ant mimics (*Myrmarachne*), poor ant mimics (*Cosmophasis* sp.) or non-mimics (other genera). Most of the spiders are now in the collection of the Natural History Museum, London. Identification of the spiders was confirmed by F.R. Wanless, and the wasp was determined by the late Professor O.W. Richards.

TABLE 1. Salticid spiders in five habitats at Legon, May-July 1973.

RATIONALE

If ant mimicry deceives wasps so that they do not capture ant-mimicking spiders as often as non-mimics, then the proportion of ant mimics to non-mimics should be lower in wasp cells than in the natural environment. If wasps are not deceived then the proportion of ant mimics should be the same. The test of this hypothesis is to compare the incidence of ant mimics in wasp cells with those found in the field.

WHERE DOES *PISON* HUNT?

First, the wasp's hunting range must be established so that a random sample of salticids can be collected from the same place. *Pison* is small, difficult to follow in flight, and was observed hunting on only a few occasions. Each time it was running and making short flights over leaves of shrubs. It was never observed on the ground or in grass, but as I spent more time examining shrubs than any other habitat, this is not conclusive. I therefore collected salticids from several different habitats at Legon. If the species of spider taken by wasps correspond with those found in one particular habitat then the wasps are probably hunting in that habitat.

The habitats are: leaf litter; short, regularly cut grass; long grass and herbage; 1-3m high shrubs; and tree trunks. The spectrum of spiders in wasp cells is most similar to those found in shrubs and trees (Table 1). The canopy was not sampled but probably has a similar fauna. However, it is unlikely that the wasps were hunting in short grass, leaf litter or long grass.

RESULTS

Spiders in Wasp Cells and on Shrubs

Some variation in the numbers of spiders caught by each wasp (Table 2) is due to the different numbers of cells completed by the wasps when collected. Cells with full grown larvae or pupae were ignored since the spiders in them were reduced to carapace cuticles, but cells with eggs or young larvae contained spiders that were intact and so are included. The spiders caught by each wasp came from 2-9 cells, e.g. on 3 Feb 1973, the first cell contained a pupa, the second a full grown larva, and the third had nine spiders but no egg. The wasp presumably was killed before fully provisioning this cell.

Of 872 spiders found, 837 were salticids (Table 2); 160 were 'good' ant mimics (i.e. *Myrmarachne* spp.), judged by the human eye, and a further 15 can be classed as poor (behavioural) ant mimics (i.e. *Cosmophasis* spp.). In 1973, every shrub in Zoology (twice) and in Botany (once) was searched (see Edmunds, 1978). All salticids found were scored as either a good mimic, a poor mimic or a non-mimic. The differences between types are highly significant ($\chi^2_{(2)} = 49.04$, $p < 0.001$; Fig. 1). *Pison* clearly take significantly fewer good ant mimics than they do poor mimics or non-mimics compared with their incidences in the environment.

However, wasps searching by running quickly over vegetation are unlikely to find spiders resting in their retreats beneath or between leaves. So perhaps the comparison should be made between the numbers of spiders in wasp cells and the numbers foraging on leaves (excluding those in retreats). These figures are also given in the upper part of Fig. 1 (the black bars only): 61.9% of spiders on shrubs were good mimics compared with 19.1% in wasp cells. This too is highly significant, again indicating that wasps take many fewer good mimics than poor or non-mimics ($\chi^2_{(2)} = 64.15$; $p < 0.001$). The proportion of poor

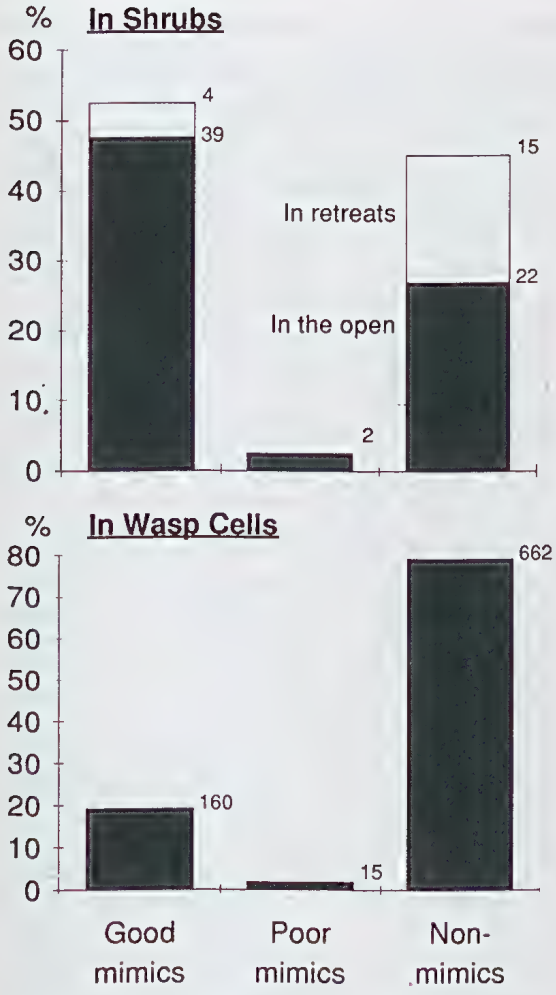

FIG. 1. Comparison of good, poor and non-ant mimicking salticids on shrubs and in cells of *Pison xanthopus*.

mimics taken by wasps is not significantly different from that of the non-mimics, so in the analysis that follows the poor (behavioural) mimic *Cosmophasis* is treated as a non-mimic.

Spatial or Seasonal Variation

These comparisons are of spiders on shrubs in February and May 1973 with spiders in wasp cells collected over 3.5 years. The relative numbers of *Myrmarachne* and of other salticids vary throughout the year and over different parts of the University campus, and this may account for the differences in proportions of spider prey taken by wasps. Evidence against this possibility is (1) that there was no significant difference in the relative numbers of *Myrmarachne* and of other salticids collected on shrubs in February and in May 1973 (Edmunds, 1978); (2) that the three wasp cells (taken 22 Jan- 3 Feb 1973) from close to where the shrubs were surveyed had between them eight *Myrmarachne* and 54 other salticids compared with 24 *Myrmarachne* and 26 other salticids on the shrubs on Feb 2; this difference is highly significant ($\chi^2_1 = 15.0$, $p < 0.001$); and (3) that the data (Table 2) show no clear evidence of spiders occurring at particular sites or in certain seasons. So, while there may be some variation in spider species at different times and places at Legon, such variation is unlikely to account for the very different numbers of salticids taken by wasps assuming that they take different species in proportion to their frequency in the population.

No Wasps Near Dangerous Ants

Most *Myrmarachne* taken by *Pison* were black and identified as *M. legon* and *M. elongata* (Wanless, 1978) but some immature specimens could not be identified. Only one specimen of the very common *M. foenisex*, in a total of 160 *Myrmarachne*, was taken. It was a juvenile whose body was red-brown and black (Edmunds, 1978, Fig. 1), quite unlike *Oecophylla*, but very similar to the smaller ant *Crematogaster castanea* which only lives close to *Oecophylla* (Edmunds, 1978). *M. foenisex* closely associates with the aggressive red weaver ant *Oecophylla longinoda*, of similar colour. Adult *M. foenisex* are probably too large for *Pison* to attack, but since it captures many young black *Myrmarachne* one might expect it to take young *M. foenisex* as well. Young *M. legon* are quite similar to young *M. foenisex*, but they do not associate with *Oecophylla* nor with *C. castanea*. Many young *M. legon* but very few *M. foenisex* were taken by *Pison*. Hence, *Pison* probably avoids hunting on plants overrun by *Oecophylla*.

If *Pison* does not hunt on plants with *Oecophylla*, then salticids found with these ants need to be omitted from the comparison of ant mimics and non-mimics on shrubs and in wasp cells (Table 3). Of salticids on shrubs, 49% are good ant mimics compared with 19% in wasp cells. This difference is highly significant, and remains so if spiders in retreats are excluded ($p < 0.001$).

Wasps clearly take fewer *Myrmarachne* than one would predict if they caught them in proportion to their occurrence in the environment. This is therefore good evidence for the defensive value of ant mimicry against predation by *Pison*.

TABLE 2. Spiders in cells of *Pison xanthopus* at Legon, Ghana, 1969-1973. Key to Places at University of Ghana, Legon: Faculty of Agriculture, Agric.; Depart. of Botany, Bot.; Institute of Statistical, Social and Economic Research, ISSER; 36 Legon Hill, Hill; Depart. of Mathematics, Maths; Depart. of Zoology, Zool. [1] - 17 Thomisidae, 6 Theridiidae, 5 Clubionidae, 2 Oxyopidae, 1 Araneidae, 1 Selenopidae, 1 Philodromidae. [2] - Oxyopidae. [3] - Gnaphosidae. Taxon head is abbreviated in order: My, *Myrmarachne* sp.; Co, *Cosmophasis* sp.; Ps, *Pseudicius* sp.; Rh, *Rhene* sp.; Te, *Telamonia* sp.; Me, *Menemerus* sp.; Vi, *Viciria* sp.; So, *Sonoita lightfooti;* Th, *Thyene* sp.; Sa, *Saitis* sp.; Mo, *Mogrus* sp.; Fi, Fissident sp.; Os, other Salticidae; Of, other spider families.

Do Individual Wasps Hunt Specific Prey?

All wasps do not take a similar spectrum of spiders, but each individual preys on one or two species of spider (Table 2). Thus the first wasp in the table preyed on *Rhene* sp., the second and third on *Pseudicius* sp. and the fourth on black species of *Myrmarachne*. Ant mimicry was obviously of defensive value against the first three wasps who between them took only eight *Myrmarachne* out of 73 spiders (11%), while it failed to protect them from the fourth wasp which took 34 *Myrmarachne* out of 46 prey (74%). Overall, 25 individual wasps took only 38 *Myrmarachne* out of 693 spiders (5.5%), indicating that they had been deceived by the mimicry. The other seven wasps took 122 *Myrmarachne* out of 179 spiders (68.2%) indicating that they had overcome the defence of mimicry to the extent that they preyed almost exclusively on ant mimics (a wasp on 6 July 1972 took 25 *Myrmarachne* and no other spiders, while in the other six wasps *Myrmarachne* taken were never less than 45%).

For the poor ant mimic, *Cosmophasis*, the 15 spiders taken by wasps (Table 2) represent 1.7% of all salticids taken, or 2.1% excluding *Myrmarachne*. This is less than their relative frequency on shrubs (2.4% of all spiders or 5.1% excluding *Myrmarachne*), but the differences are not significant. However, one wasp (on 5.2.72) caught 11 *Cosmophasis* while all other wasps very rarely took them. Therefore, even poor mimicry of ants appears to give some protection against most wasps, but occasionally a wasp will specialize on this species, just as other wasps do with *Myrmarachne*.

Hunting by the Searching Image Method

The term searching image was used to describe the way in which tits (Paridae) collect caterpillars for their young: each bird tends to bring insects

TABLE 3. Percentages of *Myrmarachne* (Myrm) and other salticids on shrubs at Legon, and in cells of *Pison xanthopus*. Figures in brackets are numbers and percentages found in open (i.e. not in retreats).

Source of spiders	N	Myrm	Others	$\chi^2_{(1)}$
Shrubs-all data	82 (63)	52.4 (61.9)	47.6(38.1)	
Wasp cells	837	19.1	80.9	46.3 (59.8)
Shrubs-omitting *M. foenisex* & all spiders with ants *Oecophylla* & *Crematogaster castanea*	53(41)	49.1 (58.5)	50.9 (41.5)	
Wasp cells	836	19.0	81.0	25.5 (34.6)

of predominantly a single species for several days and then to abruptly switch to another species (Tinbergen, 1960). Tinbergen hypothesized that the birds recognised caterpillars by particular characters which they 'assimilated in a kind of learning process' and that in their search for prey they looked for these particular characters. Later authors have used the words 'searching image' and 'search image' interchangeably, but its definition has been refined following Croze (1970), Dawkins (1971), Krebs (1973), Lawrence and Allen (1983) and Guilford and Dawkins (1987). It is now generally understood to mean a perceptual change in a predator that temporarily increases its ability to detect particular cryptic prey which it has recently encountered. Searching image needs to be distinguised from various other types of preference that predators may show for particular prey (Krebs, 1973; Lawrence and Allen, 1983), so it is probable that the behaviour observed by Tinbergen which he called hunting by means of a 'specific searching image' would today not be considered a proven example of searching image behaviour.

Individual *Pison xanthopus* clearly concentrate on one or a few species of prey; is this because it hunts using a searching image or by some other method? In a recent critique of the search image concept Guilford and Dawkins (1987, 1988a,b) argue that all studies purporting to demonstrate searching images can actually be explained better in terms of variation in search rate. They make two predictions which can distinguish between the two hypotheses. First, the search rate hypothesis predicts that mimetic prey should take longer to find than non-mimics, so wasps that have learned to find them will slow down their search rate. The searching image hypothesis makes no such prediction. Second, the searching image hypothesis predicts that because of perceptual specialization, wasps concentrating on one type of prey will ignore others. The search rate hypothesis makes no prediction about concentration on one prey interfering with finding other prey. These observations do not explicitly test either prediction, but I consider that *Pison* is not hunting by adjusting its search rate because different wasps concentrate on different prey implying that capture of several prey of one species interferes with capture of other species. The two wasps at ISSER on 5th and 6th of July 1972 took very different prey. If they had been hunting simply with different search rates then the first wasp should have taken some *Myrmarachne* while the second should have taken some *Pseudicius*. This total concentration on one species of prey is not easy to explain on the search rate hypothesis.

If *Pison* is not capturing prey by adjusting its search rate, there are at least three other hunting methods that might result in the concentration on particular species of prey shown in Table 2:-

1. Wasps might have some sort of preference for one prey rather than another. This is unlikely if the preference is based on taste because the wasps sting but do not eat the prey.

2. Wasps could be searching in different places:-

a. Individual wasps might search in different microhabitats. If each species of spider lives in a slightly different microhabitat on the shrubs then individual wasps could catch different species of spider. Evidence in favour of this is the wasp on 18 Mar 1972 which concentrated on thomisid and other non-salticid spiders. Because it initially caught some of these spiders it is reasonable to suppose that it learned to hunt in particular areas or in a particular way such that it continued to catch these spiders instead of salticids.

b. Wasps might search in one area before going on to another. If spiders are clumped instead of being randomly spaced, then individual wasps hunting in the same general area could capture different species of spider. I often found two or three spiders of one species on a shrub so the distribution is clumped rather than random. However, there is no exclusion of one species by another, and the clumping may simply be of recently mated pairs or of parents with young that have failed to disperse. This impression has not been quantified, but I consider it unlikely that it could explain the extreme specialization on one species (Table 2).

3. The wasps may have a perceptual searching image as implied by Croze (1970). Wasps of other genera can learn the configuration of landmarks near their burrows (see Tinbergen,

1958), and this presumably involves some perceptual memory not unlike that in ourselves when we search for something with a particular image in our mind.

It is unclear which of the above methods of prey capture or if another method (e.g., Krebs, 1973) is involved. But certainly some such behaviour occurs both in *Pison* and in other wasps, e.g. the sphecid *Chalybion fuscipenne* (J. Edmunds, 1990).

CONCLUSIONS

Clearly, ant-mimicking spiders are common, more so than non-mimics in some habitats. Ant mimicry may give protection against wasps such as *Sceliphron* which prey on spiders of various families (Edmunds, 1974; J. Edmunds, 1990). The results confirm the suggestion from a preliminary, less rigorous study (Edmunds, 1974), that ant mimicry is of protective value against the specialist predator *Pison xanthopus*. The evidence that behavioural ant mimicry protects *Cosmophasis* against *Pison* is not conclusive; it may be protective against other wasps or against birds. Wanless (1978) and Curtis (1988) have evidence that spiders of this genus prey on ants, so this mimicry could also be aggressive rather than defensive in function.

ACKNOWLEDGEMENTS

I am grateful to Fred Wanless for help with identification of the salticids, Paul Hillyard for identifying the other spiders, and Janet Edmunds for critically reading the paper.

ABUNDANCE AND STRUCTURE OF FOSSORIAL SPIDER POPULATIONS

PETER G. FAIRWEATHER

Fairweather, P.G. 1993 11 11: Abundance and structure of fossorial spider populations. *Memoirs of the Queensland Museum* **33**(2): 513-518. Brisbane. ISSN 0079-8835.

Preliminary findings from an ecological study of large fossorial spiders, especially mygalomorphs, made in two locations in eastern New South Wales are given. The abundance of burrowing spiders was assessed in eight habitats: dry sclerophyll forests on sandstone and shale substrata, wet sclerophyll forests on sandstone, pastures, suburban gardens, pine windbreaks along roadside verges, coastal cliffs, and coastal swamps. The spiders included several species of Lycosidae, two Idiopidae and one Hexathelidae. Each species was restricted in its range of habitats and dominated the burrowing spider assemblage in only one or two habitats. The population structure of burrow sizes is described and compared for dense populations.□*Araneae, Idiopidae, Hexathelidae, Lycosidae, ecology, burrowing, sampling, distributions, habitats, size frequencies.*

Peter G. Fairweather, Graduate School of the Environment, Macquarie University, New South Wales, 2109 Australia; 5 November, 1992.

The field ecology of burrowing spiders in Australia has rarely used quantitative methods (but see Humphreys, 1988). Nor were field experimental manipulations used to test specific hypotheses, as in other branches of ecology (Underwood, 1990). These first quantitative observations of the abundance, size structure and habitat associations of large burrowing spiders from two locations near Sydney are part of environmental studies of funnelweb and trapdoor spiders.

The abundance, distribution and ecological interactions of fossorial spiders have been studied overseas in detail (see e.g. Buchli, 1969; Laing, 1978; McQueen, 1983; Conley, 1985; Fernandez-Montraveta *et al.*, 1991; Miller & Miller, 1991). The general biology, systematics and evolution of Australian mygalomorph spiders have been studied (see Main, 1976; Raven, 1988). The few quantitative ecological studies from Australia focussed on arid habitats (e.g. Main, 1987; Kotzman, 1990), upland sites (e.g. Humphreys, 1976), or used pitfall trapping (e.g. Curry *et al.*, 1985). In contrast, this study was on the warm temperate coast of eastern Australia.

METHODS

Study Sites and Habitat Types

Two locations near Sydney, New South Wales, and situated on Hawkesbury sandstone substratum, were sampled. Galston (33°41'S, 150°21'E) is a semi-rural village that has become suburban since 1972 and retains pockets of bush. Study habitats were located at 170-210m altitude. Patonga (33°30'S, 151°15'E) is a coastal village on the Hawkesbury River estuary and surrounded by Brisbane Waters National Park (Benson & Fallding, 1981). Study habitats were located at 5-80m altitude. At each location, all sites were within 2km of each other. I sampled six habitats in each location, although only three were present in both locations (Table 1).

Sampling and Analysis of Data

The sampling, October 1991-March 1992, was non-destructive. Quadrats (0.25 m^2) were randomly placed and then searched for individual spiders, burrows and trapdoors. All rocks, logs and litter in each quadrat were overturned and searched. I counted spiders, burrows or webs of each species in each quadrat. I sampled 10 quadrats in each of two sites in each habitat at each location (n=240 quadrats in all). The paired sites were replicate patches of habitat at the same elevation, as similar as possible, at least 100m apart and 100-1000m^2 in area. Site boundaries were located randomly on habitat maps before sampling. Spatial variability in each habitat was assessed by comparing spider densities in each pair of sites.

This design allowed a three-factor hierarchical ANOVA to examine the partitioning of spider abundance (as density=no. per quadrat) among the fully nested factors of Location, Habitat within Locations and Site within Habitat (Sokal and Rohlf, 1981). ANOVAs were done after assumptions were checked using Cochran's test for heterogeneity of variances. Means and standard errors of spider densities were calculated for each habitat and site. All statistical and graphical analyses were performed with SYSTAT Version 5 software (Wilkinson, 1990).

Location	Habitat type	Trees	Shrubs	Ground layer	Litter	Common spider	Less common spiders

KEY TO HABITATS

DSF: characteristic open woodland (Benson & Fallding 1981; Benson & Howell 1990) in exposed positions on Hawkesbury sandstone plateaux, dominated by *Angophora costata*, *Eucalyptus haemastoma*, *E. gummifera* and *E. sparsiflora*; understorey of sclerophyllous shrubs of Fabaceae, Proteaceae and Myrtaceae; litter layer dense but dry; sandy soil; many ant nests and sandstone outcrops.

WSF: in moist gullies and other sheltered locations; many of the same tree species in the canopy, also *E. piperita* and *E. eximia*; compared with DSF; shrubs and creepers more mesophyllic and denser, with pockets of smaller trees–*Pittosporum undulatum*, *Tristaniopsis laurina* and *Ceratopetalum apetalum*; litter layer dense, moist, compacted; ant nests fewer; soil with more humus but about the same amount of rocky outcrops.

GL: cultivated exotic grasses regularly mown to <4 cm high, and probably also treated with fertilisers, herbicides and pesticides; little bare ground and almost no litter.

PRV: pine trees (*Pinus radiata*) along road verges, rarely mown and graded; deep litter of pine needles; soil with humus-rich, dry layer above hard clay-loam; understorey some *Acacia* and *Pittosporum* shrubs, & grasses.

STF: open forest in Fagan Park on ridgetop Wianamatta shale (Benson & Howell 1990), dominated by turpentine, *Syncarpia glomulifera*; other trees included *E. punctata*, *E. paniculata*, *E. acmenioides*, *E. resinifera*, *E. globoidea* and *A. floribunda*; shrub layer mainly of young trees; ground cover of grasses, logs and sparse litter.

SS: estuarine swamp dominated by she-oaks, *Casuarina glauca*; ground layer of *Juncus kraussi*, she-oak needles and saltmarsh succulents; lowest areas inundated by highest tides, but areas around sandstone outcrops higher and drier. Bushfire burnt this habitat and dry sclerophyll forest early 1991.

SC: sea cliffs immediately above rock platforms in the estuary; vertical walls of loamy soil covered with sparse leaf litter, mosses; some creepers and grasses common around roots of trees and shrubs on cliff edge. The least extensive habitat in area; 10 m or less high along seashore.

At Galston, the last habitat was pasture grazed by horse and cattle. Grass height, 6-40 cm; grasses probably fertilised infrequently; patches of bare soil rare.

At Patonga, a lawn and bare ground area around a sporting ground was the last habitat, very similar to the pasture at Galston except grass mown regularly to <4 cm high.

TABLE 1. Habitat characteristics, with spiders and occurrence of rocks, logs or tree roots. Common spiders = density > 1 per m^2. Abbreviations used in text are also given for each habitat.

Species were identified by burrow characteristics and observations of spiders seen at the burrow entrances either at night or during late afternoons on overcast days. Initially, I excavated at least 30 burrows of each type to obtain specimens for more thorough identification, and to investigate burrow structures and food remains. I measured maximum diameter of all burrows in quadrats (and outside them at some sites to increase sample sizes to >30). I tested for differences among size frequency distributions of burrow diameters using Kolmogorov-Smirnov (KS) 2-sample tests.

Sampling was repeated in late summer (Feb.-March) in some habitats to assess temporal variation between, before, and after the breeding season (roughly mid-sampling). In particular, abandoned burrows (with signs of decay and unoccupied) were noted. Burrows under rocks and logs were counted in some habitats because funnelwebs seemed restricted to such locations (e.g. short burrows in unconsolidated soils).

RESULTS

Spider Species

Six species in three families are here grouped into four ecological types. *Misgolas gracilis*

(Rainbow & Pulleine, 1918) is a large idiopid that builds deep, oblique burrows with a trapdoor among leaf litter in friable soils. The lids varied from flimsy and merely silk-covered with a thin layer of dirt to quite robust plugs for older spiders; this may be related also to the amount of litter present. In moist areas, the lid often grew moss and liverworts. *M. gracilis* was found only in SC and PRV habitats (Table 1).

Misgolas rapax Karsch, 1878 is also large with a burrow like *M. gracilis* but without a trapdoor. Often litter and vegetation around the burrow entrance were incorporated into the flared opening. Their burrows were more vertical than those of *M. gracilis*. The idiopids were identified using Main (1985), Mascord (1970, 1980). *M. rapax* was found in eight habitats but abundantly only in SS (Table 1).

Atrax robustus Cambridge, 1877 is the Sydney funnelweb spider (Hexathelidae). Several similar species are known from areas near the study locations, but all spiders collected were identified as *A. robustus* using Gray (1988), Scott (1980), Main (1985), Mascord (1970, 1980) (some smaller spiders were minimally confamilial). Most spiders were found under rocks and logs where characteristic silk tubes led to shallow burrows made in mostly unconsolidated soils and humus. Thus, all spiders were examined in the field but collections were limited to avoid depletion of the populations and for safety. *Atrax* was found in only two habitats but was a dominant in both (Table 1).

Wolf spiders (Lycosidae) built narrow, vertical burrows without lids and with much flimsier silk linings than did *M. rapax*. They were identified using McKay (1985) and references therein. The species excavated were *Lycosa godeffroyi* L. Koch, 1865, *L. leuckartii* (Thorell, 1870) and *Pardosa serrata* (L. Koch, 1877), the latter with characteristic palisades around the burrow. Other species but not excavated include *L. furcillata* L. Koch, 1867, *L. pictiventris* L. Koch, 1877, and *L. palabunda* L. Koch, 1877. Due to this uncertainty over the exact identity of the occupants of some burrows, I lumped data on all lycosid burrows into 'wolf spiders'. I found these in nine habitats but most commonly in WSF (at Patonga only) and PRV (Table 1).

Abundances

No spiders or burrows were found in quadrats sampled in the pastures or sports ground (Table 1, Fig. 1), although lycosids had been seen there. Neither habitat will be discussed further. Very

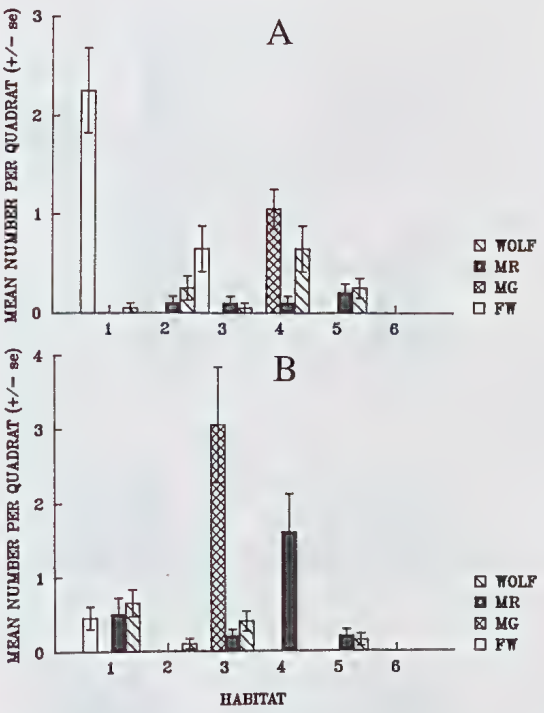

FIG. 1. Abundance (no. per 0.25m^2) of each species group versus habitat. A. at Galston, habitats are: 1=WSF, 2=DSF, 3=STF, 4=PRV, 5=GL, 6=pasture; B. at Patonga, habitats are: 1=WSF, 2=DSF, 3=SC, 4=SS, 5=GL, 6=sport ground. MR=*M. rapax*, MG=*M. gracilis*, FW= *Atrax* and WOLF=lycosids. Means and standard errors calculated from n = 20 quadrats in each habitat (i.e. sites were pooled).

sparse populations (of only lycosids and *M. rapax*) were found in open habitats–DSF and GL.

The abundance in the five occupied habitats at each location showed differences between habitats and species groups. An ANOVA of total spider density among locations/habitats/ sites (Table 2) showed no significant difference between the locations but large differences among the habitats within locations. At Galston, highest spider densities were found in PRV and WSF habitats, fewer in STF and very few in GL and DSF habitats. At Patonga, SC had the greatest densities, followed by WSF and SS habitats, and very few in the GL and DSF habitats.

Habitats with dense spider populations in either location were dominated by a particular species. At Galston, *Atrax* was the most common spider in the WSF and STF habitats but was not found in other habitats. At Patonga, *Atrax* was found only in the WSF habitat. *M. rapax* occurred in four habitats at Patonga and Galston, but

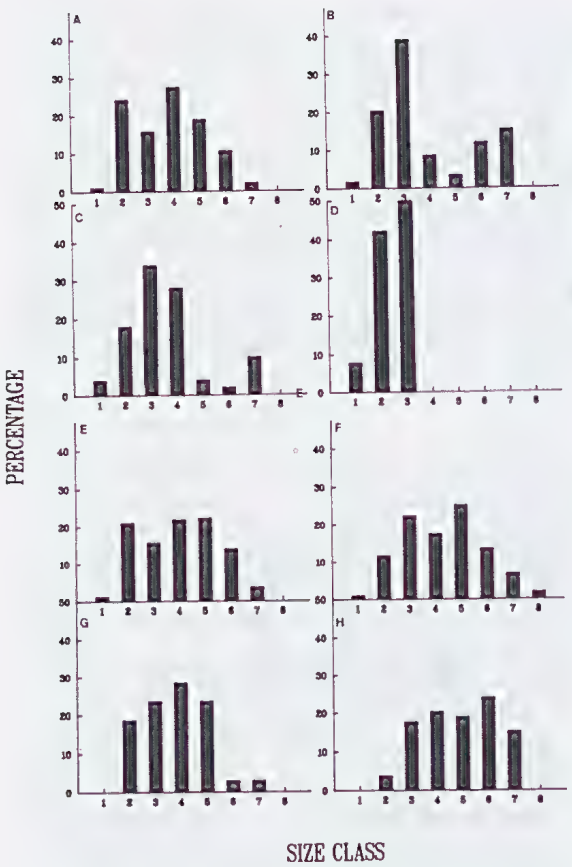

FIG. 2. Representative size frequency distributions of burrow diameter for dense populations of each species. Diameters grouped into eight equal size classes (to show large range with reasonable numbers in each): 1 =0-4.9mm; 2 =5-9.9; 3 =10-14.9; 4 =15-19.9; 5 = 20-24.9; 6 = 25-29.9; 7 = 30-34.9; and 8 ⩾ 35mm across the burrow entrance. A) *Atrax* from WSF, Galston, $n = 95$; B) *Atrax* from STF, Galston, $n = 59$; C) *Atrax* from WSF, Patonga, $n = 50$; D) lycosids from PRV, Galston, $n = 38$; E) *M. gracilis* from SC, Patonga, $n = 189$; F) *M. gracilis* from PRV, Galston, $n = 83$; G) *M. rapax* from SS, Patonga, $n = 102$; H) *M. rapax* from GL, Galston, $n = 79$.

dominated only in the SS habitat. *M. gracilis*, in contrast, was found in only one habitat in each location, but dominated the spider assemblage in both. In the SC habitat at Patonga, this species had the greatest mean density found in this sampling (>12 m^{-2}). Lycosids were found in five habitats at Galston and four at Patonga but they were never dominant. No species group was either positively or negatively correlated with any other in these samples (for all r, $P > 0.05$, $n = 200$).

The patchiness of mean spider abundance in any habitat was examined by the Sites within Habitat factor in the nested ANOVA (see Sokal and Rohlf, 1981). For total spider density and *M. rapax* alone, the two sites sampled within each habitat differed significantly (Table 2) . Because the sites were chosen randomly from the total habitat, this result indicates medium-scale variability in abundance of total spiders and *M. rapax* (i.e. at scales of about 100m).

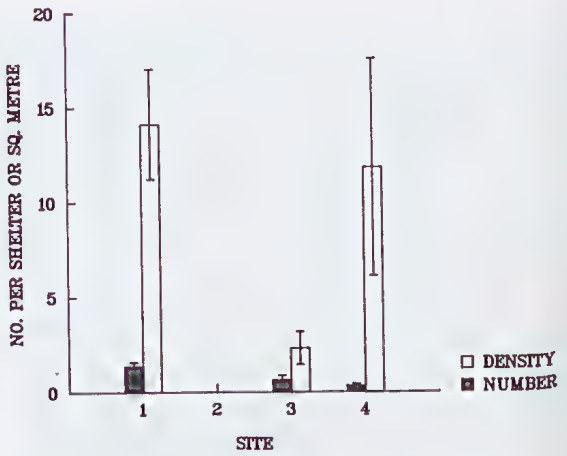

FIG. 3. Abundance of *Atrax* under rocks and logs in some habitats, expressed as no. per rock or log, and density (no. per m^2 of rock or log microhabitat). Area of each rock and log estimated from product of two, perpendicular linear dimensions in contact with the ground. Sites (sample sizes) were: 1=WSF at Galston (n = 43 rocks); 2=DSF at Galston (n=27 rocks); 3=STF at Galston (n =20 logs); and 4=WSF at Patonga (n=18 rocks).

Size Frequencies

Sample sizes of burrow diameter of sufficient number could be obtained only in habitats with dense populations. The burrow size structure (Fig. 2) of these populations showed differences (by KS tests) among species that were consistent across habitats. Very small burrows (< 5mm) were not found for *M. rapax* and only commonly for lycosids. *Atrax* showed bimodality in two habitats with the modes occurring at sizes corresponding to pre-reproductive juveniles and mature females (Fairweather, unpublished data). The other species had more unimodal burrow diameter frequency distributions. Lycosid burrows were much narrower on average than the mygalomorphs (Fig. 2). *M. gracilis* had the largest burrows overall.

Temporal Variation

Sampling before and after the breeding season showed few changes. The proportion of burrows of *M. gracilis* in the PRV habitat (Galston) that

were abandoned and decaying increased from 4.6% (n= 64) in December to 9.6% (n = 60) in March. These abandoned burrows did not, however, differ in size from the occupied ones (P> 0.05 by KS tests), suggesting no size selectivity in either mortality or abandonment by breeding males. The proportion of *Atrax* that were juvenile (i.e. <15mm and with no enlarged pedipalps on males) increased from November to February from 12% (n = 67) to 44% (n = 84) across all three occupied habitats.

Microhabitats

Within each habitat, burrows were found more frequently in particular situations. For example, *M. rapax* in the SS habitat (Patonga) were only found in areas around rock outcrops and none in the lower, inundated part of the swamp. *M. gracilis* was most abundant in moist, mossy patches in SC habitat (Patonga) and in areas covered with litter rather than bare ground in the PRV habitat (Galston). All *Atrax* webs encountered were seen under or against either rocks or logs, although thorough searches were also made amongst litter and in grass clumps. This prompted sampling centred on rocks or logs in three habitats at Galston and one at Patonga (Fig. 3). The abundance of *Atrax* under rocks and logs differed with habitats. None were found in DSF, despite abundant rocks. Counts of webs per rock or log were similar in the three occupied habitats. When expressed on a per area basis (i.e. m^2 of rock or log), the densities were much greater and differed among these habitats (Fig. 3).

DISCUSSION

This study suggests several hypotheses.

1. These species rarely encounter each other in nature, suggesting little competition occurs among them. I located each species group in more than one habitat, but they tended to dominate different ones. *Atrax* were favoured by apparently more moist conditions under shelter; although exfoliated rocks were abundant in the drier DSF habitat, no *Atrax* were found beneath them. *M. gracilis* was found in relatively exposed positions (sea cliff and road verge) with the most compact soil, whereas *M. rapax* dominated more open habitats (in terms of the litter and ground layers). Lycosids were the most widespread group, which may reflect that data of several species were lumped. Characterisation of habitats regarding soil, litter and vegetation conditions is needed.

2. Specific habitat characteristics favour different species. As well as the above habitat segregation, microhabitat preferences were also shown by several groups, most strikingly for *Atrax*, which was found in moist areas under shelter. Predictive relationships of abundance with environmental variables (e.g. soil nutrients, organic matter, compaction and moisture; litter amount, moisture and temperature; size and depth of shelter) may be established. Experiments on the effects of shelter, litter and moisture conditions on the abundance of these spiders are needed.

Factor	df	*F*-ratios

Location	1	0.19	1.21	0.38	1.93	0.003
Habitat	8	3.34*	73.43*	8.93	0.88	13.6*
Site	10	33.25	0.25	1.88	9.54*	0.31

TABLE 2. Three-factor, hierarchical ANOVA of density (number per quadrat) of total spiders and each species group analysed separately. * =Significance at P <0.05 level; df, degrees of freedom; df for residual, 180, and for total, 199. Total N=200 0.25 m2 quadrats; only five habitats used here.

3. Fossorial spiders respond adversely to many human impacts on their environments. This has implications for the interaction of these spiders with people and their activities. Few or no fossorial spiders were resident in habitats that lacked a litter layer or were regularly mown, watered, treated with chemicals or graded. The spiders can burrow in such open habitats (Fairweather pers. obs.), so perhaps the conditions may not be attractive to prey. There is some longer term evidence of declines in two of these populations associated with increasing urbanisation, direct disturbance, bushfire and vegetative change (Fairweather unpub. data).

4. Dense populations have been established for several years, at least. Size frequency distributions of burrows revealed juveniles in each dense population, therefore recruitment had occurred and no population was relict. Several very large burrows were present in the populations of the three mygalomorphs, probably indicating matriarchs (*sensu* Main, 1987). The abundance and size structure did not alter from October to March, which implies short-term stability for these long-lived spiders. Behaviour consistent with breeding behaviour over summer was seen for the mygalomorphs. Lycosids with egg sacs were seen only in spring and autumn.

5. Predation by some populations may strongly influence the assemblages of their prey. M. gracilis and *Atrax* were quite dense in particular

microhabitats, with some very large spiders; this and their predatory habits suggest that their role as predators in the ground-layer ecosystem would be worth further study.

In conclusion, large fossorial spiders are not evenly distributed across a variety of habitats, and each habitat is dominated in numerical terms by one or few species. Although the study was done in two contrasting locations, the generality of these results awaits scrutiny with further data as does the cause of any of the patterns described for the first time here.

ACKNOWLEDGEMENTS

This study was supported by a Macquarie University Research Grant and benefited from the assistance of N. Babicka. G. Napier commented upon a draft of the manuscript and two anonymous referees improved its clarity.

BIOGEOGRAPHIC PATTERN OF PHYLOGENY IN A CLADE OF ENDEMIC HAWAIIAN SPIDERS (ARANEAE, TETRAGNATHIDAE)

ROSEMARY G. GILLESPIE

Gillespie, R.G. 1993 11 11: Biogeographic pattern of phylogeny in a clade of endemic Hawaiian spiders (Araneae, Tetragnathidae). *Memoirs of the Queensland Museum* 33(2): 519-526. Brisbane. ISSN 0079-8835.

The biota of the Hawaiian archipelago offers an ideal system with which to study the dynamics behind the evolutionary process, both because the islands harbour many speciose lineages, and because they are arranged within a chronological time frame. Over the past 5 years I have begun to uncover an unexplored radiation of one of Hawaii's most abundant and conspicuous invertebrate groups: the spider genus *Tetragnatha*. The current study focuses on a small clade within the lineage, in which all the component species have abandoned web-building, instead foraging as cursorial predators. I examine 2 primary questions: 1. What has been the relative importance of strict geographic isolation (populations on different volcanoes) versus divergence between contiguous habitats (populations on the same volcano) in the evolution of this clade? 2. Does the phylogeny indicate a pattern of ecological and distributional change which could suggest that ecological rather than sexual shifts may underlie species formation? I generated a phylogeny based on morphological characters, and compared this phylogeny to the biogeographic pattern of the Hawaiian Islands. The results suggest that, for this clade of cursorial species, speciation requires strict geographic isolation, and ecological (more than sexual) shifts appear to play a role in initiating divergence. Considering the islands as a series of evolutionary snapshots, I would also speculate that speciation is commencing on the youngest island (Hawaii), and developing on the adjacent older island of Maui. □*Tetragnatha, phylogeny, Hawaii, speciation, allopatry.*

Rosemary G. Gillespie, Hawaiian Evolutionary Biology Program, University of Hawaii at Manoa, Honolulu, Hawaii 96822, U.S.A.; *28 October, 1992.*

Species represent one of the basic units of evolution, yet the processes by which they are formed remain poorly understood (Mayr, 1963). Studies of the Hawaiian biota have lent considerable insight into the mechanisms underlying speciation. These studies are highlighted by the Hawaiian *Drosophila*, in which sexual selection through female choice appears to play an integral role in inducing species formation among small populations colonizing geographically isolated islands (Carson, 1968; Carson and Kaneshiro, 1976; Kaneshiro, 1988). One may ask whether it is possible to generalize from these studies that adjustments in the sexual environment are largely responsible for driving species radiations. Other studies outside the Hawaiian Islands have found that ecological changes in isolation are more important in driving species proliferation (Mayr, 1963; Grant, 1986). When a species is released from interaction with related species, by whatever means, it may broaden its habitat use and exhibit much more variation among individuals (Lack, 1971; McCune, 1990). The argument is that if such a reproductively isolated incipient species were reunited with its parent, selection could act on the ecological variability to minimize the resources jointly used by both species, leading to further ecological divergence (Mayr, 1963; Grant, 1986).

The Hawaiian archipelago (Fig. 1) provides a natural laboratory for studies of speciation (Simon, 1987). First, the extreme isolation of the islands has allowed repeated and explosive diversification of species in a large number of lineages including honeycreepers (Berger, 1981; Freed et al., 1987), land snails (Cooke *et al.*, 1960), crickets (Otte, 1989) and drosophilid flies (Kaneshiro and Boake, 1987). Further, the islands are a series of volcanoes arranged within an identifiable chronological time frame; the currently high islands range from Kauai, the oldest and most eroded, to Hawaii, the youngest, highest and largest, with 5 separate volcanoes.

This study uses a lineage of spiders to examine speciation patterns within the context of the Hawaiian archipelago. The spiders belong to the long-jawed orb-weaving genus *Tetragnatha*, which comprises a large number of endemic species in the Hawaiian Islands (Gillespie, 1991, 1992). Outside the archipelago, *Tetragnatha* are among the most widespread and conspicuous spiders worldwide, yet collectively they are also

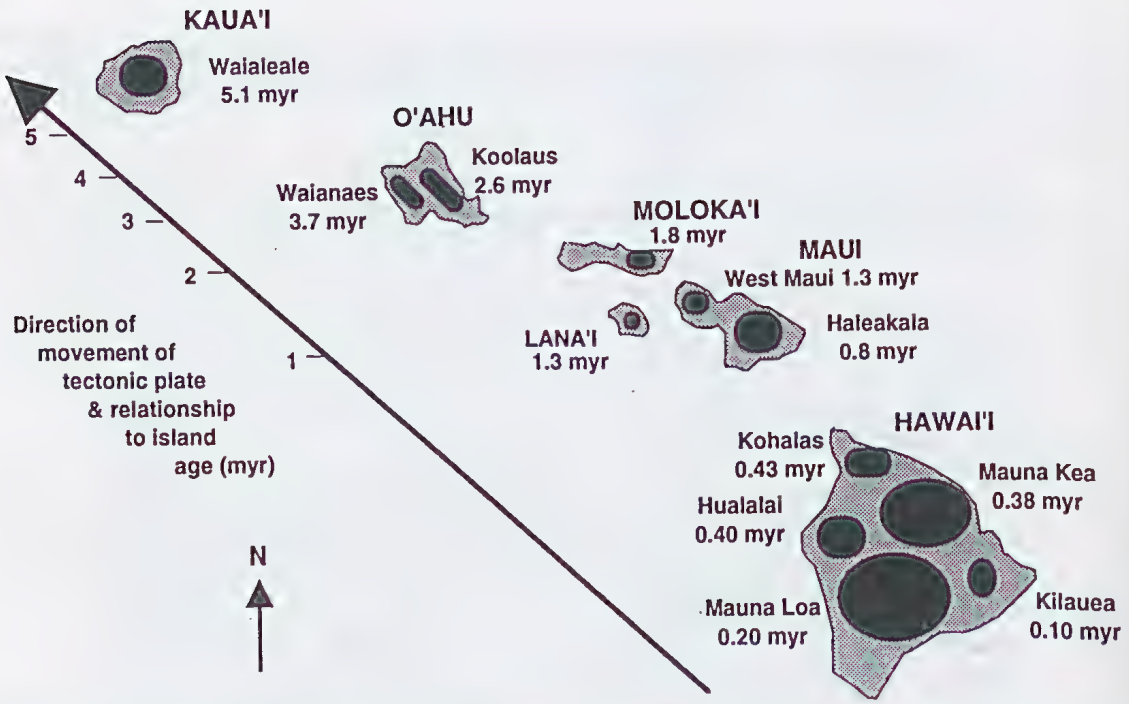

FIG. 1. Major land masses of the Hawaiian archipelago, indicating approximate age, and direction of movement of tectonic plate.

one of the most homogeneous, both in morphology (elongate bodies and long legs) and ecology (orb web generally built over or near water) (Wiehle, 1963; Levi, 1981; Gillespie, 1986, 1987). Hawaiian species of *Tetragnatha* represent a paradox, exhibiting considerable morphological and ecological diversity. Until 1992, the sole reference to endemic Hawaiian representatives of the genus was based on descriptions of a single species by Karsch (1880) and 8 species by Simon (1900, redescribed by Okuma, 1988). I have now described an additional 16 species (Gillespie, 1991, 1992), and have collected more than 60 new taxa that span a broad spectrum of colours, shapes, sizes, ecological affinities, and behaviours. In terms of courtship behaviour, however, Hawaiian representatives of the genus display the simple cheliceral locking mechanism characteristic of the genus (Levi, 1981; Gillespie, pers. obs.).

Here I examine a small clade (the 'spiny-leg' clade) within the radiation of Hawaiian *Tetragnatha*. Representatives of this clade are characterized by a cursorial habit, and do not build webs (Gillespie, 1991). Further, in common with other representatives of the genus (Levi, 1981), but in striking contrast to the *Drosophila* radiation, these spiders display minimal courtship behaviour. Because explanations for species formation in the Hawaiian *Drosophila* rely heavily on the elaborate courtship behaviour of the group, the absence of such behaviour in the Hawaiian *Tetragnatha* suggests that alternative explanations might be required to account for species proliferation. The questions I address in this study are: 1. What has been the relative importance of strict geographic isolation (taxa diverge on different volcanoes) versus divergence between contiguous habitats (taxa diverge on the same volcano) in the evolution of the spiny-leg clade of Hawaiian *Tetragnatha*? I generated a phylogeny for the clade based on morphological characters, and then compared the phylogeny to the biogeographic pattern and history of the islands. 2. Does the phylogeny indicate a pattern of ecological and distributional change which could suggest that ecological rather than sexual shifts may underlie species formation?

METHODS

Collection and Ecological Measurements

Spiders were collected by visual night searching at various times of the year between 1987 and 1991 in wet, mesic and dry native forest in all of the currently high Hawaiian Islands (Kauai,

Oahu, Molokai, Lanai, Maui and Hawaii; Fig. 1). Habitats from which spiders were taken were scored as wet (>450cm average annual rainfall), mesic (250-450cm) or dry (<250 cm). Elevation was categorized as low (<1000 m), medium-low (1000-1700m), medium-high (1700-2000m) and high (>2000m). Microhabitat associations were determined by categorizing the specific site from which an individual was collected (roots, fern fronds, against bark, etc.) (Gillespie, 1987).

Phylogenetic Analysis

I used a cladistic approach (Hennig, 1966) based on morphological characters to determine relationships among the spiny-leg clade of Hawaiian *Tetragnatha*. I scored a total of 30 characters relating to cheliceral armature (upper and lower tooth rows), leg spination, and colour of the cephalothorax and abdomen (Table 1). In addition, I scored characters from the detailed structure of the male palp using a Hitachi S-800 scanning electron microscope. I used a Hawaiian web-building species of *Tetragnatha*, *T. stelarobusta* Gillespie as an outgroup in the analysis because molecular data indicate that this species belongs to a closely related sister clade of the spiny-leg species (H.B. Croom, pers. comm.).

Characters were analyzed as unordered states (i.e., any character state permitted to transform directly into any other state) using Fitch (Fitch, 1971) and Wagner (Farris, 1970) parsimony in PAUP (Swofford, 1990) under the accelerated transformation method of optimization. Character states were polarized as primitive or derived by outgroup comparison (Maddison *et al.*, 1984), and characters were scaled for equal character weighting regardless of the number of states. A branch-and-bound search was conducted to find the shortest tree. The data were then reanalyzed by successive approximations, weighting characters according to their rescaled consistency index (Farris, 1969, 1989).

Relationship between Species Phylogeny and Island Biogeography

To test the importance of strict geographic isolation in initiating divergence, and the extent to which regular ecological and distributional changes have accompanied species formation, I compared the resulting phylogeny to the biogeographic locations of the component taxa within the Hawaiian archipelago.

RESULTS

Collection and Ecological Measurements

Representatives of the spiny-leg clade of Hawaiian *Tetragnatha* occur on each of the high islands. All are restricted to wet forest except for *T. brevignatha* Gillespie, *T. restricta* Simon and *T. quasimodo* Gillespie, which occur in wet, mesic, and sometimes dry, forest. The ranges over which the different species were found is listed in table 2. Microhabitat associations were loose, although the bright green species (*T. tantalus* Gillespie, *T. polychromata* Gillespie, *T. brevignatha*, *T. macracantha* Gillespie, *T. waikamoi* Gillespie and *T. kauaiensis*) were collected almost entirely from leaves, whereas the darker coloured *T. kamakou* Gillespie, *T. perreirai* Gillespie, *T. pilosa* Gillespie, *T. quasimodo* and *T. restricta* were collected from brown or red-brown substrates.

Phylogenetic Analysis

When characters were scaled for equal weighting regardless of number of states and unordered, a total of 7 most parsimonious trees were generated (consistency index 0.517, retention index 0.509). Subsequent weighting by successive approximations had little effect on the tree topology, and gave a single tree of unweighted length 76 (consistency index 0.725, retention index 0.765). Fig. 2 shows the tree with explanations of the characters defining each node. The characters defining species are marked as bars.

Relationship between Species Phylogeny and Island Biogeography

As can be seen from this phylogeny based on morphological characters (Fig. 2), the most closely related species are never found on the same island. The only regular pattern of ecological and distributional change through the Hawaiian Islands is the broadening habitat usage on the younger islands. In particular, taxa on the oldest islands (Kauai and Oahu) are all endemic to single volcanoes, while on the youngest island, Hawaii, there are no species endemic to the island, despite its much larger size (5 volcanoes). In addition, taxa on the youngest island occupy a much broader range of habitat types: *T. brevignatha*, for example, is found at all elevations and in dry, mesic and wet forest on Hawaii Island, whereas representatives of this species on East Maui occur only in mesic forest at middle elevations. Distributions of representatives of the clade on East Maui show some anomalies. In particular,

TABLE 1. Characters used for generating phylogeny. stel = *T. stelarobusta*; kau = *T. kauaiensis*; pil = *T. pilosa*; mac = *T. macracantha*; pol = *T. polychromata*; tant = *T. tantalus*; wak = *T. waikamoi*; brev = *T. brevignatha*; perr = *T. perreirai*; kam = *T. kamakou*; rest = *T. restricta*; quas = *T. quasimodo.*

there are three bright green species, one endemic to this volcano (*T. macracantha*), one shared with West Maui (*T. waikamoi*) and *T. brevignatha* shared with Hawaii Island. The East Maui species exhibit parapatric ranges, with only very narrow zones of overlap, and are more closely related to species on other islands rather than to each other.

DISCUSSION

Differentiation between species of the spiny-leg clade of Hawaiian *Tetragnatha* appears never to have occurred on the same mountain mass: in no situation are two sister species found on the same volcano, or even on the same island. This phylogeny based on morphological characters therefore strongly suggests that strict geographic isolation (between islands only) is necessary for the initiation of species formation. Such isolation appears also to underlie speciation events in the Hawaiian *Drosophila* (Carson and Templeton, 1984). The phylogeny of the Hawaiian spiny-leg *Tetragnatha* also indicates that species colonize in a generally southerly direction, with the most ancestral taxa occupying the oldest island, Kauai. In addition, colonization of the most recent island (Hawaii) may be associated with ecological release: populations of each of the three species that have colonized Hawaii Island, *T. quasimodo*, *T. restricta* and *T. brevignatha*, occupy a broad

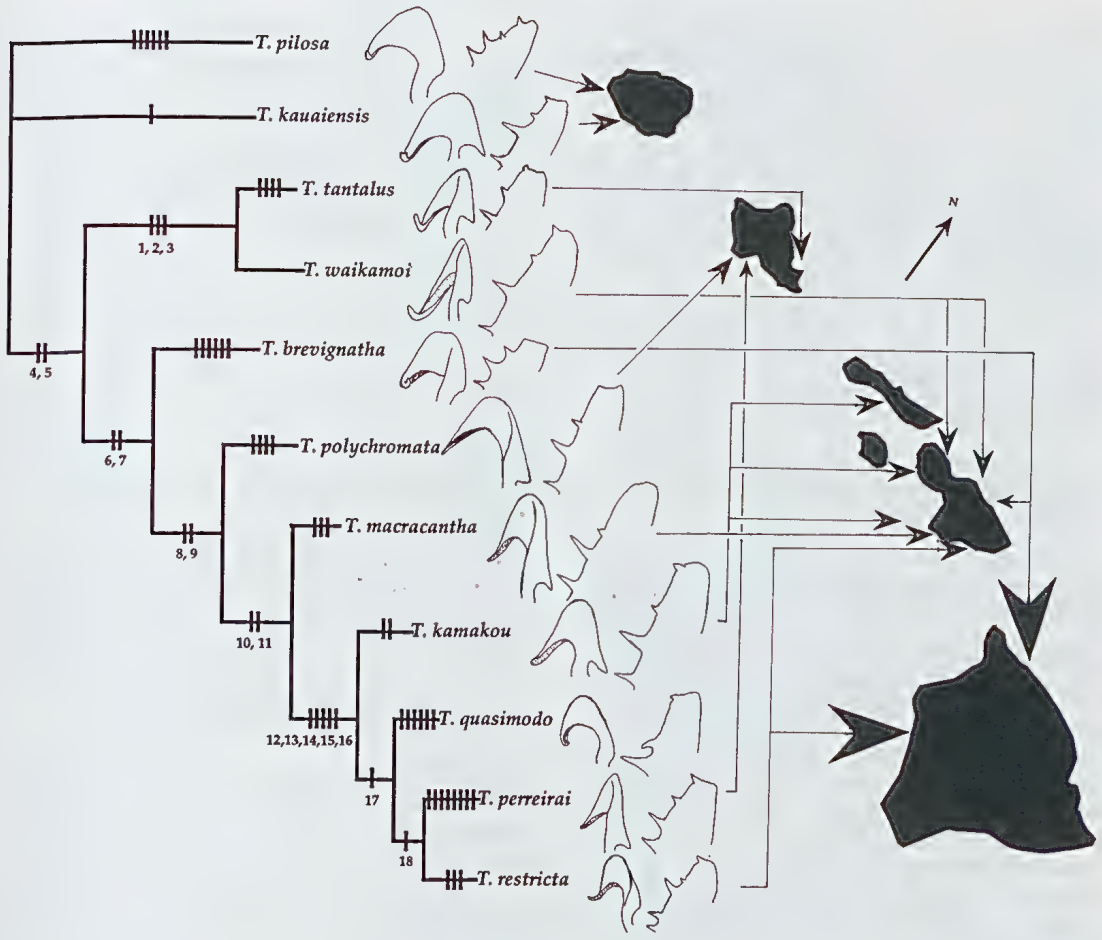

FIG. 2. Phylogeny of the Hawaiian spiny-leg *Tetragnatha* based on morphological characters. Explanations are given for characters defining each node; characters defining species are marked as bars. Sketches of the tip of the male conductor (left) and the upper surface of the apical portion of the male chelicera (right) are included for ease of comparison. Arrows point to the location of a species in the archipelago, with the size of an arrow tip being approximately proportional to the size of the distribution of a given species.Character changes defining each node are as follows. **1**, Conductor terminal projection: short->long. **2**, Conductor cap ridge: lateral–>medial. **3**, Conductor cap: rounded–>pointed. **4**, Conductor cap tip: blunt–>pointed. **5**, Colour: brown/variable–>green. **6**, First upper cheliceral tooth lost. **7**, First lower cheliceral tooth lost. **8**, First 2 lower margin cheliceral teeth–> well separated. **9**, Conductor backward projection at level–> below cap. **10**, Conductor cap: low–>high. **11**, Backward projection conductor spur–>angled down. **12**, Venter: pale–>dark. **13**, Abdomen colour: green–>brown. **14**, First dorsal cheliceral tooth–>finger. **15**, Cheliceral 'sl' tooth–> closer to 'T'. **16**, First 2 lower cheliceral teeth–> closer. **17**, Conductor backward projection hooked up–> angled down. **18**, Lower tooth row long–> short.

range of habitat types. In particular, *T. brevignatha* is found in almost every habitat type on Hawaii Island, whereas representatives of the species on East Maui are confined to a narrow band of mesic forest at middle elevation.

There are some distinct differences between the pattern of phylogeny I have generated here for the Hawaiian *Tetragnatha* and patterns suggested for the Hawaiian *Drosophila*. The Hawaiian *Drosophila* generally demonstrate single volcano endemism, one species having its closest relatives on an adjacent volcano. In contrast, the phylogeny I have generated for the spiny-leg species of Hawaiian *Tetragnatha* suggests a non-uniform and disjunct pattern. Possible explanations for the *Tetragnatha* pattern may best be

considered by viewing the Hawaiian archipelago as a series of evolutionary snapshots, with speciation starting on Hawaii Island and developing on East Maui. The three species on the recently formed Hawaii Island are likely to be relatively recent colonists that have expanded their range and habitat use. Such ecological release subsequent to colonization is considered an important step in initiating species divergence in Galapagos finches (Grant, 1986). However, the widespread species on Hawaii Island are remarkably homogeneous, and none are endemic to the island. It may be that Hawaii Island is too young for speciation to have occurred in the spiny-leg Hawaiian *Tetragnatha*. The situation suggests that considerable movement of individuals occurs within the island, and gene flow between islands has been sufficient to prevent speciation during the period of existence of Hawaii Island.

The adjacent older volcano of East Maui was once part of the island complex, 'Maui Nui' (comprising Molokai, Lanai, East and West Maui). This island was likely first invaded by *T. tantalus*. Males may be better colonists than females (Bishop, 1990), but spiderlings would also arrive, and eventually give rise to a population that would expand its range on that island. However, colonists would continue to arrive on Maui Nui, and, at least initially, the original colonists would not be reproductively isolated from the secondary colonists of the same species. It is also possible that, if the secondary colonists included closely related heterospecifics, hybridization might occur, as newly forming taxa tend to have poorly developed sexual discrimination (Kaneshiro, 1976, 1983; Carson *et al.*, 1989). Indeed, it is possible that both *T. macracantha* and *T. brevignatha* arose through hybridization, which may play an important element in the formation of species in general (Endler, 1989).

As sexual discrimination and ecological adaptation develop, invaders would presumably lose their ability to colonize an occupied land mass. The pattern of distribution of representatives of the spiny-leg clade on older islands suggests that closely related taxa cannot maintain coexistence on the same land mass unless they have undergone sufficient ecological divergence. The situation on East Maui may therefore represent an unstable state: ultimately, a single species will take over the land mass, as a result of introgression or competitive displacement.

The mechanism I have proposed for speciation among representatives of the spiny-leg Hawaiian *Tetragnatha* remains speculative. However, the repeated ecological release of newly forming taxa strongly suggests that ecological changes have played some role in initiating species divergence, as does the finding that two populations (Maui versus Hawaii) of an apparently diverging species (*T. brevignatha*) differ only in terms of their habitat occupation. I suggest that, unlike the Hawaiian *Drosophila* in which sexual selection has been heavily implicated in the speciation process (Kaneshiro, 1983; Kaneshiro and Giddings, 1987), ecological factors (range expansion, reinvasion, competition) may be more important among the spiny-leg species of Hawaiian *Tetragnatha*.

ACKNOWLEDGEMENTS

The study was supported by grants from the Hawaii Bishop Research Institute and the Hawaii Natural Area Reserves System with additional support from the Smithsonian Institution, the Bishop Museum, Haleakala and Hawaii Volcanoes National Parks, Maui Land and Pineapple Company, the Nature Conservancy of Hawaii, Pacific Tropical Botanical Gardens, the U.S. Fish and Wildlife Service, the University of Maryland (Dept. of Entomology), and the University of Hawaii (Dept. of Zoology). I am indebted to the following for their assistance in collecting specimens: R. Bartlett, J. Burgett, H. L. Carson, I. Felger, J. I. Gillespie, J. Halloran, J. Jacobi, K. Y. Kaneshiro, J. Kiyabu, L. Loope, D. Lorence, A. C. Medeiros, S. Montgomery, C. Parrish, S. Perlman, W. Perreira, D. Preston, V. and B. Roth, R. Rydell, W. Stormont, J. Strazanac, M. White and K. Wood. I am grateful to J. A. Coddington, H. B. Croom, H. W. Levi, S. R. Palumbi, N. I. Platnick and to G. K. Roderick for providing advice, discussion and comments.

A NEW SPECIES OF KARSCHIIDAE (SOLIFUGAE, ARACHNIDA) FROM KAZAKHSTAN

ALEXANDER V. GROMOV

Gromov, A.V. 1993 11 11: A new species of Karschiidae (Solifugae, Arachnida) from Kazakhstan. *Memoirs of the Queensland Museum* **33**(2): 527-528. Brisbane. ISSN 0079-8835.

The new solpugid species *Karschia mangistauensis* of the family Karschiidae is described from material collected in south-western Kazakhstan. The relationship of the new species is given, as well as the list of solpugids currently known from Kazakhstan.
En se basant sur le matériel récolté au Sud-Ouest du Kazakhstan on décrit une nouvelle espéce de solifuge *Karschia mangistauensis* de la famille Karschiidae. On donne les affinités de la nouvelle espéce aussi que la liste des solifuges connues à présent au Kazakhstan.□*Solpugids, Karschiidae, Karschia, Kazakhstan.*

Alexander V. Gromov, Institute of Zoology Kazakhstan Academy of Sciences, Akademgorodok, Alma-Ata 32, 480032 Kazakhstan Republic, CIS; 8 March, 1993.

The solpugid fauna of Kazakhstan is poorly known. Only 13 species were recorded from the region by Birula (1938): these are *Karschia zarudnyi* Birula, *Eusimonia turkestana* Kraeplin, *Anoplogylippus dsungaricus* Roewer, *A. rickmersi* (Kraeplin), *Hemigylippus lamelliger* Birula, *Galeodes araneoides* Pallas, *G. turkestanus* Kraepelin, *G. caspius* Birula, *G. fuscus* Birula, *G. pallasi* Birula,*Paragaleodes heliophilus* Heymons, *P. pallidus* Birula and *Daesia rossica* Birula.

The present paper concentrates on material collected from Mangyshlak and Ustyurt Plateaus (south-western Kazakhstan). Solpugids were preserved and studied in 70% alcohol using a binocular microscope MBS-1. Their determination was done according to Walter (1889), Birula (1938) and Roewer (1932-1934, 1941).

MORPHOLOGY AND BIOLOGY
Family KARSCHIIDAE

Karschia mangistauensis sp. nov.
(Figs 1-10; table 1)

Material Examined

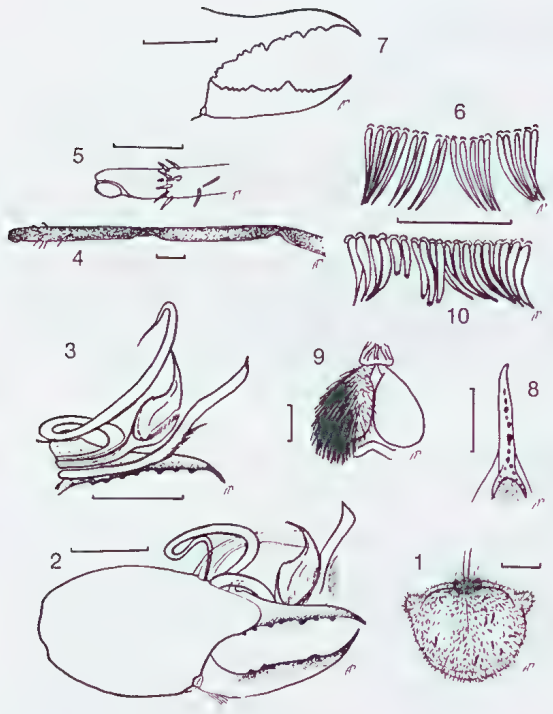
TYPES. Holotype ♂, Zhylandy Cape, Yeraliev District, Mangyshlak Plateau, Mangistau Area, South-Western Kazakhstan, (43°06'N, 51°39'E), 2 May 1991, A.V. Gromov. Paratypes: South-Western Kazakhstan: Mangistau Area: Mangyshlak Plateau: 2 ♂, 2 ♀, same data, except 2-4 May 1991, K.U. Balmukanov, A.V. Gromov, K.B. Dzhankurazov; 1 ♂, Aktau City [Shevchenko], (43°11'N, 51°39'E), 28 April 1991, K.U. Balmukanov; Ustyurt Plateau: 1 ♂, Kugusem Well, 68.5 km E of Akkuduk Village, Yeraliev District, (43°10'N, 54°53'E), 2-5 May 1990, S.I. Ibraev; 1 ♀, Sulykkyzylsai Well, 69.5 km NE of Akkuduk Village, Mangistau District, (43°28'N, 54°43'E), 12 May 1991, E.E. Kopdykbaev. Holotype and 1 ♀ paratype preserved in Zoological Institute, St Petersburg [Leningrad], the remaining material in the author's collection.

Diagnosis

The new species is closely related to *Karschia cornifera* Walter, 1889 from Turkmenistan, from which it differs by the colouration, by the shape of upper modified mesolateral seta near the base of cheliceral fingers, by the number of teeth on the fixed finger and by the spinulation of pedipalps.

Description

Male (holotype). Total length 21 mm. Body colouration light yellow-brown, with greyish head and thorax and grey-yellow abdomen with darker tergites. Chelicerae yellow, distally including brownish-black teeth. Pedipalps (Fig. 4): proximal part of femur yellow, distal part of femur and the remaining segments greyish. Legs yellow. Ocular tubercle (Fig. 1) dark, with numerous hairs, sparse short setae and 2 long setae. Near the base of the cheliceral fingers there is a mesal row of long setae: the upper two are strongly modified and thickened (Figs 2, 3). Armature of pedipalps (Fig. 5): protarsus (basitarsus, metatarsus auct.) with 9 promesolateral spines, tarsus with 1 mesobasal spine. Third abdominal segment with 46 broad ctenidia, fourth one with 19 ctenidia (Fig. 6).



FIGS 1-10. *Karschia mangistauensis*, sp. nov. 1-6, male; 7-10, female. 1, propeltidium, dorsal view. 2, right chelicera, ectal view. 3, modified setae near base of fingers, and flagellum on left cheliceral fixed finger, mesal view. 4, 5 right pedipalp, mesoventral view; coloration (4); spinulation (5). 6, ctenidia on fourth sternite of abdomen, ventral view. 7, right chelicera, ectal view. 8, right cheliceral fixed finger, ventral view. 9, genital opercula, ventral view. 10, ctenidia on fourth sternite of abdomen, ventral view. Scale line = 1 mm.

Body length of paratypes 17-21 mm, number of promesolateral spines 6-10, mesobasal spine of tarsus sometimes absent, fourth abdominal segment with 17 or 19 ctenidia.

Female paratype. Body colouration lighter than in male, with darker pedipalps. Distal part of femur IV light brown. The head behind ocular tubercle with slight longitudinal light brown line. Ocular tubercle as in male, occupying less than 1/3 of clypeus width. Fixed fingers are straight from above, their length no more than the width of chelicerae. Armature of chelicerae as in Figs 7, 8. Genitalia (Fig. 9) with pale rosy ectolateral setae. Fourth abdominal segment with 19 pale rosy ctenidia which are thicker than in male (Fig. 10).

	Length
Chelicerae	4.4, 1.6 wide
Propeltidium	2.4, 3.5 wide
Pedipalp: total (with coxa)	18.2
tibia	4.9
basitarsus	3.8
Leg I (with coxa)	14.1
Leg II (with coxa)	12.4
Leg III (with coxa)	16.6
Leg IV (with coxa)	25.3

TABLE 1. Measurements (in mm) of *Karschia mangistauensis*, sp. nov.

Biology

Night solpugid in clayey desert under stones during day.

ACKNOWLEDGEMENTS

I am grateful to Messrs K.U. Balmukanov and K.B. Dzhankurazov (Kazakh State University, Alma-Ata) for their assistance in capturing of the new species, Mr S.I. Ibraev and Mr E.E. Kopdykbaev (Institute of Zoology, Kazakhstan Academy of Sciences, Alma-Ata) for their material kindly presented to me, and to Dr A.A. Zyuzin (Institute of Zoology, Kazakhstan Academy of Sciences, Alma-Ata) for translation of manuscript. I am also indebted to Dr Ch. K. Tarabaev (Institute of Zoology of Kazakhstan Academy of Sciences, Alma-Ata) who presented my paper at the XII International Congress of Arachnology (Brisbane, Australia).

A NEW SPECIES OF *AMAURORIOIDES* O.P.-CAMBRIDGE (ANYPHAENIDAE: ARANEAE) FROM SOUTH AUSTRALIA

D.B. HIRST

Hirst, D.B. 1993 11 11: A new species of *Amaurobioides* O.P.-Cambridge (Anyphaenidae: Araneae) from South Australia. *Memoirs of the Queensland Museum* **33**(2): 529-532. Brisbane. ISSN 0079-8835.

The littoral spider *Amaurobioides isolatus* sp. nov. is described from South Australia and is the first new species of the genus from the Australian mainland. The male palp of *A. litoralis* Hickman is re-illustrated. Biogeography is discussed. □*Araneae, Anyphaenidae, Amaurobioides, new species.*

David B. Hirst, South Australian Museum, North Terrace, Adelaide, South Australia 5000, Australia; 6 November, 1992.

The genus *Amaurobioides* O. Pickard-Cambridge, 1883 occurs in New Zealand (Cambridge, 1883), Campbell Island (Hogg, 1909), South Africa (Hewitt, 1917) and was reported from Tasmania (Hickman, 1949) and Chile (Forster, 1970). Forster (1975) included the south-east coast of Australia in the distribution of the genus but that was not cited by Main (1981) or Davies (1986). The specimen(s) to which Forster (1975) referred were deposited in the Australian Museum, Sydney (AM) but were not labelled as *Amaurobioides* (unpublished data) and have not been found (pers. comm., M. Gray). No further material has been reported from mainland Australia. Once *Amaurobioides* was found on the rocky shoreline of the eastern side of Gulf St Vincent in South Australia , deliberate searching in similar habitats on Eyre Peninsula, Fleurieu Peninsula and Kangaroo Island showed the species was widespread.

Types of *A. litoralis* Hickman, 1949 (syntype series of 1 ♂ and 3 ♀♀ from Tasmania) deposited in AM, were examined. Hickman made no special type designations but the male seen (AM KS6410) is labelled 'Holotype'. Hence, the label designation is invalid (Art. 73iii). The series also includes two females of an undescribed species (Forster, 1970). Forster, when noting that this type material comprised two sympatric species, stated that the larger form was *A. litoralis* while the smaller form was undescribed.

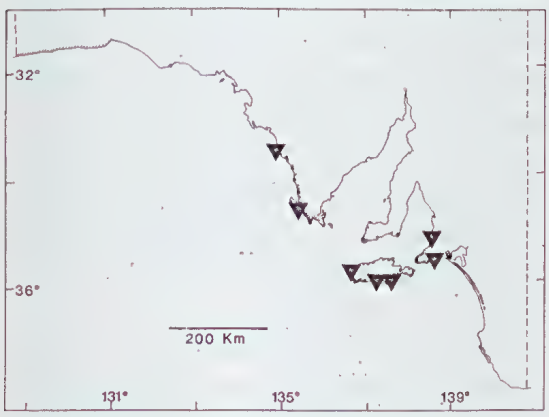

FIG. 1. Southern portion of South Australia showing the distribution of *Amaurobioides isolatus*. Shaded coastline may include suitable habitats.

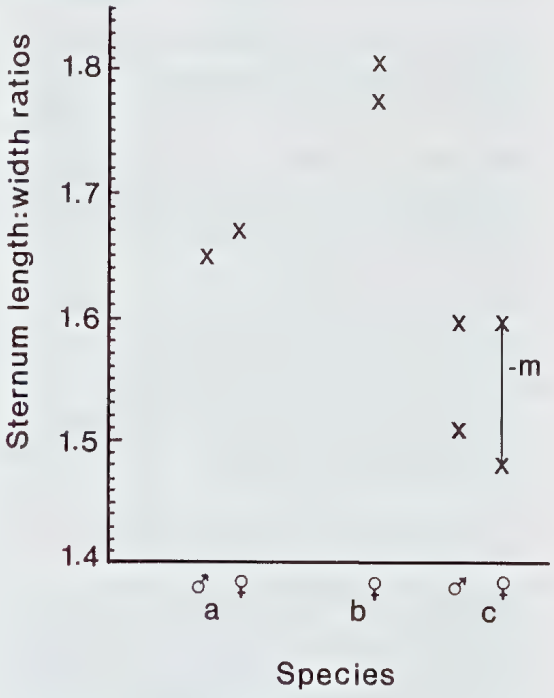

FIG. 2. Comparison of sternum length: width ratios: a, b, *A. litoralis*: small form (a); large form (b); c, *A. isolatus*. m, mean.

FIG. 3. *A. litoralis*. Tibial apophysis and cymbium of syntype ♂ AM KS6410, ventral.

The ♂ is similar in size to the sole smaller ♀ of the type series, and not to the two larger ♀♀ as suggested by Forster (also captions for figures of the two forms appear to be transposed as the larger specimen figured is called the small form). This is supported by comparisons of the sternum length:width ratio (Fig. 2). Ratios: ♂, 1.65 and smaller type ♀ 1.67; larger ♀♀, 1.77, 1.81; ♀ *A. isolatus* 1.48-1.60 (n=14, mean =1.56) and 2 ♂♂, 1.51, 1.60. Although based only on Australian material seen, the conspecific ♂ of the larger and undescribed form would probably attain a ratio in excess of 1.70.

The ♂ palp of *A. litoralis* is re-illustrated here; the ♀ epigynum was adequately illustrated in Forster (1970, figs 487, 488).

METHODS AND MATERIALS

Hairs are omitted from illustrations. ♀ genitalia were dissected then cleared in lactic acid. All measurements are in millimetres. *Abbreviations*: CL, carapace length; CW, carapace width; AL; abdomen length; AW, abdomen width, MOQ, median ocular quadrangle; aw, anterior width; pw, posterior width; L or l, length, W, width; K.I., Kangaroo Island; DH, D. Hirst.

Amaurobioides isolatus sp. nov.
(Figs 1, 2, 4-9, Table 1)

Material Examined

TYPES. Holotype ♂, Blanche Point, 35°15'S, 138°28'E, 1.iii.1986, DH, N1992206. Paratypes: allotype ♀, same data as above, N1992207; ♀ (with spiderlings), Elliston, 33°39'S, 134°53'E, 31.iii.1987, DH, D. Lee, N1992218; ♀, juv., same data, N1992216-7; ♀, 5 penult. ♂, 2 penult. ♀, same data as holotype but 25.i.1986, N1992208-15; penult. ♀, Petrel Cove, 35°36'S, 138°36E, 1.ii.1991, DH, N1992219; ♀, 4 juv., Point Avoid, 34°41'S, 135°19'E, 31.iii.1987, DH, D. All in South Australia and deposited in South Australian Museum.

Diagnosis

The ♂ of *A. isolatus* is recognised by the shape of the primary conductor. *A. isolatus* further differs from the two Tasmanian species in having the sternum relatively broader while the ♀ epigynum is smaller and less sclerotised. The ♂ has spination of tibia I identical to the ♀, a feature shared with *A. maritimus* O.P.-Cambridge, from which it is separated by the genitalia.

Description

MALE. CL 3.79, CW 2.56. AL 4.48, AW 2.41.

Colour in alcohol: Carapace yellow-brown, yellow posterior to fovea and laterally to above anterior legs, caput dark orange-brown, clypeus and lateral edge of face brown. Chelicerae red-brown, darker distally. Maxillae and labium orange-brown, anterior margins cream. Sternum cream, margins orange. Legs cream-yellow, anterior metatarsi and tarsi darker, coxae cream. Palp cream, cymbium brown. Abdomen cream with dark red-brown pattern dorsally and laterally, typical for genus. Venter darker around spiracle and posteriorly to spinnerets, dark area extending anteriorly from spiracle in two narrow lines almost to epigastric furrow.

Carapace elongate, longer than broad in ratio 19:13, short imperfect longitudinal fovea [presumably straight in normal specimens]. Striae barely evident, adpressed setae black, upright setae on caput between fovea and ocular region. Eye group occupies less than half width of caput. AME 0.10, ALE 0.17, PME = PLE 0.18.

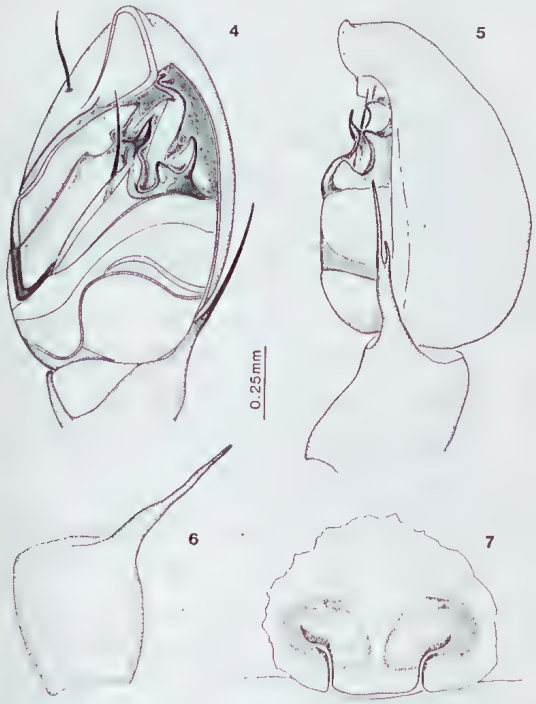
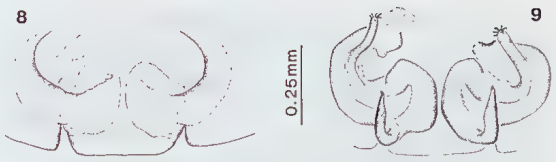
TABLE 1. Leg lengths of *Amaurobioides isolatus*. Values are for holotype ♂ (allotype ♀).

Interspaces: AME-AME 0.05, AME-ALE 0.04, PME-PME 0.11, PME-PLE 0.12, AME-PME 0.14, ALE-PLE 0.08. MOQ; aw: pw: l = 0.26: 0.47: 0.39. Width of clypeus to AME 0.10. Chelicerae with three teeth on both margins. Sternum: L 2.12, W 1.40. Legs. (Table 1) Scopula sparse, particularly on posterior pairs. Leg spination; no spines on patellae or tarsi. Ventral tibiae and metatarsi spines usually paired, occasionally single. Leg I, fe d3 p1, ti v6, me v3. Leg II, fe d3 p1, ti p1 v6, me v4. Leg III, fe d3 p1 r1, ti p1 r1 v5 (v6 on right), me p3 r3 v6. Leg IV, fe d3 p1 r1, ti r1 v3, me p2 r2 v5. Palp, fe d3 p1, pa with one stout bristle dorsally at distal end, ti many long stout bristles, cymbium with three short weak spines prolaterally.

Palp. Tibia with left apophysis having short dorsal median secondary prong (Fig. 5), right apophysis lacking accessory prong (Fig. 6), possibly normal state.



FIGS 4-7. *A. isolatus*. 4-5, Left tibial apophysis and cymbium of holotype ♂, 4, ventral, 5, retrolateral; 6, right tibia and apophysis; 7, epigynum of allotype ♀.



FIGS 8-9. *A. isolatus*. 8-9, cleared vulva of paratype ♀ N1992208, 8, ventral, 9, dorsal.

FEMALE (as ♂ except as follows).CL 4.21, CW 2.89. AL 6.97, AW 4.16.

Eyes. AME 0.11, ALE 0.20, PME 0.19, PLE 0.20. Interspaces; AME -AME 0.08, AME-ALE 0.06, PME-PME 0.12, PME-PLE 0.14, AME-PME 0.17, ALE-PLE 0.10. MOQ; aw: pw: l = 0.29: 0.50: 0.46. Width of clypeus to AME 0.06. Sternum: L 2.30, W 1.48. Legs. (Table 1)

Epigynum. Fossa broad, anterior margins vaguely defined by what appears to be subcuticular sclerotisation of vulva (Fig. 7). Vulva of paratype N1992208 shown in Figs 8, 9 [allotype not dissected].

Variation

CL of paratype ♂, 3.48; the tibial apophysis of both palps lack accessory prongs and the fovea is straight. CL of paratype ♀; 3.22-4.74, mean 4.35 (n=13).

Etymology

The specific epithet, *isolatus*, reflects the isolated nature of the species distribution.

NATURAL HISTORY

Habits are similar in other *Amaurobioides*. Silk retreats are assumed to be permanent although many spiders collected or observed at Blanche Point in February were wandering over the rocks at night. Several penultimate ♂♂♀♀ were collected in this way and kept alive for some time, one ♂ eventually maturing 3 months later. Most insects placed with the spiders, including moths and terrestrial isopods, were not fed upon. Small flies (mostly *Drosophila*) were more readily accepted (Forster, 1970: 167). Littoral isopods were not tried as a food source (Hickman, 1949). Since then a specimen of *A. isolatus* at Blanche Point lunged at and grasped a small littoral isopod half its size with its anterior legs, hesitated and then released the isopod, retreating to its position at the entrance to the nest. Small flies, often seen resting

in sheltered areas at night along the coast, are another likely food source. Females with spiderlings (26 and 42) in the retreat were found in mid-autumn at both Point Avoid and Elliston while spiderlings and an eggsac were found in separate retreats in November on Kangaroo Island.

BIOGEOGRAPHY

Most areas sampled were within the splash zone on rock faces sheltered from the full velocity of the sea, but retreats were seen in an exposed and treacherous area at Cape du Couedic, Kangaroo Island. Known populations are separated by unsuitable or sandy coastline of varying lengths (Fig. 1). *Amaurobioides* may have dispersed across the intervening ocean by parachuting on silk lines or drifting on flotsam to settle and inhabit their present littoral environments. Forster (1970) considered that claim to be overstated as a number of distinct forms, some sympatric, were present in New Zealand. Platnick (1976) reinforced that in the Laroniinae.

Since Australia's separation and subsequent drift from the other continents of Gondwanaland, the South Australian coastline has been altered by changes in sea level during the last ice-age. The rocky cliffs of Blanche Point and southern coast of Kangaroo Island which now provide a habitat for *Amaurobioides* were formed during the last ice-age over Tertiary deposits and have since been uplifted and weathered (Daily *et al.*, 1979). One population in D'Estrees Bay, Kangaroo Island, consisted of only a few individuals on a small isolated rock outcrop backed by a low sandstone ledge. Similarly, near Port Willunga and 2km south of Blanche Point, individuals exist on a few older limestone rocks remaining on the wide sandy beach which are reached by the normal high tide. Although backed by cliffs, no spiders were found on these. Cliffs also abut the sea in areas north of Blanche Point to Marino Rocks but as yet *Amaurobioides* has not been found. *Amaurobioides* is unlikely to be found from Victor Harbour on the Fleurieu Peninsula to at least Robe in the south-east of South Australia. Extensive sand dunes which now form the Coorong and much of the coast to the south are part of that area built up during inundation by the sea in the Miocene and the Pleistocene, and the few rocky outcrops now present have remained isolated since.

In summary, *Amaurobioides* is one of the few true Gondwanan spider genera left in South Australia presumably because continual changes to the coast have occurred gradually. Littoral spiders have moved with it through dispersal and colonising adjacent new areas of rocky terrain or re-establishing itself into old areas within a suitable distance from the receding or insurgent sea. The sympatry of species of *Amaurobioides* in New Zealand and Tasmania probably occurred by migration over land following uplift or weathering of unsuitable coastline between two separated species and exposing a continuous rocky habitat, rather than by dispersal on silk lines.

ACKNOWLEDGEMENTS

I am grateful to Dr M. Gray (AM) for the loan of types of the Tasmanian *Amaurobioides* and to Mr L.N. Nicolson for commenting on an early draft of the manuscript.

IMPLICATIONS OF THE PHYLOGENY OF PIMOIDAE FOR THE SYSTEMATICS OF LINYPHIID SPIDERS (ARANEAE, ARANEOIDEA, LINYPHIIDAE)

GUSTAVO HORMIGA

Hormiga, G. 1993 11 11: Implications of the phylogeny of Pimoidae for the systematics of linyphiid spiders (Araneae, Araneoidea, Linyphiidae). *Memoirs of the Queensland Museum* **33**(2): 533-542. Brisbane. ISSN 0079-8835.

The araneoid family Pimoidae (new rank) is hypothesized to be the sister group of Linyphiidae. *Louisfagea* Brignoli is a junior synonym of *Pimoa* Chamberlin and Ivie (new synonymy). The characters that support the monophyly of Pimoidae and of Linyphiidae plus Pimoidae are discussed. Explicit outgroup comparison to the closest relatives of linyphiids (i.e., pimoids) allows studies of character evolution and character polarization within linyphiids and the assessment of previous phylogenetic hypotheses for the family. Preliminary data on the implications of pimoid phylogeny for linyphiid systematics are evaluated, based mainly on morphological characters. Linyphiid monophyly is discussed.

La familia araneoide Pimoidae (nuevo rango) es, hipotéticamente, el grupo hermano de Linyphiidae. El género *Louisfagea* Brignoli se considera sinónimo de *Pimoa* Chamberlin and Ivie (nueva sinonimia). Se discuten los caracteres que apoyan la monofilia de Pimoidae y de Linyphiidae más Pimoidae. La utilización explícita del criterio de comparación con el grupo externo de los linífidos (es decir, los pimóidos) permite estudiar la evolución y polarización de caracteres en linífidos, así como la evaluación de anteriores hipótesis filogenéticas sobre esta familia. Se evaluan los datos preliminares, basados en caracteres morfológicos principalmente, sobre las implicaciones de la filogenia de los pimóidos para la sistemática de los linífidos. También se discute la monofilia de Linyphiidae. □*Pimoidae, Linyphiidae, Pimoa, cladistics, phylogeny, monophyly, homology.*

Gustavo Hormiga, Department of Entomology, NHB 105, National Museum of Natural History, Smithsonian Institution, Washington, DC 20560, U.S.A. and Maryland Center for Systematic Entomology, Department of Entomology, University of Maryland, College Park, MD 20742, U.S.A.; *27 October, 1992.*

Linyphiids are one of the dominant spider groups in the Holarctic region. Despite their overwhelming diversity and involved taxonomic history the phylogenetic structure of the family and their relationship to other araneoids are very poorly understood. In this paper I present some preliminary data on the systematics of pimoids, confirming their sister-group relationship to linyphiids, and on the cladistic structure of a small sample of linyphiid genera. A revision and numerical cladistic analysis of the pimoids and the sample of linyphiid taxa (Hormiga, in press), together with detailed character information, will be published elsewhere shortly. The study of the phylogeny of the pimoids requires the inclusion of at least a sample of linyphiids (their putative sister-group) in order to assess character state polarities by means of outgroup comparison. It is in such a context that the present study should be considered, since the small sample of genera used here can by no means account for the whole range of linyphiid diversity. However, quantitative cladistic analysis of the data presented here enables for some testable hypotheses on linyphiid systematics and character evolution, by explicitly stating phylogenetic relationships in terms of synapomorphies rather than by the more speculative approaches that have commonly been used in traditional linyphiid higher systematics. This approach enables us to evaluate comparative morphological data (or any other kind of biological data) in a cladistic context. Hypotheses on phylogeny and character homology hypotheses are indistinguishable because 'every hypothesis of homology is a hypothesis of monophyletic grouping' (Patterson, 1982). Finally, the present study allows for a preliminary test of the phylogeny of the linyphiid subfamilies proposed by Wunderlich (1986).

MATERIALS AND METHODS

Taxa

Nine linyphiid, five pimoid, and two non-linyphiid araneoid genera that are possible outgroups of the pimoid-linyphiid complex are used in this study. The linyphiid taxa selected represent the subfamilies and tribes used by Wunder-

lich (1986) in his phylogenetic scheme for Linyphiidae (given here in parentheses): *Linyphia triangularis* (Clerck) and *Microlinyphia dana* (Chamberlin and Ivie)(Linyphiinae, Linyphiini); *Bolyphantes luteolus* (Blackwall) and *Lepthyphantes tenuis* (Blackwall)(Linyphiinae, Micronetini); *Erigone psychrophila* Thorell and *Walckenaeria directa* (O.P.-Cambridge) (Erigoninae); *Haplinis diloris* (Urquhart) and *Novafroneta vulgaris* Blest (Mynogleninae); and *Stemonyphantes blauveltae* Gertsch (Stemonyphantinae). The pimoids (which contain 21 species, including 11 new species (Hormiga, in press) are represented here by five species: *Pimoa* (=*Louisfagea*) *rupicola* (Simon), *P.* (=*Louisfagea*) *crispa* (Fage), *P. altioculata* (Keyserling), *P. breviata* Chamberlin and Ivie, and *P. curvata* Chamberlin and Ivie. *Tetragnatha versicolor* Walckenaer and *Zygiella x-notata* (Clerck) are used as outgroups of the pimoid-linyphiid clade. The affinities of *Zygiella* are problematic: the genus is currently placed in Tetragnathidae, although not long ago it was thought to belong in Araneidae. Recent analyses of Araneoidea relationships by Coddington and Scharff suggest that *Zygiella* is either sister to Araneidae or Araneinae, i.e. it is the most basal taxon within araneids or basal within the araneine clade (Scharff and Coddington, pers. comm.).

Taxonomic note: I have used taxonomic decisions that will be soon discussed in greater detail elsewhere. The Pimoinae Wunderlich are raised to familial status (Pimoidae, NEW RANK) and are therefore removed from the Linyphiidae. Treating pimoids as a linyphiid subfamily produces a great change in the diagnosis of Linyphiidae, since it is largely based in male genitalic characters which are absent in the Pimoidae (e.g., intersegmental paracymbium, loss of the araneoid conductor, loss of the araneoid median apophysis, presence of a radix and a column, etc.). Once it is established that pimoids and linyphiids are sister-groups, the assignment of ranks is arbitrary. The exclusion of pimoids renders Linyphiidae more homogeneous and easier to diagnose. *Louisfagea* Brignoli, as presently defined, is polyphyletic (Hormiga, in press). The removal of *crispa* would leave the remaining species of *Louisfagea* as a paraphyletic genus. *Louisfagea* is regarded here as a junior synonym of *Pimoa* Chamberlin and Ivie (NEW SYNONYMY). Throughout this paper the taxon name Linyphiidae (linyphiids) does not include the pimoids.

Characters

The data set contains 47 characters (Table 1): 33 male and female genitalic characters, 5 spinneret spigot characters, 7 other morphological somatic characters, and 2 behavioral characters. The data consist mostly of original observations, but a few characters have been extracted from the literature. Although this data set integrates information from several character systems, it especially focuses on male palp and spinneret spigot morphology. The methods of study and of homology assessment of spinneret spigot morphology follow those of Coddington (1989). The work on linyphiid morphology (including the descriptive studies on male palp, spinneret spigot, and tracheal system morphology) will also be published elsewhere.

Analysis

The data set was analyzed using the computer program for phylogenetic analysis Hennig86 ver. 1.5 (Farris, 1988). Multistate characters were treated as non-additive (unordered).

RESULTS

Characters

Character distributions are summarized in Table 1. The desmitracheate tracheal system (*sensu* Millidge, 1984; character 35) is a synapomorphy of the erigonine clade. I have not been able to confirm some of the tracheal morphologies described by Millidge (1986). I have examined the tracheal system of several erigonine genera (*Erigone aletris* Crosby and Bishop, *E. psychrophila*, *Gonatium rubens* (Blackwall), *Grammonota angusta* Dondale, and *Hypselistes florens* (O.P.-Cambridge)) and have not found evidence of the median tracheae open-

TABLE 1. Rows represent characters and columns taxa. The first state is 'state 0', the second is 'state 1', etc. '?' represents missing data, and '—' non-applicable states. The last two columns give the consistency index (CI) and the weight (W) assigned to the character in the successive character weighting analysis (see text). Taxon numbers: 0 = *Tetragnatha versicolor*, 1 = *Zygiella x-notata*, 2 = *Linyphia triangularis*, 3 = *Microlinyphia dana*, 4 = *Bolyphantes luteolus*, 5 = *Lepthyphantes tenuis*, 6 = *Erigone psychrophila*, 7 = *Walckenaeria directa*, 8 = *Haplinis diloris*, 9 = *Novafroneta vulgaris*, 10 = *Stemonyphantes blauveltae*. The remaining taxa are species of *Pimoa*: 11 = *rupicola*, 12 = *crispa*, 13 = *altioculata*, 14 = *breviata*, 15 = *curvata*. Characters: 1-30, male genitalia; 31-33, female genitalia; 34-40, somatic morphology; 41-45, spinneret spigot morphology; 46, 47, behaviour.

ing directly to separate spiracles, as Millidge reported. The mentioned erigonines posses a tracheal atrium (*contra* Millidge, 1986:57), which, using an aqueous solution of chlorazol black, stains similarly to the rest of the tracheal system. The spiracle is most visible at both ends, where it is wider and rounded, although there is a slit connecting both ends. Such ends are not a closed circle (i.e., they are not separate spiracles), as Millidge's illustrations seem to suggest (e.g. his figure 5), since they are open at its inner part to the interconnecting slit. *Stemonyphantes blauveltae* and *Allomengea pinnata* (Emerton) have tracheal atria opening through a single spiracle, contrary to Millidge's assertion that in both genera the atrium opens via two spiracles. Atria opening via a single spiracle were also found in *Drapetisca alteranda* Chamberlin, *Centromerus sylvaticus* (Blackwall), *Lepthyphantes flavipes* (Blackwall), *L. tenuis* (Blackwall), and *L. intricatus* (Emerton). These latter genera were also reported by Millidge (the first one only implicitly) to have the atrium opening via two spiracles. In the two latter species the slit is very similar to the one reported here for the erigonines, with markedly wider round ends (this fact might have caused them to be taken as having two spiracles).

The spinneret spigot morphology characters (41-45) support the monophyly of the pimoids and of the pimoid-linyphiid clade (Hormiga, in press). Linyphiid and pimoid spigot morphology is consistent with the araneoid groundplan (Coddington, 1990b; Peters and Kovoor, 1991; Hormiga, in press). The pimoid-linyphiid clade lacks the PMS aciniform brush found in primitive orbicularians (character 41), but so do many tetragnathids and the theridiids. Pimoids and linyphiids share the position of the mesal cylindrical spigot on the periphery of the PLS, but this is not exclusive to the pimoid-linyphiid clade: it is also found in *Zygiella x-notata* (pers. observ.) and in some other tetragnathids (Coddington, pers. comm.; Platnick *et al.*, 1990). An enlargement of the base of the peripheral cylindrical spigot of the PLS (character 43) is characteristic of pimoids and linyphiids. Pimoids have drastically reduced the PMS and PLS aciniform fields (characters 42 and 45): they either have one or none aciniform spigots on each spinneret. *Stemonyphantes* has also lost, presumably in parallel, the aciniform spigots in both the PMS and the PLS.

The use of the mating sequence and the transfer of sperm (characters 46-47) as taxonomic characters in linyphiids was studied by van Helsdingen (1965, 1969, 1983). Blest and Pomeroy (1978) studied the sexual behavior of *Haplinis diloris*. I have used data from van Helsdingen's observations as valid for the different species of *Lepthyphantes* and *Microlinyphia* in my data, under the assumption that there is no variation for the characters under study at the intrageneric level. For *Erigone psychrophila*, I have also used data from other species in the same genus, namely *E. dentipalpis* and *E. longipalpis* (Gerhardt (1927, 1923) cited in van Helsdingen (1983)). The male position during the construction of the sperm web (fork and web) and during ejaculation is below the sperm web in erigonines and mynoglenines, and above (only the web, the fork is constructed from below) in Linyphiini and Micronetini.

Analysis

The data (Table 1) were analyzed using the implicit enumeration option of Hennig86, which found four equally parsimonious cladograms with a length of 81 steps and consistency and retention indices of 0.74 and 0.81 respectively. These four topologies differ in the interrelationships of pimoids and in the position of *Stemonyphantes*, which in one of the four cladograms is sister to the pimoids. This latter topology is the result of the parallel loss of the aciniform fields in pimoids and linyphiids. Deactivating the characters that account for the number of aciniform spigots in the PMS and PLS (42 and 45, respectively) and using the implicit enumeration option three cladograms are obtained. These three cladograms are the same as those obtained with the 'active' characters, with the exclusion of the topology that clusters *Stemonyphantes* with pimoids. Successive character weighting (Farris, 1969; Carpenter, 1988) was used, as implemented by Hennig86, to choose a cladogram from the set of four equally parsimonious cladograms. A single iteration produced one cladogram (Fig. 1), which corresponds to one of the original set of four. This result is stable in a second iteration. Because this cladogram is based on the most consistent characters it is preferred as a hypothesis for explaining the relationships of this sample of taxa. The cladistic analysis of this selection of pimoid taxa produces results (i.e. tree topologies) fully congruent with those obtained in Hormiga (in press), in which a total of 20 pimoid species were analyzed together with the same sample of linyphiids and the two outgroup genera.

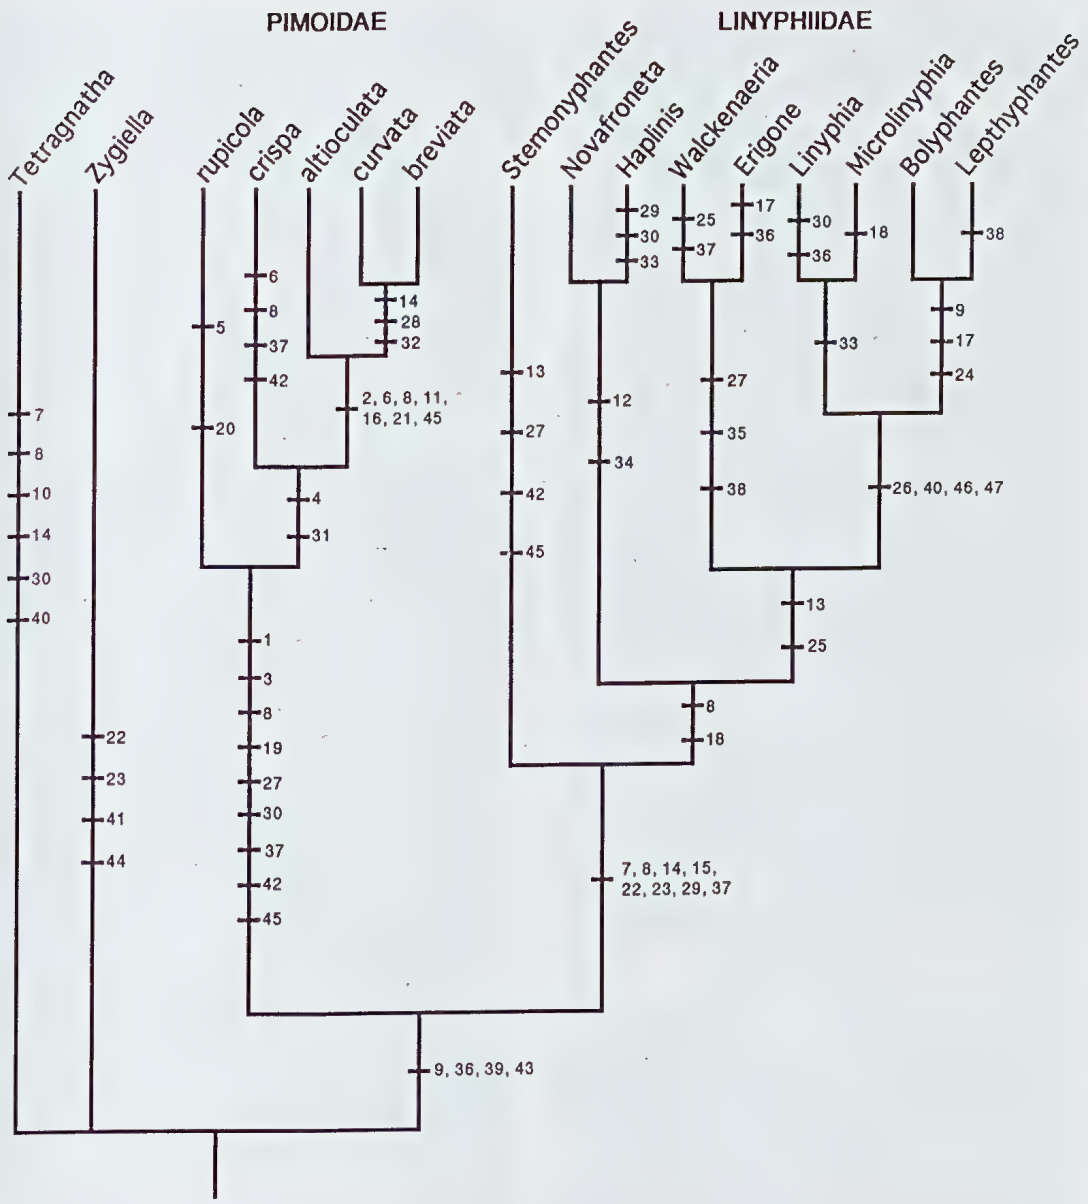

FIG. 1. Preferred minimum length cladogram for the taxa and characters in Table 1 (three equally parsimonious alternative topologies exist; see text). The cladogram length is 81 steps; the consistency and retention indices are 74 and 81, respectively.

DISCUSSION

Monophyly of the Pimoid-Linyphiid Clade

Pimoids and linyphiids emerge as a monophyletic assemblage, unambiguously supported by the presence of cheliceral stridulatory striae, patellar autospasy, and the enlargement of the peripheral cylindrical spigot base in the PLS. Paracymbial apophyses are secondarily absent (i.e. lost) in the pimoid-linyphiid clade, although they are regained in the Micronetini. All these characters (except the patellar autospasy) exhibit some degree of homoplasy.

Millidge (1988) rejected the inclusion of Linyphiidae in Araneoidea, and instead related them to Agelenidae (*s. lat.*), Amphinectidae, and

other taxa currently placed in Amaurobioidea and Dictynoidea. His hypothesis on the exclusion of linyphiids from Araneoidea has been elegantly rebutted by Coddington (1990b), who stated that linyphiids exhibit 9 out of the 10 synapomorphies that support the monophyly of Araneoidea. Pimoids share the same 9 araneoid synapomorphies. Peters and Kovoor (1991) studied the structure, histochemistry, and function of the spinning apparatus of *Linyphia triangularis* and concluded that the data did not provide any indication of close relationship between Linyphiidae and Agelenidae. Certainly Millidge's hypothesis lacks character support. The available data clearly argue in favor of the inclusion of the pimoid-linyphiid clade in Araneoidea. Furthermore, Millidge's idiosyncratic method of phylogenetic inference is flawed because, among other things, it seems to suggest the use of symplesiomorphies (by 'reversing' the outgroup comparison method) to establish family relationships (p. 254). It is well known that grouping by plesiomorphic character states produces paraphyletic groups (Hennig, 1966) and therefore should be avoided.

A major problem in araneoid phylogeny is the placement of the theridiid and the linyphiid-pimoid lineages, in which the orb web architecture has been lost (Coddington and Levi, 1991). Cyatholipidae have been suggested as another possible sister group of linyphiids (Coddington, 1990a). While the sheet web might support this hypothesis, the evidence provided by the morphological data is, at the moment, inconclusive.

Monophyly of Pimoids

Pimoid monophyly is supported by nine synapomorphies, six of them from male palpal morphology and two from spigot morphology. It is interesting to note that none of the pimoid-linyphiid synapomorphies refer to palpal morphology, which is quite different in these two lineages and might reflect a very old time of divergence and/or a rapid rate of character change for the male genitalia. The highly derived spigot morphology of pimoids is unique among araneoids. With the exception of *Stemonyphantes* no other araneoids have been reported to loose all the aciniform gland spigots.

Monophyly, Character Analysis, and Cladistic Structure of Linyphiids

Linyphiid monophyly is supported by eight synapomorphies. Seven of these eight characters (i.e. all except character 8) are homoplasious. With the increasing number of studies that use quantitative cladistic methods it is becoming clear that homoplasy is quite common (Coddington and Levi, 1991). Coddington (1990b) noted that many of the most useful characters for the inference of araneomorph phylogeny were homoplasious. Griswold (in press), in his study of the Lycosoidea, arrived at a similar conclusion for female genitalic characters. Linyphiids are not an exception, and this fact will not surprise most linyphiid taxonomists. For example, intersegmental paracymbia (character 7), similar to the linyphiid type, are also found in *Tetragnatha* and *Pachygnatha* (Levi, 1981:274, 286). Millidge (1988:258) considers the two latter cases as integral paracymbia, different from the linyphiid type, in which case the homoplasy would be removed from this character. But regardless of possible instances of homoplasy, the intersegmental paracymbium is a putative synapomorphy for linyphiids. Coding the paracymbial morphology (character 8) is not an easy task. I have taken a conservative approach by coding it with a high number of character states (seven), in part due to the high morphological diversity of this structure. The coding used produced no extra length (the character's consistency index is 1), but by itself it provides little grouping information (only two states occur in more than one taxon). The states are thus 'ordered' by the tree topology generated by all characters (the final optimization of the character on the cladogram was done by hand, because several equally parsimonious optimizations exist). Blest (1979) and Wunderlich (1986) consider that mynoglenines and erigonines share the same type of paracymbium ('simple paracymbium'). Van Helsdingen (1986:122) argued against this view by pointing out that many linyphiine genera also have the so-called 'simple' paracymbium. Although in some cases erigonines and mynoglenines seem to have morphologically 'simpler' paracymbia (short proximal and distal branches, sometimes J-shaped, without apophyses) than some of the linyphiini and micronetini, I cannot see a clear-cut distinction between these two states. I have coded all the linyphiids (except *Stemonyphantes*) as having the same overall paracymbium morphology (with a proximal and a distal branch of varying length and being more or less J or U-shaped). The paracymbium type found in *Stemonyphantes* is considered by Millidge (1988) as an intermediate form between the integral and intersegmental types. This latter type of paracymbium is inferred to be the primitive state for

linyphiids. This state is subsequently transformed into the paracymbium morphology found in the rest of linyphiids. Coding mynoglenines and erigonines as sharing the same unique character state (i.e., the 'simple' paracymbium), as Blest and Wunderlich have suggested, produces no changes in the cladogram topology.

The presence of a median apophysis and a conductor on the tegulum is regarded as plesiomorphic for araneoids (Coddington, 1990a). Pimoids have a conductor and a median apophysis (Hormiga, in press). The absence in linyphiids of a true (i.e. tegular) conductor and a median apophysis (Coddington, 1990a) are regarded as synapomorphies for linyphiids (characters 15 and 14, respectively). Two potential synapomorphies of linyphiids, the radix and the column, are waiting for resolution of the outgroup of the pimoid-linyphiid clade in order to be tested. The linyphiid radix (character 22) might be homologous to the araneid radix, and therefore plesiomorphic for linyphiids, if araneids are the sister group of pimoid-linyphiids (Coddington, 1990a). The same happens with the linyphiid column or stalk (*sensu* Saaristo, 1971; character 23) that connects the radix to the tegulum/suprategulum. The column could be homologous to the distal haematodocha if araneids are sister to the pimoid-linyphiid clade (Coddington, 1990a). If that is not the case, the homology of the linyphiid radix and column with its presumed equivalents in Araneidae might be refuted, and these characters would function as synapomorphies of linyphiids (this latter alternative is the one mapped on Figure 1). Linyphiids seem to have reduced the number of prolateral trichobothria in the male palpal tibia (character 29) from two (pimoids and outgroups in the data set) to one. However this putative synapomorphy of linyphiids might loose generality (i.e. might be refuted) in a data set with a larger sample of taxa. The same might happen to the number of retrolateral teeth on the female chelicera (character 37), which is four or more in all but one of the linyphiid taxa in the data set, and acts as putative synapomorphy for linyphiids.

The linyphiid suprategulum (character 13) is a projection of the tegulum that bears the column and through which the sperm duct passes (Saaristo (1971, 1975); Millidge (1977); Coddington (1990a)). However, the suprategulum might not be homologous across all linyphiids. The tegular projection that Blest (1979, figs 596-602) and Blest and Pomeroy (1978, figs 2, 4) call the 'suprategulum' in New Zealand mynoglenines does not bear the column (which in some cases is far from it, e.g. *Pseudafroneta*, in Blest's figure 597) and has no sperm duct going through it. I have interpreted the mynoglenines as lacking a suprategulum (*sensu* Saaristo) and coded its tegular apophysis as a structure synapomorphic for mynoglenines and not homologous to the suprategulum ('mynoglenine tegular apophysis', character 12). However, the tegular apophysis of *Haplinis* seems to be functionally analogous to the suprategulum in some linyphiids (van Helsdingen (1965, 1969); Blest and Pomeroy (1978)) in engaging the socket of the epigynal scape, but data on the functioning of the genitalia across taxa are still very scarce. The suprategulum of *Stemonyphantes* is articulated to the tegulum by means of a membranous connection (van Helsdingen, 1968:124; pers. observ.) and is different from the rest of linyphiid suprategula which are fused to the tegulum (character 13). The cladogram in Figure 1 suggests the possibility of independent origins for these two types of suprategula, and therefore questions its homology (secondary absence of the suprategulum in the mynoglenines -versus independent gains-requires one additional step).

The linyphiid embolic membrane (van Helsdingen, 1969) is not homologous to the araneoid conductor because of their different position (but see Coddington, 1990a:16). The embolic membrane (character 18) is a putative synapomorphy for all linyphiids, with the exclusion of the basal genus *Stemonyphantes*. The 'embolic membrane' *Microlinyphia* is not an outgrowth of the column, as in most linyphiids (van Helsdingen, 1986:123), but a structure 'arising from (the) membranous connection of radix, base of embolus, and dorsal side of lamella' (van Helsdingen, 1970:6). I have interpreted it as not homologous to the column-positioned embolic membranes, but the nature of this membrane remains dubious. The alternative, i.e. coding it as an embolic membrane shifted to a radical position in *Microlinyphia*, produces no change in the cladogram topology.

The terminal apophysis (character 25) is a synapomorphy for erigonines plus linyphiines, but its interpretation offers several problems. The first is its homology with its homonym in araneids (Saaristo 1971, 1975; Coddington, 1990a). Such homology is dependent, among other things, on a sister-group relationship between araneids and linyphiids (plus pimoids), but even so the homology is not obvious. *Zygiella x-notata* (which is considered here as an araneid) lacks anything

similar to a terminal apophysis, pimoids lack the radix (therefore, we do not know if they ever had such apophysis), and basal linyphiids (i.e. *Stemonyphantes* and the mynoglenines) have simple radices and no terminal apophysis. The cladogram in Fig. 1 suggests independent origins (i.e. non homology) for the terminal apophysis in araneids and linyphiids. If the embolic division of *Stemonyphantes* is interpreted as simple (and not simplified) it also suggests that complex embolic divisions in araneids and in linyphiids arose independently. This latter interpretation would question the monophyly of araneids plus linyphiids (e.g. Coddington, 1990a:14). Second, and at a less inclusive level, not all erigonines and linyphiines have a terminal apophysis. Evaluation of the homology of these apophyses requires a more detailed cladistic structure for the family (i.e. more taxa and more characters). Another radical sclerite, the lamella characteristica (character 26), is a putative synapomorphy for the linyphiines. Further support for the monophyly of Micronetini plus Linyphiini is given by the loss of metatarsus IV trichobothrium (character 40) and the position of the male during the construction of the sperm web and during ejaculation (characters 46 and 47). The phylogenetic information provided by the latter two characters should be regarded as provisional, because of the high number of missing entries for these characters in the matrix. According to Blest and Pomeroy (1978) *Haplinis* is unique among linyphiids in having an expansion of the palp prior to its locking to the female genitalia, while in the remaining linyphiids for which this trait is known the male first locks its palp to the epigynum and then expands the haematodocha. However, in a recent study on African linyphiids Scharff (1990:62) described a similar expansion prior to locking for *Neriene kibonotensis* (Tullgren). More data on the distribution of this character are needed in order to establish it as a mynoglenine synapomorphy.

Erigonine monophyly is supported by the retrolateral tibial apophysis of the male palp, the loss of the female palpal claw, and the desmitracheate tracheal system (*sensu* Millidge, 1984). In the present dataset the epigynal atrium (character 33) is the only synapomorphy supporting the monophyly of Linyphiini. An epigynal atrium is also present in the mynoglenine genus *Haplinis* (Blest, 1979:100) but absent in *Novafroneta* (Millidge 1984:241). The cladogram suggests independent origins for these two atria; its homology is therefore questionable (similar epigynal atria are also present in other linyphiids, not included here, that are not closely related to the Linyphiini; Millidge, 1984; van Helsdingen, *in litt.*). Three synapomorphies support the monophyly of Micronetini: the paracymbial apophyses, a short embolus (it also occurs in *Erigone*), and the presence of Fickert's gland in the radix.

The nature of the clypeal glands is another interesting problem in linyphiid evolution. Whether the mynoglenine sub-ocular sulci are or are not homologous to the male erigonine post-ocular sulci is a matter of debate. Mynoglenine sub-ocular sulci are found both in males and females (they are very similar in both sexes; juveniles also have functional sulci, at least in the species of *Haplinis* studied by Blest and Taylor, 1977), they do not play any active role during the courtship (at least in the species studied by Blest and Pomeroy, 1978), and they probably elaborate defensive secretions (Blest and Taylor, 1977; but this latter hypothesis has not been empirically tested, although the unique ultrastructure of the clypeal secretory cells is consistent with the synthesis of a toxic product). On the other hand, erigonine post-ocular sulci (as well as the cephalic elevations) are found (mostly) in adult males. These erigonine sulci usually have pores associated with glands that are cytologically different from those of the mynoglenine sulci (Blest and Taylor, 1977; Schaible *et al.*, 1986; Schaible and Gack, 1987), and they play an active mechanical role during the courtship (they are gripped by the female cheliceral fangs). Nevertheless, these erigonine glands are not always associated with cephalic specializations. Mynoglenine and erigonine ocular sulci can be interpreted as homologous structures within the same transformation series or as two independent developments. The available evidence is not easily interpreted in either way. The mynoglenine and erigonine sulci differ in their position, in the cytological structure of their associated glands, and in their behavioral role. It seems that the available data argue against the homology hypothesis, since they fail to meet the classical homology criteria of position and detailed similarity. Congruence with other character systems offers a powerful test of the homology hypothesis of the sulci. Blest (1979:165) argued that the most economical hypothesis (i.e. parsimonious) 'would suggest that the sulci of the mynoglenine type gave rise directly to the kind found in Erigoninae'. Mapping his hypothesis on his cladogram (*op. cit.*, p. 172, which in parenthi-

cal notation can be summarized as: Mynogleninae (Linyphiinae, Erigoninae)) requires the gain of the mynoglenine type of sulci in the common ancestor of all linyphiids, profound modifications (morphological, cytological, and behavioral) of the sulci to achieve the erigonine type of sulci (either in the ancestral erigonines or at the level of the linyphiine-erigonine ancestor) and finally the loss of the sulci (and its accompanying glands and behavior) in the linyphiines. The alternative hypothesis (i.e. non homology of mynoglenine and erigonine sulci) maps on the mentioned cladogram as two independent gains of the two types of sulci. The evolution in parallel of the erigonine and mynoglenine sulci would then account for their differences. Although the latter hypothesis is more parsimonious (in both Blest's and my cladogram) this question cannot be truly tested until more data (taxa, particularly those with any type of sulci and/or glands, and information on the glands) are included in the data set. This is due to the effect that mynoglenine and erigonine cladogram topologies might have on the optimization of the character(s) on the linyphiid cladogram. Only then we will be able to asses alternative hypotheses on the evolution of these cephalothoracic specializations.

The linyphiid tracheal system needs to be studied in detail and re-evaluated. New morphological descriptions are needed, since at least some of the available comparative data are inaccurate (see above). Millidge's (1986, figure 12) scheme for the evolution of the tracheal system in linyphiids is therefore not valid, because it is partially based on inaccurate data.

The most parsimonious hypothesis to explain the data presented in this study is the cladogram depicted in Figure 1, which suggests (as well as the three equally parsimonious alternatives that exist) relationships different from those proposed by Wunderlich (1986:106). The mynoglenines are considered here to be relatively basal linyphiids, while Wunderlich suggested them as sister to the erigonines. Both hypotheses agree on considering the pimoids and *Stemonyphantes* as the most basal clades, and on the monophyly of the Micronetini plus the Linyphiini. To use either of these two phylogenies as a classification would be premature. Wunderlich did not explicitly list the synapomorphies that define the monophyletic groups in his cladogram, synapomorphies are mixed up with diagnostic characters (some of which are not synapomorphic), and there is no mention of the genera included in each monophyletic group, even in a schematic manner. My study should be considered only a preliminary sketch of linyphiid relationships. Clearly, a much larger sample of taxa is needed before the main monophyletic groups can be established. The addition of new taxa and new characters might affect the cladogram topology presented here. As we have seen, non-homoplasious characters for wide ranges of taxa are more the exception than the rule, and different character systems often delimit conflicting monophyletic groups. When large numbers of taxa and characters are studied quantitative studies are imperative. Cladistic studies provide explicit and testable hypotheses of relationship and are recognized as the most reliable method for retrieving the phylogenetic pattern that underlies organic diversity. Not until this approach is adopted will advances in linyphiid higher classification become a reality.

ACKNOWLEDGEMENTS

I am indebted to Drs. J.A. Coddington, C. Mitter, C.E. Griswold, N.I. Platnick, and N. Scharff for helpful discussion and comments on an earlier version of this manuscript. Financial support for this study was provided by the University of Maryland and the Smithsonian Institution.

CRITERIA FOR IDENTIFYING THERMAL BEHAVIOUR IN SPIDERS: A LOW TECHNOLOGY APPROACH

W.F. HUMPHREYS

Humphreys, W.F. 1993 11 11: Criteria for identifying thermal behaviour in spiders: a low technology approach. *Memoirs of the Queensland Museum* 33(2): 543-550. Brisbane. ISSN 0079-8835.

The widespread occurrence of thermal behaviour in diurnally active web spiders is either largely ignored or not recognised. Thus it obfuscates some explanations of the function of the stabilimentum on spiders webs. Thermal behaviours of four spiders (*Nephila edulis*, *N. maculata*, *Gasteracantha minax* and *Neogea* sp.) are examined using technology which is often inappropriate for field studies. Many thermal behaviours are recognised as well as behaviours which facilitate thermal behaviour. The thermal correlates of these behaviours are established. Some observational criteria are derived, which require only simple equipment, by which thermal behaviours may be recognised in the field and distinguished from other behavioural patterns.□*Araneae, orb-weavers, thermal behaviour, thermoregulation, stabilimentum.*

W.F. Humphreys, Western Australian Museum, Francis Street, Perth, Western Australia 6000, Australia; *26 October, 1992.*

Many orb-web spiders remain active at the web hub during the day, where they can continue to feed, mate, and defend their web site from the same and other species, as well as produce or respond to attractant signals (acoustic, tactile, visual or chemical). The seasonal and diurnal duration of this activity can be extended by adopting behaviours that warm the spider (Robinson and Robinson, 1974, 1978; Biere and Uetz, 1981) when it would otherwise be too cold or else that prevent it from overheating (Lubin and Henschel, 1990; Humphreys, 1978, 1987a, 1991, 1992).

I consider below mainly behaviours that prevent overheating. In essence, in hot weather the spider postures so as to align the long axis of its body with the sun's rays and in this position it tracks the sun's apparent movement during the day. Such behaviour is not exclusive to spiders of open country nor in tropical climates but is found also in both temperate and tropical forest spiders (Biere and Uetz, 1981; Humphreys, 1991, 1992 and unpublished). The standard interpretation of this thermal behaviour relies on a simple physical model; posturing minimises the projected surface area (silhouette) exposed to the sun's radiation and so reduces the heat load (Fig. 1), lowering equilibrium body temperature (Willmer and Unwin, 1981: but see Humphreys, 1986) or, in an anti-predator hypothesis, minimising the silhouette against the brightest background, else the body area most brightly illuminated.

Recent observations have shed some light on this seemingly simple process and revealed a sequence of behaviours serving to reduce progressively the heat loading, behaviours that are themselves mostly graded (Humphreys, 1992). These include stilting, drooping, orientation, front leg raising, abdomen pointing, posturing, front leg rotation and web abandonment. Associated behaviours include silk laying and agitation (Humphreys, 1992 and unpublished). In addition, the use of a disc stabilimentum as a sun shade, suggested by Robinson and Robinson (1973: 283), is an effective thermal behaviour in *Neogea* sp. (Humphreys, 1992). Such behaviours not only maintain the animal within its heat tolerance range, but also serve to maintain the body temperature (T_b) within a narrow range (presumably some optimum temperature) for extended periods of time (Humphreys, 1974, 1978, 1991). As body temperature has wide implications in physiological, behavioural, ecological and evolutionary contexts (Willmer, 1991), it is important to recognise thermal behaviour in spiders in order to allow different types of explanations for their behaviours.

That the thermal behaviour of spiders is not being recognised or is not being reported in the literature can be drawn from work on stabilimenta on spiders' webs. While stabilimenta have many different forms, they are mostly thought to provide mechanical support (Robinson and Robinson, 1973), to function as anti-predator devices (Eberhard, 1973, Edmunds and Edmunds, 1986; Lubin, 1986), to attract prey (Ewer, 1972; Craig and Bernard, 1990) or to collect water (Olive, 1980; see also Ewer, 1972; Robinson and Robinson, 1973: 283). *Neogea* sp. in

Papua New Guinea uses a disc stabilimentum as a parasol, which, together with a sequence of other behaviours, each themselves graded, reduces its heat loading (Humphreys, 1992). The demonstration that stabilimenta may be used in a thermoregulatory role raises questions concerning many observations which have been interpreted as supporting the anti-predator role of stabilimenta.

Some observations and deductions have resulted in an anti-predator function being ascribed to the stabilimentum. However, in the absence of other information, these observations are equally open to interpretation in terms of thermoregulatory hypotheses (see Humphreys, 1992). For example -1. Only spiders that remain at the hub of the web during the day produce stabilimenta (Eberhard, 1973). 2. Spiders with stabilimenta may shuttle from one side of the web to the other (*ibid.*). 3. The legs assume an 'aligned posture' by day but not by night (*ibid.*). 4. The amount of silk used is directly related to openness of the habitat (Marson, 1947).

Eberhard (1973) found that *Uloborus diversus* Marx used more silk in its stabilimentum on light than on dark nights (see also 4. above). The trend for larger stabilimentum at brighter sites camouflaged those spiders most susceptible to attack. However, without pertinent behavioural data, it is not possible to refute the hypothesis that the open sites are more exposed to direct sunlight and thus that the stabilimenta are used to protect the spider from ultra violet light (but see Craig and Bernard, 1990) or to reduce its heat load.

Posturing by spiders that remain by day at the web hub is rarely mentioned in the literature on stabilimenta and defense mechanisms. For example, although Edmunds and Edmunds (1986: 83) found that species of *Argiope*, *Nephila*, *Leucauge*, *Cyrtophora* and the Gasteracanthinae remain at the hub of the web during the day, they made no mention of posturing. In the Australasian region species in all these genera readily posture and track the sun (Humphreys, 1991, 1992; W.F. Humphreys, unpublished).

Clearly, thermoregulation hypotheses need more consideration in field studies of diurnally active spiders. More recently this has occurred (Henschel *et al.*, 1992; Humphreys, 1991, 1992; Lubin and Henschel, 1990; Ward and Henschel, 1992) but such studies often require expensive equipment to examine the thermal behaviour. Such equipment may be inappropriate to a field biologist primarily interested in observation and manipulation to examine behavioural or sociobiological problems. There needs to be some observational criteria using only low technology by which thermal behaviour may be recognised and distinguished from other behavioural patterns.

The examination of thermoregulation in orb-weaving spiders is problematical as most methods used on vagrant spiders (thermal preferendum apparatus, thermocouple implantation, temperature transmitters) are not appropriate. The most promising apparatus for such studies is the use of remote infrared telemetry (Suter, 1981; Humphreys, 1991, 1992), although model spiders may be effectively used to determine T_e (Riechert and Tracy, 1975; Henschel *et al.*, 1992).

Can criteria be established which would enable workers, using cheap and readily available equipment, to establish that spiders are behaving in a manner consistent with thermoregulation and to identify the thermal conditions under which they initiate such behaviour?

METHODS

Observations on *Nephila edulis* (Labillardière) were made both on Rottnest Island and in Perth, on *Gasteracantha minax* Thorell in the south-west, of Western Australia, and on *Nephila maculata* (Fabricius) in mangrove at Port Benoa, Bali, Indonesia.

Spider temperatures were recorded from 1100 -1500 hours using an infra-red thermometer, described elsewhere (Humphreys, 1991, 1992). The temperature was recorded of undisturbed spiders resting above and below the hub of the web, both in the shade and in the sun. It was recorded at intervals and as soon as possible (<3s) after a change in behaviour. Spider behaviour changed according to the incident light; this varied because the site was sometimes shaded by trees or by clouds. To induce more behavioural sequences the spider was sometimes shaded artificially and the direction and strength of the incident sunlight adjusted using a mirror. A plane mirror was used to alter the apparent position of the incident radiation at about the same intensity as the natural sunlight and a concave mirror was used to alter the apparent position of the incident radiation and at an intensity continuously variable from greater to less than the intensity of the direct sunlight. In the field, control of intensity was crude in the wind owing to movement of the web, and hence the spider; control of the intensity

Behaviour	Mean	s.d.	n	Range
Repose in shade	32.6 a	2.10	12	29.0-35.1
Repose in partial sun	32.4 ab	1.59	19	29.2-34.3
Repose in sun	35.0 b	1.66	47	31.6-38.3

TABLE 1. Mean temperature (T_b °C) of *N. edulis* in Repose position on Rottnest Island, Western Australia. T_b of spiders in Repose differs according to energy intensities of their location (shaded, partly shaded, sunlight: ANOVA - $F_{S\ 2,75} = 19.895$, $P<0.001$). Common letters include means not differing significantly (Fisher's PLSD at $\alpha= 0.05$).

of radiant energy is therefore relative and greater or less than the natural incident radiation.

The following temperatures are mentioned: T_a = of ambient shaded air; T_b = of the spider 's body which by default is the abdomen (T_{ab}), otherwise the thorax (T_{th}). The environmental temperature (T_e) which is used as a shorthand for the effective heat load on the spider taking account of all energy gains and losses. Means are followed in parentheses by the standard deviation of the mean, and sample size.

Definitions required for this discussion are given below (see also Humphreys, 1991, 1992).

Abandon web: the spider leaves the web, often after a sequence of very agitated movements, and moves to the shade provided by the objects to which the main anchor lines of the web are attached.

Abdomen pointing: the abdomen alone is orientated to the sun as a prelude to full posturing. This behaviour is strongly represented in some species (Humphreys, 1992).

Agitation and body lift: the spider appears agitated and circles its body around the web's hub and in the process the body is raised away from the web. The latter is sometimes seen on its own and they are included here under the same behaviour. This body lift is not comparable to stilting (Humphreys, 1992).

Drooping: the spider hangs limply from the back legs with apparent loss of hydrostatic pressure; the appearance is like that adopted by a spider immediately after moulting while the new cuticle is hardening.

Fabian position (Humphreys, 1991): the spider aligns its long axis parallel to the direction of incident sunlight with the prosoma facing away from the sun. This position may be achieved by orientation and/or posturing. When the incident sunlight is parallel to the web plane then the Fabian position may be the same as the Repose position (Humphreys, 1991). Continued adoption of the Fabian position results in the long axis of the spider tracking the sun during the day.

Front legs raised: legs I and II are raised off the web and aligned parallel to the incident radiation; this occurs as a graded sequence with the first pair being raised before the second pair.

Orientation: the angle of the saggital plane of the spider is rotated to lie parallel to the solar azimuth while the long axis of the body stays in the plane of the web.

Part orientation: the spider is not in the Repose position and has partly orientated its saggital plane between the Repose position and the orientated position.

Posturing: change in the angle between the web plane and the anterior-posterior axis of the spider.

Repose position: spiders occupy the lower or upper surface of the hub with the prosoma pointing downwards; the anterior-posterior axis of the spider is parallel to the plane of the web.

Rotate front legs: following front legs raising the legs are rotated forwards such that they are stretched out in front of the spider and lie in the shade of its body when it is fully postured; this may occur as a graded sequence with the first pair being rotated before the second pair.

Silk laying: adjusts the web stuctrure near the hub apparently to aid leg placement the better to posture and orientate to achieve the full Fabian position. This facilitates subsequent thermoregulatory behaviour but is not itself thermoregulatory.

Start to posture: when the spider changes the angle between its anterior-posterior axis and the plane of the web such that its long axis is parallel to the incident radiation.

Stilting: describes the 'standing on tiptoe' behaviour of scorpions used to prevent overheating (Alexander and Ewer, 1958); here it describes similar behaviour in spiders (Humphreys, 1992).

EVIDENCE

Statements otherwise unsupported are based on my unpublished observations.

Repose Position And Thermoregulation

Spiders adopt the repose position if T_e is below some critical level and they do so whether they are in shade or sun, hence, direct sunlight alone does not cause spiders to posture. However, T_b in sun is higher than in shade (Table 1). For example, during cool weather (low T_e) in the sun and during hot weather in the shade all individuals are in the Repose position on their webs if not otherwise engaged in activities such as mating, web building, etc.

When T_e is not sufficient to cause posturing in *G. minax* the proportion of spiders in the Repose

position during daylight does not differ between sunlit (36/38) and shaded (32/33) sites (χ^2_1 = 0.016, P= 0.90).

The mean T_b temperature of *N. edulis* in the Repose position was directly related to the intensity of the incident radiation such that spiders in the sun were hotter than partly or fully shaded spiders (Table 1).

Spiders on non-horizontal webs almost invariably rest on the underside of the web with the prosoma pointing down. However, spiders resting in positions other than the Repose position should not be taken as proof of thermoregulatory behaviour because some species, such as *Verrucosa* and *Cyclosa*, reputedly adopt a head up stance (Foelix, 1982: 139), as does *G. minax* at night and *Argyrodes antipodianus* O.P. Cambridge, generally.

Orientation and Posturing: Evidence for Thermoregulatory Function

In hot weather, spiders orient or posture on the web to attain the Fabian position and then track the sun's apparent movement. They do this irrespective of web orientation. Heat and sunlight are needed to obtain these behaviours. On very hot days, spiders may leave the web altogether and seek shade. Large spiders assume Fabian posture earlier than small ones possibly because under given environmental conditions large spiders reach higher body temperatures. However, small spiders may have lower threshold T_b's.

In hot weather an individual spider in the sun will use reorientation and/or posturing to align the anterior-posterior axis of its body parallel to the direction of incident sunlight with the prosoma facing away from the sun and thus achieve the Fabian position (Robinson and Robinson, 1974, 1978; Humphreys, 1991, 1992). The spider will adjust this position during the day and track the apparent movement of the sun (Humphreys, 1991).

In hot weather all individuals in the sun orientate in the same direction irrespective of the orientation of their webs; namely they all assume the Fabian position by posturing and/or reorientation (Humphreys, 1991).

Heat alone does not cause the thermal behaviour because in hot weather under heavily overcast conditions spiders do not assume the Fabian position. However, if intermittent direct sunlight strikes the spider it assumes the Fabian position intermittently.

On very hot days spiders may assume the Fabian position in the morning and afternoon but leave the web to seek shade during the middle of the day. Such activity patterns have been reported for many heliothermal spiders (Humphreys, 1978, 1987a, 1987b) and other taxa (e.g. reptiles: Heatwole, 1970).

N. edulis abandons the web at 44.8°C (±0.50, 3) and moves into shade. In Perth, Western Australia, when the shaded air temperature was extreme (46.2°C) many *N. edulis* failed to seek cooler places and fell dead from their shaded webs through heat stress (G.A. Harold, pers. comm., 1991).

Large spiders assume the Fabian position earlier in the day than do small spiders (e.g., *N. maculata*)–this is consistent with the thermoregulation hypothesis because larger bodies have a higher temperature excess (Willmer and Unwin, 1981). However, the threshold temperatures for given behaviours could be size related and lower in small than in large spiders. This is consistent with the seeming generality that the tolerance zones of animals are related to the temperatures experienced. For example, very small *N. edulis* start to posture at 36.0°C (±2.39, 4), significantly cooler, by an average of 4.4°C ($Fs_{1,25}$ =13.279, p=0.002), than adult spiders undergoing the same behaviour (40.4°C ±2.16, 27).

Orientation and Posturing in Response to Manipulation

Experiments with redirected and intensified sunlight can be conducted to influence the behaviour of spiders to assist in determining whether the behaviour is thermoregulatory without having to measure body temperature. The results are consistent for several species including *Arachnura higginsi*, *N. edulis*, *N. maculata*, *G. minax* and *Neogea* sp.

In cool sunny weather when the spiders are in the Repose position, additional heating (by concentrating redirected sunlight using a concave mirror), results in the spider orientating–and/or posturing if necessary–to assume the Fabian position. The redirected sunlight does not alone alter the behaviour of the spider (sunlight redirected at natural intensity using a plane mirror). Hence, posturing is dependent on the intensity of the heat applied.

In hot weather a spider which has assumed the Fabian position will resume the Repose position if clouds obscure the sun or it is artificially shaded even if lower than the natural insolation is reflected onto it by means of a concave mirror.

Spiders in the Fabian position in the sun will, if artificially shaded, assume a new Fabian position

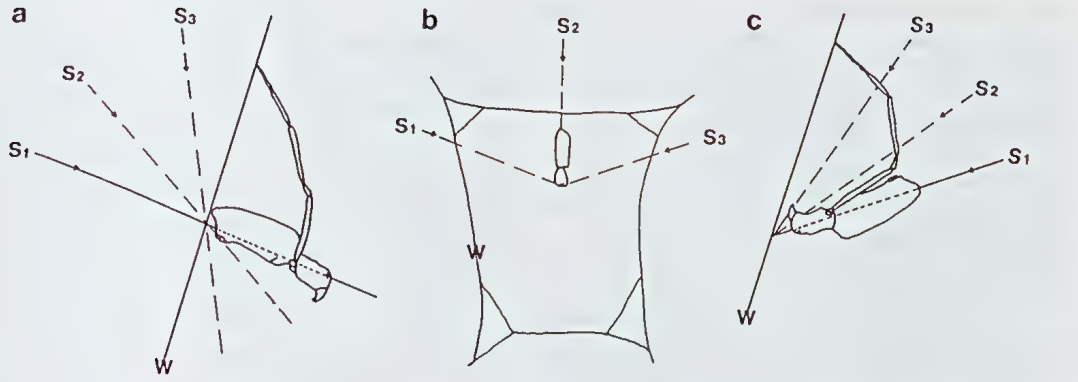

FIG. 1. Thermoregulatory postures adopted by golden web spider, *N. clavipes*. Lines projecting from three successive positions of sun (*S1*, *S2*, *S3*) indicate corresponding orientations of long axis of spider's body. Lateral views (a,c) and plan view (b) of web show posture assumed in response to ventral (through the web) insolation; b lateral insolation; c dorsal insolation (redrawn from Robinson and Robinson, 1974).

if the direction of the sun is artificially changed by means of a mirror.

In hot weather when the spiders are in the Repose position in the shade, redirection of unconcentrated sunlight, by means of a plane mirror or a concave mirror, results in the spider orientating and/or posturing if necessary to assume the Fabian position.

In hot weather, when the spiders are in a Fabian position, adding reflected sunlight from a plane mirror results in the spider orientating with respect to the mean angular direction of the two sources of incident radiation (when angle <90°). A spider posturing between two heat sources will turn towards the one increased in intensity and *vice versa*. Hence, the Fabian position moves towards the incident radiation of the mirror if the heat reflected from the mirror is increased and towards incident radiation of the sun if the heat reflected from the mirror is decreased.

If redirected light comes from above the horizontal plane of the web spiders rapidly change their Fabian position; if redirected light comes from below the horizontal plane of the web, a naturally impossible position, spiders appear confused and change position frequently and some species never achieve the Fabian position (e.g. *N. maculata*).

Cascading Behaviours

Many thermally related behaviours that have been categorised are themselves graded so that they each develop progressively rather than switch from one state to another.

For example as *Neogea* sp. warms in the sun, it exhibits a progression of distinct behaviours, each of which is graded and which are associated with increasing temperature of the abdomen (Humphreys, 1992). When a spider in the Repose position on the disc stabilimentum is heated by the sun it initially 'stilts', as has been described for scorpions. The spider gradually raises its body away from the disc surface until it has full downward extension of all legs and seems to be standing on 'tiptoe', thus removing the body of the spider as far as possible from the disc's surface.

On further heating, *Neogea* sp. progressively orientates its body and then gradually postures, starting with the abdomen. It rotates the tip of the abdomen towards the incident radiation and this minimises the projected surface area of the abdomen exposed to the sun. As the posturing develops the prosoma also is aligned with the abdomen so that the entire spider is orientated prosoma from the sun with minimal silhouette area exposed. Eventually the legs themselves are rotated forwards until they are parallel to the long axis of the spider in which position they are in the shadow of the abdomen, as is the prosoma; this is the full Fabian Position from which the spider tracks the sun (Humphreys, 1991, 1992). By these means the spiders potentially can obtain very fine control of their silhouette area and hence on their temperature.

In *N. edulis* many behaviours were recognisable as similar to those observed in other spiders (e.g. orientation, posturing, agitation: Humphreys, 1991, 1992), whereas others have not previously been reported or recognised (e.g. drooping). Some behaviours recognised may be components of the same behavioural sequence. For example, Agitation, in which the spider circles around the hub, involves the body being raised slightly from the

web, a behaviour sometimes seen on its own. Both behaviours are included here under the same category. Thermally there appears little difference between three categories recognised here as different behaviours (agitation and body lift, front legs raised, and start to posture). Work conducted under more controlled conditions in the laboratory may separate thermally these behaviours or allow their pooling using more rigorous criteria.

Eleven behavioural categories are recognised in *N. edulis*, ranging from Repose to web abandonment which occur between T_b of 33.9 and 44.8°C (Table 2). The spider temperature associated with many of these behaviours is significantly different from others. Some of these behaviours reduce the projected body surface area exposed to the sun and thus, under the predictions of the physical model, should result in lower equilibrium body temperature, all else being equal (e.g. orientation, posturing, leg raising, leg rotation and web abandonment). Other behaviours may not be thermoregulatory but are associated with the onset of the next behaviour in the graded series (e.g. agitation and body lift) or facilitate a subsequent stage (e.g. silk laying to enable correct leg placement for full posturing).

As in *Neogea* sp. (Humphreys, 1992), some behaviours themselves form a graded series which should proffer gradually increased thermoregulatory effects. Both front leg raising and front leg rotation occur initially in the front legs followed by the second pair of legs. In addition contralateral legs are not necessarily lifted or rotated at the same time.

Behaviour	Mean	s.d.	n	Range
Repose - see Table 1	—	—	—	
Part orientation	33.9	0.57	6	33.1-34.7
Drooping	36.5	1.57	8	35.4-38.8
Orientation	38.7a	2.30	9	34.2-40.3
Agitation and body lift	38.7a	2.09	21	35.2-43.5
Front legs raised	38.9a	2.84	11	35.0-43.3
Start to posture	40.4b	2.16	27	34.8-43.6
Silk laying	41.1bc	1.34	6	39.3-42.6
Rotate front legs	42.4cd	0.99	10	41.2-44.3
Abandon web	44.8d	0.50	3	44.3-45.3

TABLE 2. Mean temperature (T_b °C) of *N. edulis* on Rottnest Island, Western Australia, associated with different behaviours (ANOVA - $F_{8,93} = 15.233$, $P<0.001$). Common letters include means not differing significantly (Fisher's PLSD at $\alpha= 0.05$).

DISCUSSION

Two classes of observation refute the hypothesis that posturing serves an anti-predator role as stated in the introduction.

Firstly, if the Fabian position reduce the silhouette area against the brightest part of the sky as an anti-predator defense (i.e. to make them less visible) then they should posture to the sun under clear conditions irrespective of the intensity of the sunlight; they do not. Furthermore, under conditions of patchy heavy clouds (cumulus and cumulo-status) against a clear sky, the spiders should assume a Fabian position with respect to the brightest sector of the sky; they do not.

Secondly, many thermally related behaviours are themselves graded so that they are exhibited progressively as the spider warms. This provides the strongest evidence for the thermoregulation hypothesis because partial stilting, posturing or orientation (Humphreys, 1992) makes no sense under alternative hypotheses but is entirely consistent with, and predicted from, the thermoregulation hypothesis.

The body temperature of a spider is a complex function of many intrinsic factors (size, morphology, attitude, physiology, reflectance, etc.) as well as factors extrinsic to the individual (e.g. wind speed, turbulence, air temperature, incident radiation and its spectral characteristics; Monteith and Unsworth, 1990). It is because T_b is a complex function of intrinsic and extrinsic factors that makes T_a a poor predictor of thermal behaviour. Hence, the observation that a spider may not always assume the Fabian position (or other presumptive thermoregulatory behaviour) at the same T_a does not imply that the behaviour has no thermoregulatory significance. For example, *Lycosa godeffroyi* Koch in Canberra began basking at much lower T_a in winter (4°C) than in summer (17°C) and reached 35°C on clear winter days at T_a of 11°C (Humphreys, 1974, 1978); the latter shows the dominant role of boundary layer effects for such surface dwelling spiders. Although orb-weaving spiders are often high above the ground, such boundary layers may assume more importance in those orb weaving spiders that incorporate a surface in their web (e.g. *Neogea* sp. and leaf curling species; Humphreys, 1992).

These many classes of observation support the hypothesis that the posturing and/or reorientation that spiders undergo in intense sunlight is of thermoregulatory significance. Many are not alone adequate to support unequivocally the thermoregulation hypothesis (e.g. Table 3: 4, 6 , 9), some, in combination with others, support the

Condition at spider	Manipulation	Behavioural response and thermal consequences
1[a] Cool weather in shade	Nil	Repose; $T_b=T_a$

TABLE 3. Summary of characteristics of thermoregulatory behaviour in orb-weaving spiders. *Definitions*: Spiders assume Fabian position in hot but not in cold weather. S denotes sunlight redirected onto the spider at about intensity of natural sunlight using a plane mirror (=*S*) or at greater or less than natural intensity using a concave mirror (>*S* or < *S*). The spider is simultaneously artificially shaded (*s*) or not (*S*). Numbers with * are considered alone, and numbers followed by common letters are considered together, to support strongly the thermoregulation hypothesis.

hypothesis (e.g. 1-7), while others support no other hypothesis (e.g. 15).

While the emphasis here has been on behaviours that reduce the heat load, spiders should use behaviours to warm them in order to enhance the time they are at optimal temperatures. This is the case in burrow dwelling lycosids (Humphreys, 1974, 1978, 1987a, 1987b) as well as in orb web spiders which may seasonally orientate their webs to maximise the projected surface area to warm more or faster (Carrell, 1978; Tolbert, 1979).

While there is an indication of size related effects in thermoregulatory behaviour in *Nephila* spp., as may be expected theoretically using a simple physical model, no such size effect was observed in *Stegodyphus lineatus* Latreille (Henschel *et al.*, 1992).

While the thermal behaviour of spiders is much more sophisticated than has been accepted, the presumed advantages of such fine tuning are not understood. None the less, the recognition of such behaviour is an important aspect of field studies and the means to do so are required, especially for smaller spiders which are intractable subjects for direct recording of temperature in the field. However, the sensible use of this schema should allow easy appraisal of the overt body positions of spiders in the field as to their likely thermoregulatory significance and it should assist in disentangling thermoregulatory from other behaviours.

A thermoregulator with the battery of finely graded behaviours seen here should, under ideal conditions, be able to maintain a near constant body temperature under a wide range of environmental conditions. In practice their temperatures fluctuate markedly with every air movement, at least partly owing to their small thermal capacity. If the spiders are innately incapable, owing to their small mass, of precise thermoregulation, why have they developed such a wide range of sophisticated behaviours which should permit precise thermoregulation?

ACKNOWLEDGEMENTS

It is a pleasure to acknowledge the occasional assistance of Rae Young in the field and the Young family for allowing me to work on their property 'Mandalay'. I thank Mark Elgar and Yael Lubin for their many constructive comments. Some of this work was undertaken during the tenure of a Christensen Research Institute Fellowship and with the approval of the Madang Provincial Council; the advice and assistance of Matthew Jebb and his staff is greatly appreciated. The work was funded by the Australian Research Grants Scheme (#D181/15274) and the Australian Research Council (#A18831977 and #A18932024).

HYPERTROPHY OF MALE GENITALIA IN SOUTH AMERICAN AND AUSTRALIAN TRIAENONYCHIDAE (ARACHNIDA: OPILIONES: LANIATORES)

GLENN S. HUNT AND EMILIO A. MAURY

Hunt, G.S. and Maury, E.A. 1993 11 11: Hypertrophy of male genitalia in South American and Australian Triaenonychidae (Arachnida: Opiliones: Laniatores). *Memoirs of the Queensland Museum* 33(2): 551-556. Brisbane. ISSN 0079-8835.

Hypertrophy of male genitalic elements, particularly the stylus, is described and discussed. A stylus is regarded as hypertrophied if stylus length is sub-equal to or longer than truncus length. Greatest hypertrophy occurs in the Australian species *Cluniella distincta* Forster (stylus x4.5 truncus) and a new genus, new species from South America (x2.5 truncus). Other species discussed are *Araucanobunus juberthiei* Muñoz-Cuevas from South America, and *C. minuta* Forster, *Rhynchobunus arrogans* Hickman, *Tasmanobunus parvus* Hickman, *Tasmanonuncia* sp., *Allobunus distinctus* Hickman and *Thelbunus mirabilis* Hickman from Australia. To accommodate an elongate stylus, the truncus is often shortened, and the genital operculum and sternum modified so that the genital orifice is located more anteriad. Hypertrophy of the stylus may be associated with the hypertrophy or reduction of other terminal elements. In *Cluniella* spp. and the two South American species penetration of the stylus occurs along a very long vagina; the spermathecae are situated at the base of the ovipositor. Hypertrophy may have evolved as a consequence of sexual selection. □*Opiliones, Triaenonychidae, male genitalia, hypertrophy, morphology, sexual selection.*

Glenn S. Hunt, Division of Invertebrate Zoology, Australian Museum, P.O. Box A285, Sydney South, New South Wales, 2000, Australia; Emilio A. Maury, Museo Argentino de Ciencias Naturales 'Bernardino Rivadavia', Casilla de Correo 220 Sucursal 5, 1405 Buenos Aires, Argentina; 3 November, 1992.

The triaenonychid penis comprises a basal truncus supporting an apical complex which includes the stylus and associated plates, processes and setae. In the primitive condition, three sets of plates are present (Fig. 1A): the dorsolateral plates which are embryologically derived from the truncus and the dorsal plate and ventral plate embryologically related to the stylus (Martens, 1986). Both the dorsal and ventral plates were apparently primitively paired but are now fused, at least basally. The ventral plate carries setae. Certain taxa have undergone loss or reduction of plates (Martens, 1986; Hunt and Hickman, 1993). A few taxa have undergone extreme hypertrophy in the length of the stylus with one or more of the associated plates frequently showing correlated hypertrophy, or reduction, depending on the taxon.

HYPERTROPHIED STRUCTURES

CLUNIELLA SPP.

The most extreme hypertrophy of the stylus known for the family occurs in *Cluniella distincta* Forster, 1955 of SE Queensland and NE New South Wales (Fig. 2A). The stylus is x4.5 truncus length. There is correlated morphological change in the female where spermathecae occur basally in the ovipositor (Fig. 5C), unlike the usual condition where the spermathecae occur sub-apically. Therefore, the long stylus probably penetrates almost the whole length of the ovipositor to reach the spermathecae. The dorsolateral plates of the penis are elongate, gradually tapering to x2 ventral plate length (Fig. 2B). The dorsal plate is either lacking or intimately fused with the stylus; the latter is suggested by the subterminal lateral processes on the stylus which may be homologous to terminations of the dorsal plate (see *Thelbunus mirabilis* below, Fig. 5A). The ventral plate is reduced in size, and the number of inferior setae is reduced from three to two pairs.

The extreme stylus is accommodated within the body by shortening of the truncus, and by elongation of the genital operculum and posterior invagination of the sternum which together shift the genital opening anteriad. The sternum margins tend to follow the genital operculum (Fig. 5E; cf. female genitosternal region, Fig. 5F) but when the operculum is lifted the shape resembles that in Fig. 5H.

Cluniella minuta Forster, 1955, which overlaps in distribution with *C. distincta*, has undergone less radical elongation of the stylus (Figs 2C-D). Nevertheless, the stylus is x1.4 truncus length. The spermathecae are also basal despite the

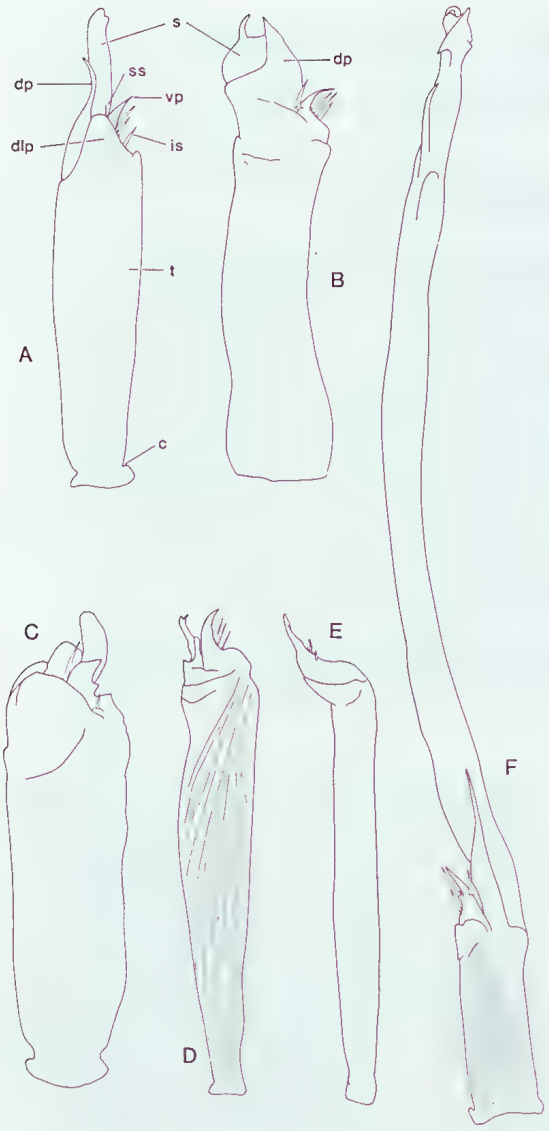

FIG. 1. Variation in ♂ genitalia of some Australian Triaenonychidae. shorter stylus. The dorsolateral plates are elongated to a similar extent to *C. distincta* while the ventral plate, though reduced, bears 3 pairs of inferior setae. The truncus is less shortened, the genital operculum is not elongate and the sternum is long and narrow. In both species, the constriction in the truncus where penis sheath membranes attach is basal.

The differences between the two species are not due to infraspecific variation, such as male dimorphism reported in some Australian genera (Hunt, 1985). Characters distinguishing *C. minuta* include a very long calcaneus compared with astragalus in leg I.

Araucanobunus juberthiei Muñoz-Cuevas, and New Genus, New Species (Maury, in prep.)

A. juberthiei from southern South America shows moderate hypertrophy of the stylus with stylus length about 1.3 truncus length (Figs 3A-B). An undescribed species referrable to a new genus (Maury, in prep.), but apparently with close genitalic affinities to *A. juberthiei*, has undergone greater hypertrophy with stylus length x2.5 truncus length (Fig. 3C). The dorsolateral plates are present in both species, but the dorsal plate is apparently lost (or intimately united with the stylus). The truncus in the undescribed species is greatly shortened, in *A. juberthiei* much less so.

Both species have an elongate genital operculum and a short, subtriangular sternum (for example, see Figs 5G-I). When closed, the genital operculum virtually obliterates the sternum.

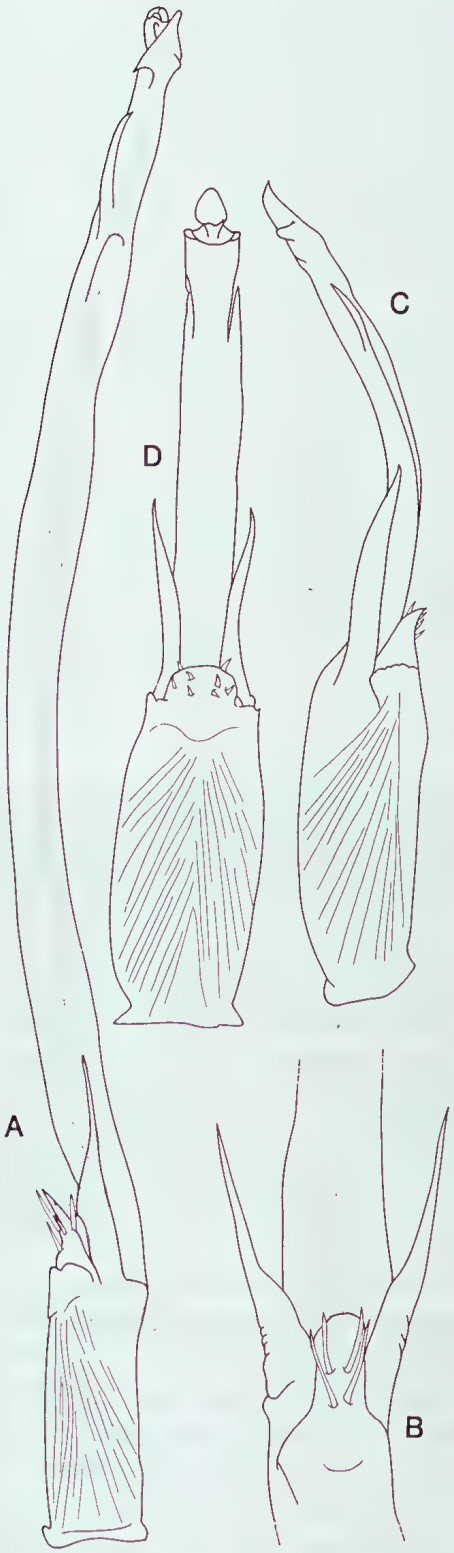
Unlike the condition in *Cluniella*, the constriction is situated mid-way along the truncus in both species (Figs 3A-D). As in *Cluniella*, the spermathecae are situated at the base of the ovipositor at the end of a long vagina (Fig. 5D: *A. juberthiei).* There appear to be no significant infraspecific variations in size or shape of the genitalia in these species.

Rhynchobunus arrogans Hickman

This species, from NE Tasmania, also has a prominent constriction at about mid-way along the truncus (Fig. 4A). *R. arrogans* belongs to a lineage distinguished by loss of the dorsolateral plates. The dorsal plate envelopes the stylus basally and terminates ventral to it. *R. arrogans* is very close to, if not congeneric with, *Glyptobunus signatus* Roewer (Hunt, in prep.). The stylus is x1.3 truncus length. The spermathecae are subterminal. The ventral plate is reduced but still carries the normal complement of setae for this lineage (Figs 4A-B). *R. arrogans* has an elongate genital operculum but lacks a triangular sternum.

Tasmanobunus parvus Hickman

This species is closely allied to, or possibly congeneric with, *R. arrogans* and *G. signatus* as



it lacks dorsolateral plates, its stylus carries a subdistal dorsal barb, and the dorsal plate terminates ventral to the stylus (Figs 4C-D). The stylus is subequal in length to the truncus and the dorsal plate has undergone complementary elongation. The constriction around the truncus is more subdued and situated somewhat more basally.

Tasmanonuncia n.sp.

This species belongs to the same general lineage as *R. arrogans* in that it lacks dorsolateral plates (Hunt, in prep.). However, the stylus carries a subdistal dorsal tuft of hairs instead of a single barb (Figs 4E-F). Stylus length is subequal to truncus length and, as with *Tasmanobunus parvus*, the dorsal plate is greatly elongate.

Allobunus distinctus Hickman

A. distinctus, from NW Tasmania, has a prominent constriction mid-way along the truncus. The stylus is modestly elongate, being subequal in length to the truncus. The ventral plate, however, is hypertrophied, uniting with other sclerotisations to form an elongate cylinder around the proximal half of the stylus (Figs 4G-H). The male of *A. distinctus* has a triangular sternum and a moderately elongate genital operculum.

Thelbunus mirabilis Hickman

Unlike the *Rhynchobunus* lineage, this NE Tasmanian species belongs to a lineage with well developed dorsolateral plates. The stylus is hypertrophied but the problem of space is partly solved by the stylus being twice folded back on itself (Fig. 5A). The dorsal plate is also elongate and closely integrated with the stylus, bifurcating into two lobes just below the stylus tip. The ventral plate setae are greatly hypertrophied and differentiated into different forms (Fig. 5B). This species also has a short triangular sternum (though not unlike the female) and an elongate genital operculum (Figs 5J-K).

Thelbunus n.sp. has a less elaborate stylus and its sternum less modified and genital operculum less elongate (sternum illustrated in Fig. 6).

Other Opiliones

Hypertrophy of the stylus has also been recorded in the neopilionid *Ballarra* spp (suborder Palpatores) from Australia (Hunt and Coken-

FIG. 2. Hypertrophied ♂ genitalia of *Cluniella* spp. A, B: *C. distincta*, A = lateral, B = ventral view of ventral and dorsolateral plates. C, D: *C. minuta*, lateral and ventral.

dolpher, 1991). Unlike the situation in *Cluniella* spp. and the South American species, the spermathecae are greatly elongate, opening into a short vagina but ending basally in the ovipositor. The long stylus is presumably inserted down the elongate spermatheca, not an elongate vagina as occurs in *Cluniella*.

Other taxa exhibit elongation of the truncus, e.g., many species of the triaenonychid genus *Lomanella* (Hunt and Hickman, 1993).

DISCUSSION

An elongate stylus is frequently, but not invariably, associated with an elongation of the genital operculum and a shortening and broadening of the sternum which together serve to elongate the cavity in which the penis lies (also, shortening of the truncus may compensate for the elongate stylus).

These changes in genitosternal architecture seem to have arisen independently in several distantly related gerera. Within the one genus, both normal and hypertrophy-related genitosternal architecture can occur. For example, *Cluniella minuta* has evolved a moderately elongate stylus while retaining a 'normal' long, narrow sternum and rounded genital operculum. *C. distincta* has undergone much greater elongation of the stylus with consequent changes in the sternum and genital operculum.

It seems more probable that the situation in *C. minuta* is more 'primitive', while the syndrome of extreme characters in *C. distincta* represents a more derived condition. Thus, in the *Cluniella* lineage, space limitations of an elongate stylus

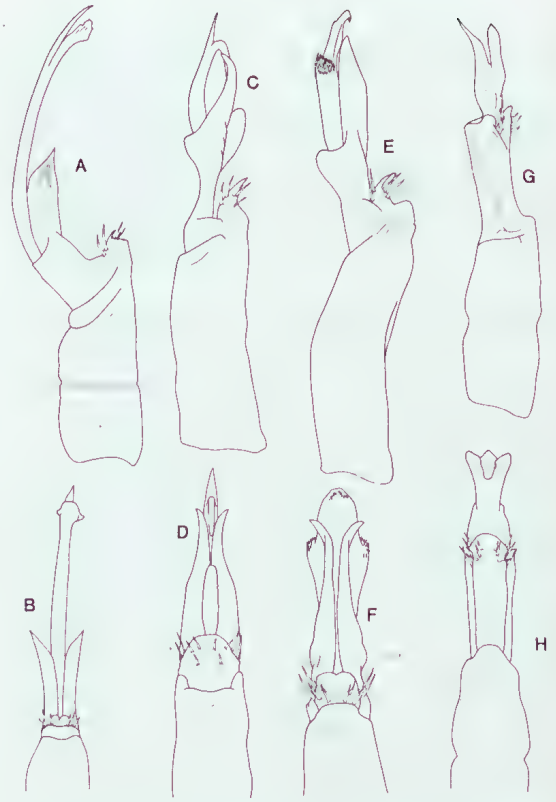

FIG. 4. Hypertrophied ♂ genitalia in Tasmanian Triaenonychidae. A, B: *Rhynchobunus arrogans*, lateral and ventral. C, D: *Tasmanobunus parvus*, lateral and ventral. E, F: *Tasmanonuncia* n.sp. (Hunt, in prep.), lateral and ventral. G, H: *Allobunus distinctus*, lateral and ventral.

seem initially accommodated by shortening of the truncus (*C. minuta* condition). Changes to the genital operculum and sternum evolved later.

Cluniella spp. and the two South American species described above show close correspondence in many features associated with stylus hypertrophy: great elongation of stylus, modification of sternum and genital operculum, shortening of truncus, and spermathecae situated basally in the ovipositor at the end of a very long vagina.

The question is whether these features indicate a close phylogenetic relationship or whether they are examples of convergence. The latter is supported because:

1. Modifications to genitosternal architecture appear to have arisen independently within the *Cluniella* lineage, evolving from the 'normal' condition as occurs in *C. minuta*.

2. Attachment of penis sheaths is basal in *Cluniella* and mesial in South American species.

3. The penes of the South American species

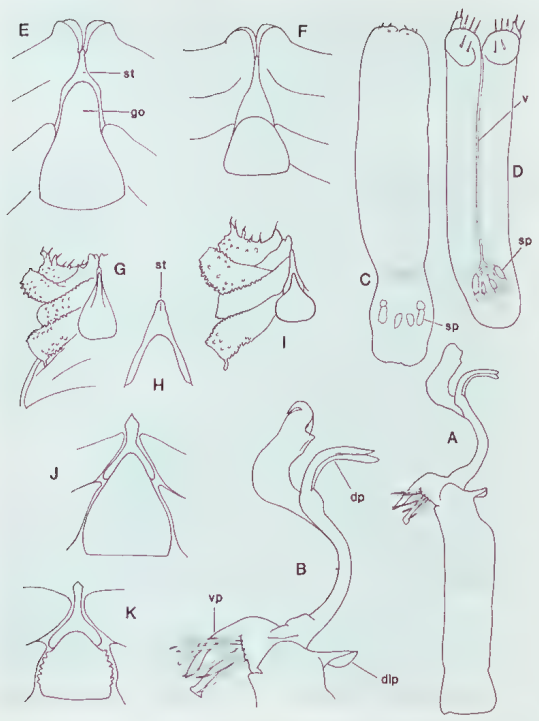

FIG. 5. Hypertrophy of genitalia in *Thelbunus mirabilis* and modified structures associated with genitalic hypertrophy in various Triaenonychidae. A, B: *T. mirabilis*, lateral and detail of lateral showing hypertrophy and modification of ventral plate setae. C,D: Ovipositor in *Cluniella distincta* and *Araucanobunus juberthiei* respectively showing basal seminal receptacles. E, F: Genitosternal region of *C. distincta*, ♂ and ♀ respectively. G, I: Genitosternal region of South American new genus, new species (Maury, in prep.), ♂ and ♀ respectively; H = shape of sternum in ♂ after genital operculum removed. show closer affinity with the South American genus *Triaenonychoides* (see Maury, 1987)) rather than with Australian genera.

4. Apart from the basal spermathecae and long vagina, the ovipositor of the South American species appears to be of the typical triaenonychid form. The ovipositor of both *Cluniella* spp. is highly derived in having a very membranous tip, in lacking well developed sensory lobes, and in carrying vestigial setae. In some specimens examined the membranous tip was inflated and had 'ballooned' out the genital orifice. This morphology suggests that the female may assist penetration by inflating the ovipositor so that it partly engulfs the stylus. Thus, assuming that the male *C. minuta* has not undergone a reversal in genitosternal architecture, the derived ovipositor seems to have evolved before shortening of the male sternum and elongation of the genital operculum.

Thus, the genomes of *Cluniella* and the two South American taxa have the capacity to allow quite remarkable convergence in a syndrome of characters. The overall effect appears the same, but the details differ.

Why have such vastly elongate styluses evolved, particularly to the extreme shown by *C. distincta*? Sexual selection by female choice is favoured by Eberhard (1985) as the most generally applicable explanation for 'extravagant' genitalia. Eberhard proposes that 'male genitalia function as 'internal courtship'. devices to increase the likelihood that females will actually use a given male's sperm to fertilize her eggs rather than those of another male'. In the case of *Cluniella* and the South American species, it is postulated that males with the largest styluses have greater success than males with smaller styluses and hence contribute more of their genes to the next generation. The genitalia may stimulate the female prior to or during copulation and so activate the appropriate responses, or it might provide the right mechanical and sensory 'fit' during copulation. The basal spermathecae in the ovipositor of *Cluniella* spp. and the two South American species (and the long stylus matching the long spermathecae in *Ballarra* spp.) suggest that the correct mechanical fit may at least be part of the answer.

A search for congeners and an analysis of inter- and intraspecific variation, as well as behavioural studies, may yield further data to resolve these questions.

ACKNOWLEDGEMENTS

PREDATOR-PREY CO-EVOLUTION OF *PORTIA FIMBRIATA* AND *EURYATTUS* SP., JUMPING SPIDERS FROM QUEENSLAND

ROBERT R. JACKSON AND R. STIMSON WILCOX

Jackson, R.R. and Wilcox, R.S. 1993 11 11: Predator-prey co-evolution of *Portia fimbriata* and *Euryattus* sp., jumping spiders from Queensland. *Memoirs of the Queensland Museum* **33**(2): 557-560. Brisbane. ISSN 0079-8835.

Portia is a salticid that preys on other spiders and *Euryattus* sp. is a salticid that nests inside suspended rolled-up leaves. *Portia* and *Euryattus* are sympatric at a site near Cairns but not known to be sympatric at other sites studied. *Portia* from the Cairns site practices a unique prey-specific predatory behaviour against *Euryattus*, and *Euryattus* from this site is efficient at detecting and defending itself against *Portia*. *Euryattus*, but not *Portia*, is present at a site near Davies Creek which, although only ca 15km from the Cairns site, is more xeric and at a higher elevation. Three types of tests were carried out to compare *Portia*'s efficiency at catching adult allopatric versus sympatric *Euryattus* (Test 1), allopatric *Euryattus* juveniles versus juveniles of another salticid species on which *Portia* is known to prey (Test 2) and allopatric versus sympatric *Euryattus* juveniles (Test 3). In these tests, *Portia* behaved similarly toward allopatric (Davies Creek) and sympatric (Cairns) *Euryattus*, except that it attacked and killed allopatric more often than sympatric *Euryattus*. Allopatric *Euryattus*, in contrast to Cairns *Euryattus*, appeared not to recognize an approaching *Portia* as a predator.□*Portia fimbriata, Euryattus, Jacksonoides, co-evolution, allopatry, sympatry.*

Robert R. Jackson, Department of Zoology, University of Canterbury, Christchurch 1, New Zealand; R. Stimson Wilcox, Department of Biological Sciences, State University of New York at Binghamton, Binghamton, New York 13902-6000, U.S.A.; *30 November, 1992.*

Portia is a genus of specialized jumping spiders (Salticidae) that prey on other spiders (Jackson and Hallas, 1986). *Portia* is a detritus mimic and has a unique, slow, choppy style of locomotion that seems to preserve its crypsis. There are seven described species of *Portia*, distributed in the tropics of Africa, Asia, and Australasia (Wanless, 1978). A population of *Portia fimbriata* (Doleschall) in Queensland uses specialized behaviour to catch other species of salticids (Jackson and Blest, 1982). This population of *P. fimbriata* also uses a prey-specific predatory behaviour against females of a particular sympatric salticid, *Euryattus* sp. (Jackson and Wilcox, 1990).

Euryattus females suspend a dead, rolled-up leaf by strong guylines from rock ledges and tree trunks, then use the leaf as a nest (Jackson, 1985). *Portia* has never been observed to attempt to catch *Euryattus* by going inside the rolled-up leaf. However, in Queensland, *P. fimbriata* uses vibratory displays to lure *Euryattus* females from their nests (Jackson and Wilcox, 1990). These displays apparently mimic courtship displays of *Euryattus* males (Wilcox and Jackson, unpubl. data). Other species of *Portia* and populations of *P. fimbriata* in areas from which *Euryattus* is absent do not perform these displays (Jackson and Wilcox, 1990).

Queensland *P. fimbriata* will wait for hours at a time for *Euryattus* to come out of its nest (Jackson and Wilcox, 1990). Often, *Euryattus* actively defends itself by leaping at *Portia* and driving it away (Jackson and Wilcox, 1990). This is unusual behaviour for a salticid. From thousands of observations of interactions between *P. fimbriata* and many different species of salticids (Jackson and Hallas, 1986), it is evident that *Euryattus* is more efficient than other salticids at recognizing and defending itself against an approaching *Portia*. Also, in laboratory tests (Jackson and Wilcox, 1990), *Euryattus* readily recognized an approaching *Portia* as a potential predator, whereas *Jacksonoides queenslandica*, another salticid on which *P. fimbriata* feeds (Jackson and Blest, 1982), did not recognize *P. fimbriata*. This suggests an evolutionary 'arms race' (sensu Dawkins and Krebs, 1979) between *Euryattus* and *P. fimbriata*. Frequent predation by *P. fimbriata* on *Euryattus* may have favoured special abilities in *Euryattus* to recognize and defend itself against *P. fimbriata*. This, in turn, may have resulted in the evolution of refinements of *P. fimbriata*'s predatory behaviour. To test this hypothesis, we must compare the behaviour of *Euryattus* in populations with and without *Portia*. Recently, such an opportunity arose when *Euryattus* were found in an area in which *Portia* was not known.

MATERIALS AND METHODS

Cages, maintenance, terminology, basic testing procedures and analysis are given in Jackson and Wilcox (1990). Laboratory cultures of sympatric *Euryattus*, *J. queenslandica* and *P. fimbriata* were established, using spiders collected from rainforest near Cairns at about sea level (see Jackson, 1985; Jackson and Hallas, 1986). A laboratory culture of allopatric *Euryattus* was established from spiders collected in an *Acacia-Eucalyptus* woodland beside Davies Creek, near Davies Creek National Park in the Atherton Tableland (about 15km from the study site near Cairns and at c. 500m elevation). *Portia* has never been recorded from this and other Atherton Tableland habitats (Wanless, 1978; Jackson, unpubl. data). Unless noted otherwise, all spiders tested were reared in the laboratory from eggs of field-collected spiders. No individual spiders were used in more than one test. In this paper, we refer to *Euryattus* from Cairns and Davies Creek as 'sympatric *Euryattus*' and 'allopatric *Euryattus*', respectively. There were no evident differences related to general behaviour between these two populations of *Euryattus*. In particular, similar leaves were suspended by females for nests and males courted with similar vibratory displays.

The systematics of the genus *Euryattus* remains uncertain. Whether the two populations of *Euryattus* we studied are one or two different species is not now known. Voucher specimens were deposited at the Florida Collection of Arthropods (Gainesville) and the Queensland Museum.

We conducted three tests. In Test 1, *Portia* was given access to an adult allopatric *Euryattus* female in her nest. In Test 2, on alternate days, *Portia* was given access to a juvenile (2-3mm in body length) allopatric *Euryattus* and a juvenile (2-3mm) *J. queenslandica* in a bare cage (i.e., no nest or other objects present). In Test 3, on alternate days, *Portia* had access to a juvenile (2-3mm) of an allopatric and a juvenile of a sympatric *Euryattus* in a bare cage. To begin each type of test, *Portia* was placed into a cage containing the other spider shortly after lights came on in the laboratory (0800 hours). Spiders were observed continuously until predation occurred or until 4h had elapsed. Each test was either identical or at least similar to tests carried out previously (Jackson and Wilcox, 1990).

Data from Test 1 using allopatric *Euryattus* adults were compared to data from the identical type of tests using sympatric *Euryattus* adults in an earlier study (Jackson and Wilcox, 1990) to see whether *Portia*'s capture efficiency against allopatric *Euryattus* adults was greater than against sympatric *Euryattus* adults. Test 2 using allopatric *Euryattus* juveniles was compared to type 2 tests in Jackson and Wilcox (1990) using sympatric *Euryattus* juveniles and *J. queenslandica* juveniles. We already know that *Portia* captures *J. queenslandica* juveniles more efficiently than it captures sympatric *Euryattus* juveniles (Jackson and Wilcox, 1990). Here we examine whether *Portia*'s capture efficiencies against these two salticids vary when *Euryattus* is allopatric. Test 3 enabled us to compare *Portia*'s efficiency at capturing allopatric and sympatric *Euryattus* juveniles.

Adult body length is c.8mm for both *J. queenslandica* and *P. fimbriata* and for both populations of *Euryattus*. Jackson and Wilcox (1990) used three size classes, defined by the ratio of prey to predator body volume, when testing *P. fimbriata* with juvenile salticids: small (0.1-0.25), medium (0.5-1), and large (1.5-2). Only two of these (medium and large) were used here.

McNemar tests for significance of changes were used for statistical analyses of the results from Tests 2 and 3, these tests being designed as paired comparisons (Sokal and Rohlf, 1981): each individual *Portia* was used in one test with one salticid and another test with the other salticid 48 h earlier or later (decided randomly). Yates' corrections were applied to the McNemar tests, and the Bonferroni adjustment (see Rice, 1989) was made to significance levels whenever single data sets were used in multiple comparisons.

RESULTS

Test 1: *Euryattus* Adult in Nest

P. fimbriata behaved similarly toward allopatric (herein) and sympatric (Jackson and Wilcox, 1990) *Euryattus*, except that it attacked and killed allopatric *Euryattus* more frequently than sympatric *Euryattus* (Fig. 1, test of independence, $P<0.01$). Allopatric *Euryattus* appeared less prone than sympatric *Euryattus* to recognize *P. fimbriata* as a predator: 85% of the *P. fimbriata* got onto the leaf with allopatric *Euryattus*, but only 43% got onto the leaf with sympatric *Euryattus*; 23% of sympatric *Euryattus*, but only 4% of allopatric *Euryattus*, drove *P. fimbriata* away (Fig. 1).

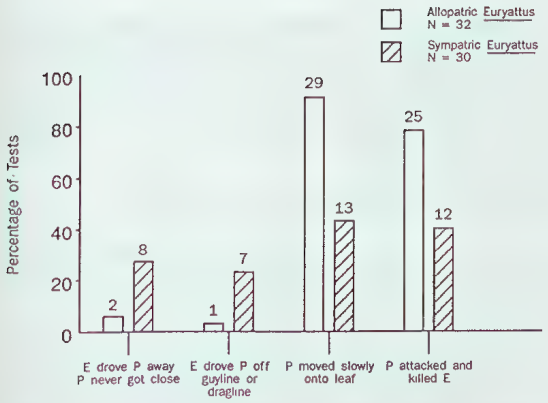

FIG. 1. *P. fimbriata* (P) tested with adult allopatric (Davies Creek) and sympatric (Crystal Cascades) *Euryattus* females (E) in suspended, rolled-up leaves. Data for sympatric *Euryattus* from Jackson and Wilcox (1990). Close: on leaf or guyline connected to leaf, or dropping on dragline toward leaf. For each outcome of test, number given above bar and percentage is read from axis.

Test 2: Juvenile *Euryattus* and *Jacksonoides queenslandica*

There was no evidence that *Portia* captured or stalked *J. queenslandica* more frequently than allopatric *Euryattus* (Figs 2, 3, McNemar tests, NS). Allopatric *Euryattus* did not appear to recognize *Portia* as a predator any more readily than did *J. queenslandica*.

Test 3: Cairns and Davies Creek *Euryattus* Juveniles

There was no evidence that *Portia* stalked sympatric *Euryattus* any more frequently than allopatric *Euryattus*, but *Portia* caught allopatric

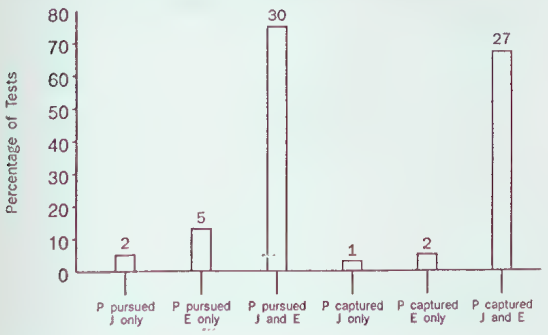

FIG. 2. Responses of *P. fimbriata* (P) to medium size (see text) allopatric *Euryattus* (E) and sympatric *J. queenslandica* (J). 40 paired tests: each *Portia* tested with one *Euryattus* and, on an alternate day, with one *Jacksonoides* (see text). Data for 'P pursued neither J nor E' and 'P captured neither J nor E' not displayed.

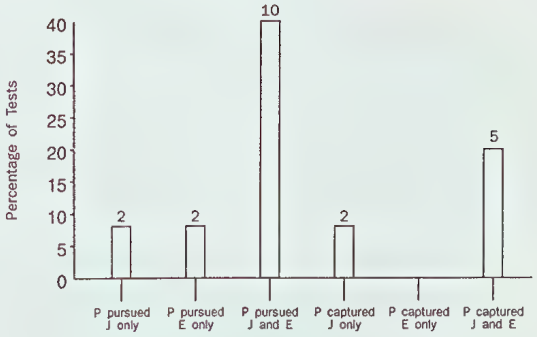

FIG. 3. Responses of *P. fimbriata* (P) tested with large (see text) allopatric *Euryattus* (E) and sympatric *J. queenslandica* (J). 25 paired tests: each *Portia* tested with one *Euryattus* and, on an alternate day, with one *Jacksonoides* (see text). Data for 'P pursued neither J nor E' and 'P captured neither J nor E' not displayed.

Euryattus more often that it caught sympatric *Euryattus* (Figs 4, 5).

DISCUSSION

Only one population of *Portia fimbriata* from Cairns studied (Jackson and Wilcox, 1990) is sympatric with *Euryattus*. *Euryattus* suspends a rolled-up leaf for a nest, and this is the only salticid sympatric with the Cairns *Portia*, or with any other *Portia* studied, known to do this. Only the Cairns *Portia* is known to use a prey-specific predatory behaviour against *Euryattus*. The sympatric (Jackson and Wilcox, 1990), but not the allopatric, *Euryattus* appears readily to recognize and defend itself against *Portia*. In fact, the al-

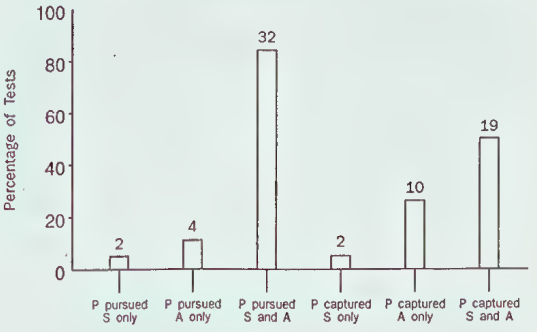

FIG. 4. Responses of *P. fimbriata* (P) to medium size (see text) sympatric (S) and allopatric (A) *Euryattus* sp. juveniles. 38 paired tests: each *Portia* tested with one sympatric and, on an alternate day, with one allopatric *Euryattus* (see text). Data for 'P pursued neither S nor A' and 'P captured neither S nor A' not displayed.

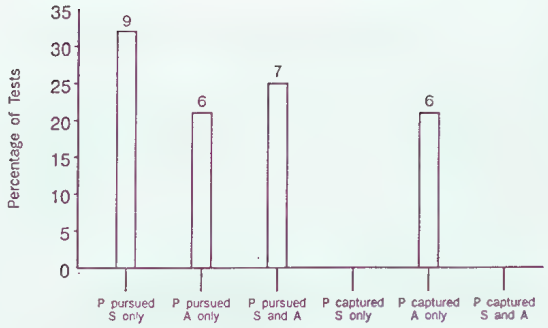

FIG. 5. Responses of *P. fimbriata* (P) to large (see text) sympatric (S) and allopatric (A) *Euryattus* sp. juveniles. 28 paired tests: each *Portia* tested with one sympatric and, on an alternate day, with one allopatric *Euryattus* (see text). Data for 'P pursued neither S nor A' and 'P captured neither S nor A' not displayed.

lopatric *Euryattus* appears to be no better than *J. queenslandica* at escaping predation by *Portia* , whereas *Portia* captured *J. queenslandica* more efficiently than it captured the sympatric *Euryattus* (Jackson and Wilcox, 1990). The ability of the Cairns *Euryattus* appears to be a predator-specific antipredator behaviour.

Population differences were evident despite there being no known prior experience of the predator by the prey or the prey by the predator under laboratory rearing conditions in this and the earlier (Jackson and Wilcox, 1990) study. These findings suggest that, in the Cairns area, *Portia* and *Euryattus* appear to have acted as selective agents on the evolution of each other's behaviour.

ACKNOWLEDGEMENTS

We thank Curt Lively, Mark Elgar and Marianne Willey for useful discussion and critical reading of the manuscript. Financial support was provided by grants from the National Geographic Society (3226-85) and the U.S.-New Zealand Cooperative Program of the National Science Foundation (NSF Grant BNS 8617078).

"WE'LL MEET AGAIN", AN EXPRESSION REMARKABLY APPLICABLE TO THE HISTORICAL BIOGEOGRAPHY OF AUSTRALIAN ZODARIIDAE (ARANEAE)

R. JOCQUÉ

Jocqué, R. 1993 11 11: "We'll meet again", an expression remarkably applicable to the historical biogeography of Australian Zodariidae (Araneae). *Memoirs of the Queensland Museum* 33: 561-564. Brisbane. ISSN 0079-8835.

The largest subfamily of the Zodariidae, the Zodariinae, contains 31 genera and has endemic representatives on all tropical continents. The sequence in this clade first indicates that the Australian zodariid fauna is the result of a combination of vicariance and dispersal events. Only three zodariid genera are not endemic to Australia. It is argued that two of these, *Mallinella* and *Asceua*, have reached Australia by dispersal over forest-covered areas. It is remarkable that the endemic Australian genera in the Zodariinae are more closely related to the African ones than are the Neotropical genera which is in contrast with the current ideas on chronology in plate tectonics. A possible explanation might be found in the past and present distribution of forests. The appearance of this type of vegetation on the Cretaceous-Tertiary boundary, might also be invoked to explain bipolar distributions in Africa.

La plus importante des sous-familles des Zodariidae, les Zodariinae, contient 31 genres, dont des endémiques sur chaque continent tropical. La séquence dans ce grand clade indique d'abord que la composition de la faune australienne serait le résultat d'une combinaison de vicariance et de dispersion. Seuls trois genres trouvés en Australie n'y sont pas endémiques. On avance l'argument selon lequel deux d'entre eux ont réussi à atteindre l'Australie par dispersion à travers des aires couvertes de forêts. Il est remarquable que les genres endémiques australiens soient plus proches des genres africains que de ceux d' Amérique du Sud ce qui contredit les idées courantes concernant la chronologie de la dérive des plaques. Une explication possible pourrait se trouver dans la distribution passée et actuelle des forêts équatoriales. La génèse de ce type de végétation, à la fin du Crétacé, pourrait également expliquer la distribution bipolaire de certaines vieilles lignées d'invertébrés. □*Africa, Gondwanaland, distribution, vicariance.*

Rudy Jocqué, Koninklijk Museum voor Midden-Afrika, B-3080 Tervuren, Belgium; 13 October, 1992.

The Zodariidae are a medium-size pantropical family of mainly nocturnal, ground-living spiders. Except for the members of the subfamily Storenomorphinae they are virtually all burrowers to some degree. Some simply dive into sand (*Psammoduon*) or hide in litter (*Asceua, Mallinella*) whereas others make a complex retreat consisting of a burrow with a trapdoor (*Psammorygma, Neostorena*) or an igloo-like construction of pebbles or grains of sand (*Diores, Zodarion*). This sedentary lifestyle and the fact that zodariids do not balloon explains why most species have small distribution ranges. It also makes them an ideal subject for zoogeographical studies, moreover since a cladistic analysis of the family is available (Jocqué, 1991).

THE AUSTRALIAN ZODARIIDAE

Most Australian zodariids, estimated at several hundred species, belong to genera endemic to the Australian continent. There is no trace of any representatives of these genera on any other continent (Table 1).

Genus	Distribution	Habitat
Asceua	Palaeotropics & Australia	circumforest
Asteron	Australia	steppe -woodland
Cyrioctea	southern Gondwana	dunes
Habronestes	Australia	steppe -woodland
Ishania	South and Central America	circumforest
Mallinella	Palaeotropics & Australia	tropical forest
Neostorena	Australia	steppe -woodland
Storena	Australia	steppe -woodland
Storosa	Australia	steppe -woodland
Tenedos	South and Central America	steppe -circumforest

TABLE 1. Distribution and habitat of some zodariid genera.

Three genera have representatives elsewhere and in fact have the centre of their distribution outside Australia. The first one is *Cyrioctea*, the only genus in the Cyriocteninae, found exclusively in sandy habitats such as arid dunes and sand deserts. It has a typical Gondwanan distribution

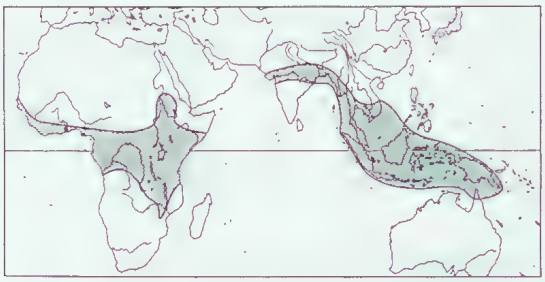

FIG. 1. Approximate distribution of *Mallinella*.

with representatives in South Africa, Chile and Australia (*Cyrioctea raveni* Platnick and Griffin). Both the other genera, *Mallinella* and *Asceua*, have an enormous distribution which appears to be linked with old world forests. One species of each has reached the northern tip of Australia.

The Australian zodariid fauna is thus apparently composed of three different stocks: a strictly endemic one, a southern Gondwanan one and a third element that could be quoted as old world forest fauna. To understand this composition we have to go back to an era before the breakup of Gondwanaland.

The Zodariidae indeed have a basic Gondwanan distribution with the more plesiomorphic taxa represented in Africa, Australia and South America. These are the Cyriocteinae, the Lachesaninae and the more plesiomorphic members of the Zodariinae. The latter taxon is now known to include what has been described as the subfamily Storeninae (Jocqué, 1991, 1992). Thirty-one out of 47 genera now belong in the Zodariinae. However, the more apomorphic members of the subfamily (Femoral Gland Clade or FGC), having several synapomorphies (femoral gland, lack of chilum, flattened incised hairs, fused chelicerae) are present only in Africa (including part of the Palaearctic) and tropical Asia. The same applies to the Storenomorphinae and the Cydrelinae which are restricted to tropical Africa and tropical Asia.

When Africa got finally separated from other major landmasses, slightly more than 100 mybp, these three groups were apparently not yet in existence. The bulk of the zodariid fauna outside that continent is therefore supposed to be derived of the plesiomorphic taxa present at the time of the split-off. However, from the above it is clear that India (and part of South East Asia ?) carried a much more modern assemblage of Zodariidae when it moved towards its present position. Indeed, there is no evidence that at least purely tropical forest organisms (e.g., *Mallinella*) originating in Africa, have been able to reach India via a northern itinerary. No forest connection has ever existed via the mediterranean and the Arabian peninsula. This paradox is discussed below.

Virtually all Zodariidae are restricted to habitats lying in a climatic zone with a marked dry season. In the Neotropics only a few species (in *Ishania* and *Tenedos*) seem to have adapted to moist forest and no zodariids have so far been found in Amazonia. In Australia no true forest-inhabiting species belonging to endemic genera appear to be present, although some species in the genera *Neostorena*, *Asteron*, *Storosa* and *Habronestes*, occur in dense woodland. But the most common and widely distributed forest inhabiting genus is doubtlessly *Mallinella*. This genus has an enormous distribution (Fig. 1): it occurs in virtually all African forests from Senegal in the west to the Chimanimani Mts. (Zimbabwe) (Jocqué, unpublished data) in the south and Kenya and Ethiopia in the east, but is remarkably absent from the South African forests which emphasizes its inability to cross unforested zones. It is present in montane rainforest in India and Nepal and occurs in virtually all dense forests in the Far East, as far as New Guinea. One species has reached the northeastern tip of Australia. This is apparently a very recent event as that species, *Mallinella zebra* Thorell, occurs on both New Guinea and Australia. Considering the fractionating of this genus in the rest of its distribution range and the fact that no speciation has occurred in this case, there is little doubt that the arrival occurred during the Pleistocene ice-ages, during which there was a land-bridge linking New-Guinea and Australia (Keast, 1983). A well documented case of a less recent Asian invader is that of *Tamopsis* (Hersiliidae) which is supposed to have arrived in northern Australia during the Miocene (Baehr, 1988). This relatively early arrival has resulted in clockwise colonization of almost the entire circumference of the Australian continent and the appearance of many strongly related species.

A second recent zodariid arrival is that of an undescribed species of *Asceua* (Jocqué, in preparation) which can be characterized as a circum-forest genus. Its ecological status is fairly similar to those genera mentioned above, which occasionally occur in dense woodland or even rainforest in the case of the South American *Ishania* and *Tenedos*. The distribution of *Asceua* (Fig. 2) is even larger than that of *Mallinella* and

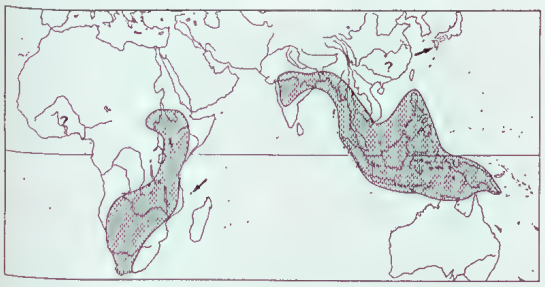

FIG. 2. Approximate distribution of *Asceua.*

the patterns overlap only partially. Although several Asian species are known to occur in rainforest (Bosmans and Hillyard, 1990; P. Schweninger pers. comm. 1989; C. Deeleman-Reinhold, pers. comm. 1988; J. Murphy, pers. com. 1988) no representatives are found in African lowland rainforest. On the other hand it is present in rather dry areas in southern Africa. Considering its very restricted distribution area in Australia, it is supposed to have arrived there at the same time as *Mallinella.*

Two closely related lines of zodariines which had been separated for about a hundred million years thus met again.

Assuming that *Mallinella* was initially better adapted to rainforest conditions, it would be interesting to study if the arrival of *Mallinella zebra* has induced a shift in the rest of the zodariid fauna in the area it now occupies, and whether it is still expanding.

GENERAL DISTRIBUTION OF THE ZODARIINAE

The monophyletic assemblage of the Zodariinae is largely composed of genera which are endemic to particular continents (Jocqué 1991, fig. 41). Remarkably, the African genera are apparently more closely related to the Australian Zodariinae than to those in South America. The five Neotropical genera are indeed near the root of the zodariine branch whereas the Australian ones are situated in between the Afrotropical and the Palaeotropical ones (the latter group has an apparently recent outflow into the Palaearctic). The reduced area-cladogram resulting from these relationships is given in Fig. 3. This statement is at least puzzling: it is in contrast with the timing of major plate tectonic events that caused the breakup of Gondwanaland, as deduced from geological data and corroborated by many biogeographical data (e.g. Nelson and Platnick, 1980). However, not only is there much controversy about the original position of many plates, the timing and the mechanics of the movement are also subject to a debate. The expansion theory of Carey (1975) and Shields (1979, 1983) positions several plates in different places than does the classical theory (Norton and Sclater, 1979; Owen, 1983). According to the latest data (Veevers *et al.*, 1991; Scotese *et al.*, 1988; Powell *et al.*, 1988) it appears that India split off from Gondwanaland together with the southern continents Australia and Antarctica. How then can one explain the fact that India and Sri Lanka share many apomorphic monophyletic taxa with Africa (e.g., *Hermippus*, Storenomorphinae, Cydrelinae, members of the FGC)? Briggs (1987) thinks that India, on its course to Asia, became again attached to north-east Africa by the end of the Cretaceous, a remarkable hypothesis that might explain the apparent faunal anomaly. It would certainly explain how forest dwelling spiders like *Mallinella* and *Asceua* have reached Asia.

The main question that is raised by the zodariid cladogram is why the Australian taxa are more strongly related to the African than to the South American ones.

A possible explanation is that the few typical forest inhabiting zodariid genera did only evolve after the main continents had broken away from Africa. Broad-leaved forests arose at least during the Cretaceous but became dominant in equatorial conditions on the Cretaceous-Tertiary boundary (Wolfe, 1987; Wolfe and Upchurch, 1986, 1987). It is strange that in the context of African biogeography no mention has been made of the dramatic shift that has been brought about by the appearance of broad-leaved evergreen forest. The conditions at ground level in this kind of forest and the former conifer forests were probably as different as they are for instance in present-day rainforest and miombo in Africa. The faunas of these vegetation types are equally very different. Dense miombo woodland and submontane evergreen forest within each other's sight on the Nyika Plateau in Malawi, contain completely different litter-layer spider faunas with hardly any genus overlap in the spider families that have been studied (Zodariidae, Linyphiidae, Lycosidae, Tetragnathidae; Jocqué, unpublished data).

The present day bipolar distribution of many ancient African taxa of ground-dwelling invertebrates might therefore be explained in the light of the evolution of broad-leaved rain forest

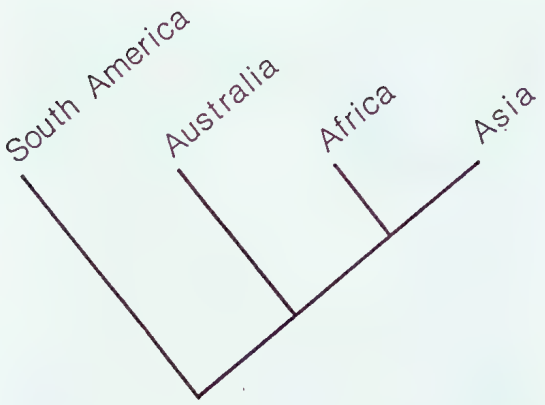

FIG. 3. Area cladogram of tropical continents as based on the clade of the Zodariinae.

during the Cretaceous. This novel type of vegetation with a very new structure and hence ecological conditions, split most existing taxocoenoses that had to adapt to the new forest conditions. In the Zodariidae only very few genera succeeded in doing so. In Africa only *Mallinella* really developed into a specialised forest spider genus.

The remote relationship of South American and African Zodariidae may well be the result of similar events at the time of the breakup of Gondwanaland favouring the dispersion of particular genera, hampering that of others.

BASIC ARCHITECTURE OF THE OVARY IN THE GOLDEN SILK SPIDER, *NEPHILA CLAVATA*

AKIO KONDO, EIKO CHAKI AND MITSUHIRO FUKUDA

Kondo, A., Chaki, E. and Fukuda, M. 1993 11 11: Basic architecture of the ovary in the golden silk spider, *Nephila clavata*. *Memoirs of the Queensland Museum* 33 (2): 565-570. Brisbane. ISSN 0079-8835.

In gravid females of the golden silk spider, *Nephila clavata* L. Koch, the ovaries are composed of flat cisternae. To clarify whether the cisternal structure is primarily or secondarily formed by pressure from mature eggs, ovary development was examined from early subadults to mature spiders. Serial paraffin sections of the early subadults definitely show that a pair of longitudinal furrows, presumptive lumina of the ovaries, lined with loose cell layers, penetrate perpendicularly into the ovarian tissue. So the basic architecture of the ovary in *N. clavata* is primarily flat cisterna.

Im Falle von reifen Weibchen von *Nephila clavata* setzen sich die Ovarien aus flachen Beuteln zusammen. Um herauszufinden, ob diese strukturelle Fläche angeboren ist oder durch den Druck der reifen Eiern gebildet wird, wurde die Entwicklung der Ovarien vom frühen Subadult bis zum reifen Adult untersucht. In den seriellen Paraffinstückchen vom frühen Subadult zeigte sich, daß ein Paar longitudinale Furchen, die mit zerstreuten Zellenschichten verstärkt wurden, d.h. die präsumptive Lumen, perpendiklar in die Ovariumgewebe gehen. Daraus kann man schließen, daß die Grundarchitektur von diesen Ovarien angeboren aus flachen Beuteln besteht. □*Spider, Nephila, ovary, histology.*

Akio Kondo, Eiko Chaki and Mitsuhiro Fukuda, Department of Biology, Faculty of Science, Toho University, 2-1, Miyama 2 chome, Funabashi-shi, Chiba, 274 Japan; 21 December 1992.

The golden silk spider, *Nephila clavata* L. Koch, is able to deposit egg masses twice (Kondo, 1988; Shimojana, 1971). Prior to the first oviposition, gravid females possess complicated ovaries whose lumina are expanded among mature eggs. After the second oviposition, the ovarian lumen of exhausted females is not closed and contains immature oocytes and yolk granule debris. In both cases, the basic architecture of the ovary is not clearly identified. In vigorous females immediately after first oviposition, the lumen of the ovary is completely closed and the ovarian epithelium protrudes many young oocytes into the body cavity. In this case the ovarian tubes elongate dorsally and ventrally to form flat cisternae, as if the lumina have been squeezed between mature eggs, already ovulated at the first oviposition, side by side (Kondo and Chaki, 1991).

Generally, however, the spiders have a pair of tubular ovaries or ring-like ovaries. The present study tries to clarify whether the cisternal architecture of the ovary of *N. clavata* is primarily or secondarily formed by pressure from mature eggs.

MATERIALS AND METHODS

Four female subadult and two adult *Nephila clavata* were collected in Funabashi, Central Japan, from late August to early September.

After removal of the cuticle, the entire body or the opisthosoma was fixed in FAA (formalin 5, ethanol 15, glacial acetic acid 1) for 5-21 hours, dehydrated in graded strength of ethanol, embedded in paraffin and sectioned at 6-10μm. Before sectioning, a cut surface of the sample containing mature eggs was treated with distilled water (Kondo, 1969). Serial paraffin sections were stained with Mayer's acid-haemalaum and eosin.

RESULTS

SUBADULTS

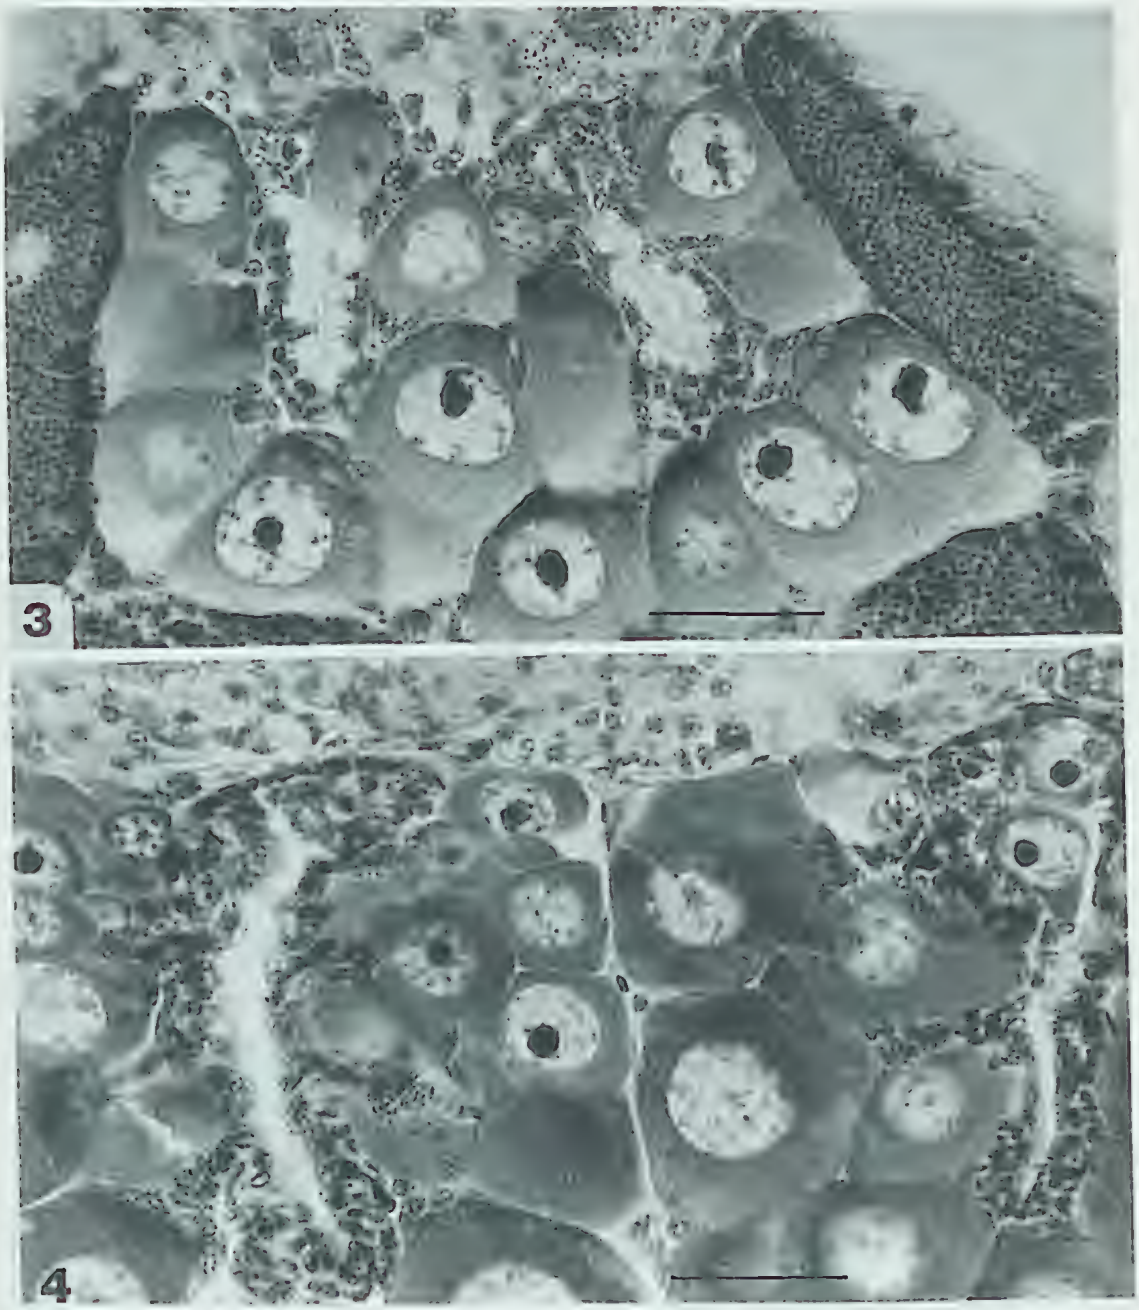
A pair of ovaries was situated behind the book lung extending to the cloacal sac and surrounded by the midgut glands dorsally and by silk glands laterally and ventrally (Figs 1, 2). Although the ovarian tissue was divided in two at the anterior and posterior ends, the left and right ovaries were not separated from each other and formed single rod-shaped tissue for the most part.

Maximum width and thickness of the ovarian tissue were 250μm and 150μm in a small subadult with cephalothorax 1.6 mm wide, 2.6 mm long, and 500μm and 220μm in a large subadult

FIGS 1, 2. 1. Longitudinal section of a large subadult.cs: cloacal sac, m: midgut, mg: midgut gland, ov: ovary, sg: silk gland. 2. Transversal section of a female immediately after final moulting. m: midgut, mg: midgut gland, ov:ovary, sg: silk gland. Scales: 0.5 mm.

whose cephalothorax was 2.8 mm and 4.2 mm respectively.

In transverse sections the ovarian tissue was trapezoidal. In a small subadult, two furrows lined with a loose cell layer penetrated from the upper side of the trapezoid into the ovarian tissue (Fig. 3). The loose cell layer may be the ovarian wall or the ovarian epithelium. Then the furrows seemed to be surrounded by a single layer of the oocytes. Most oocytes, whose cytoplasm was strongly basophilic, were cuboidal or polygonal and 40-50μm in diameter.

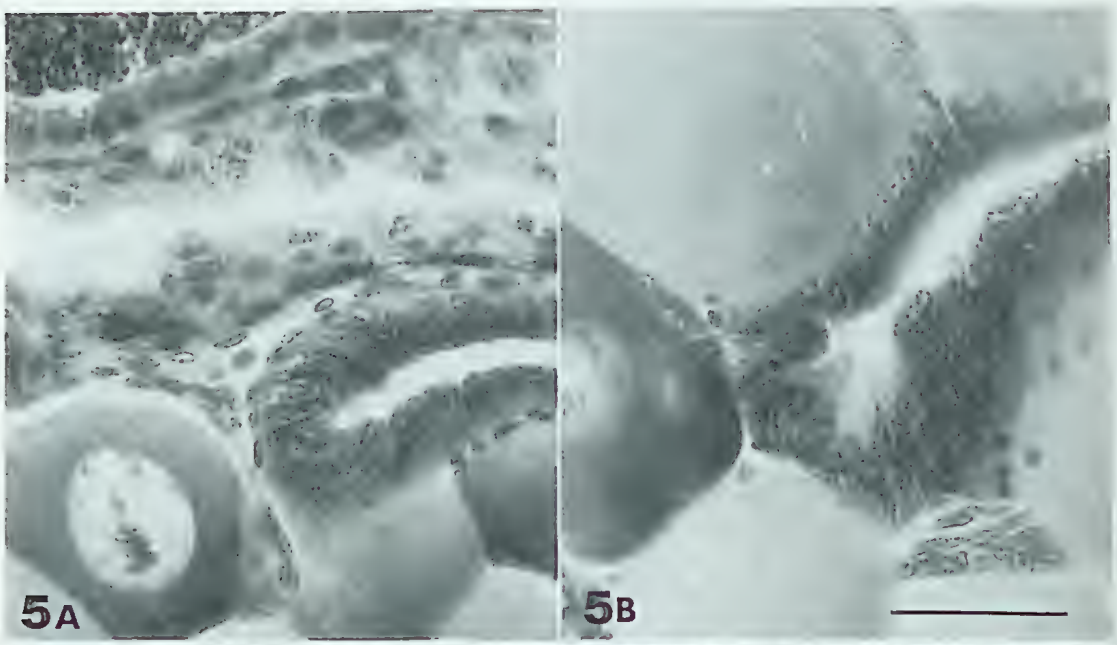


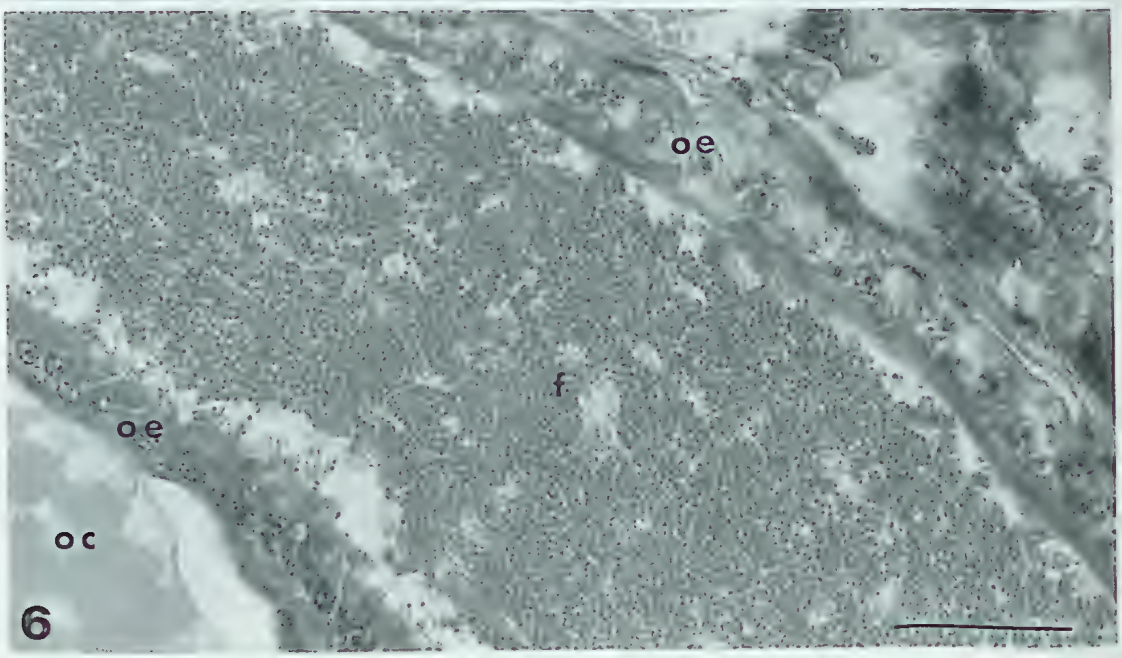
FIGS 3, 4. Transverse section of ovarian tissue in small subadult (3) and in large subadult (4). Scales: 50μm.

The spherical germinal vesicle was 25-35μm in diameter and contained an extremely basophilic and slightly eosinophilic nucleolus. Yolk granules had not formed. The vitelline body or Balbiani's yolk nucleus was not observed.

Each oocyte was connected with the ovarian wall through a short egg stalk or the funiculus. The cells constituting the ovarian wall were more or less columnar and had ellipsoidal nuclei in the basal part and vacuolated protoplasm in the distal part facing the presumptive lumen of the ovary.

In the large subadult, profiles of the oocytes closely resembled the oocytes in the small subadult, though they increased slightly in number





FIGS 5, 6. 5. Transverse section of ovary in female immediately after final moulting. A. Median dorsal part of ovary. B. Distal part of F-shaped lumen of ovary. 6. Lumen of ovary filled with eosinophilic fine granules in a gravid female. f: eosinophilic fine granules, oc: oocyte, oe: ovarian epithelium. Scales: 50µm.

and volume (Fig. 4). A prominent feature was the appearance of narrow lumina in the ovaries, while vacuolate cells in the ovarian wall remained in depth at both the anterior and posterior ends of the ovarian tissue.

ADULTS

In an adult presumably immediately after its final moult, the width of the entire ovaries was approximately 1.0 mm and the lumen of the ovary was F- or T-shaped, branching laterally (Fig. 2). The left and right ovarian epithelia were not

fused, but connected with the oviducts. Total number of oocytes counted in one female was 1,390 including the small oocytes. No oocytes were observed above the dorsal side of the horizontally developing lumina.

Oocytes reached a diameter of 170μm. Germinal vesicles were 40-60μm in diameter. The nucleolus was collapsed and dispersed into nucleoplasm. Cytoplasm of the oocyte was less basophilic (Fig. 2). The eosinophilic yolk granules were neither formed nor accumulated. The ovarian wall seemed to be a simple columnar or pseudostratified epithelium composed of slender, compactly arranged and extremely basophilic cells. Flat cells were lined up between the ovarian epithelium and the oocytes (Fig. 5).

In a gravid female whose ovaries reached 4.0 mm in width, the ovary contained many developing oocytes 380-460μm in diameter, and few immature oocytes. The developing oocytes were filled with eosinophilic yolk granules and had a germinal vesicle 50-60μm in diameter. The lumen of the ovary branches among the developing oocytes. The lumen of the ovary contained eosinophilic fine granules which were presumably a kind of cement substance used to hold the egg mass after oviposition (Fig. 6).

DISCUSSION

The formation of the ovary in *Nephila clavata* was examined from the early subadult stage. The small subadult employed was possibly a nymph of the 6th or 7th instar prior to the penultimate moult. In any case, at an early stage, the longitudinal ovarian walls arise as loose cell layers penetrating from the dorsal side of the ovarian tissue perpendicularly into the mass of the oocytes. The epithelial cells are vacuolated in their distal part and form a lumen which is I-shaped in transverse section. Then, the ovarian epithelium constructs flat rather than cylindrical cisternae.

By the final moult the lumina have been formed in the vacuolated portion of the ovarian epithelium. Immediately after the final moulting, while the oocytes increase in number and volume, a few branches of the lumen arise, mostly in the posterior half of the ovary, forming F- or T-shaped profiles in transverse sections. Simultaneously the oocytes grow and become less basophilic, perhaps due to a cytoplasmic increase. The loose cell layer in the small subadult transforms gradually into columnar epithelium composed of slender, compact and strongly basophilic cells by the final moult. Since the oocytes are connected with this epithelium through egg stalks, it seems to be the ovarian epithelium in the strict sense, though flat cells are aligned along the outside of this epithelium.

Subsequently the oocytes begin vitellogenesis and accumulate eosinophilic yolk granules in their cytoplasm. The lumina of the ovaries continues to branch amongst the oocytes and on the surface of the mass of the oocytes, and they are filled with eosinophilic fine granules which correspond to fine granules attaching to the surface of the chorion of the lycosid egg (Kondo, 1969), the spheres on the chorion (Humphreys, 1983, 1987) or cement substance of the egg mass (Kondo and Chaki, 1991).

In *N. clavata*, the ovarian epithelia of the left and right ovaries are not directly connected with each other, though in archaeid spiders they are connected through a bridge in the posterior portion of the ovaries to form a H-shaped organ (Traciuc and Legendre, 1970). Interstitial tissue, however, does not exist between the left and right ovaries, so the ovaries of *N. clavata* form a single rod-shaped organ. This rod-shaped structure was confirmed not only from both transverse and horizontal sections but also by dissection of the opisthosoma.

In conclusion, in *N. clavata* the basic architecture of the ovary is primarily composed of flat cisterna.

NEW PREY RECORDS FOR SPIDER HUNTING WASPS (HYMENOPTERA: POMPILIDAE) FROM THE NETHERLANDS

P. KOOMEN AND T.M.J. PEETERS

Koomen, P. and Peeters, T.M.J. 1993 11 11: New prey records for spider hunting wasps (Hymenoptera: Pompilidae) from The Netherlands. *Memoirs of the Queensland Museum* 33(2): 571-574. Brisbane. ISSN 0079-8835.

In the southern Netherlands, 56 spider prey were collected, and identified, together with their pompilid predators. Those data are compared with data from the literature for northwestern Europe. *Anoplius* spp. seem to prey mainly upon ground dwelling spiders. A strong preference for the wolf spider *Trochosa terricola* was found for *Anoplius viaticus*, in agreement with data from Bristowe (1948). *Episyron rufipes* and *Caliadurgus fasciatellus* attack only orbweb building spiders. Data for *Auplopus carbonarius* and *Dipogon subintermedius* suggest that these species prefer to hunt on vertical planes like tree-trunks. *Arachnospila rufa*, *Pompilus cinereus*, and *Priocnemis* spp. appear to be non-selective.

Dans le sud des Pays-Bas, 56 araignées, proies de Pompilides, on été récoltées avec leurs prédateurs et identifiées. Les données acquises ont été comparées avec les celles de la littérature concernant les observations réalisées aux Pays-Bas et dans les pays voisins. *Anoplius* spp. montre une nette prédilection pour les araignées terricoles. Conformément aux données de Bristowe (1948), *Anoplius viaticus* préfère de loin *Trochosa terricola*. *Episyron rufipes* et *Caliadurgus fasciatellus* s'attaquent seulement aux araignées qui construisent des toiles orbiculaires. Les observations sur *Auplopus carbonarius* et *Dipogon subintermedius* suggèrent que ces espèces chassent de préférence sur des plans verticaux comme des vieux murs ou des troncs d'arbres. *Arachnospila rufa*, *Pompilus cinereus* et les *Priocnemis* spp. semblent être des espèces non sélectives. □*Araneae, predation, Pompilidae, selectivity, The Netherlands.*

Peter Koomen, Havikshorst 34, NL-2317 AL Leiden, The Netherlands; Theo M.J. Peeters, P.O. Box 9258, NL-5000 HG Tilburg, The Netherlands; 6 November, 1992.

Female Pompilidae attack and paralyse spiders with their sting. Each captured spider is the food of a larva that hatches from an egg laid on the spider. Before oviposition, most European pompilids transport their prey to burrows excavated in the soil, or to pre-existing cavities, e.g., behind bark or between stones (Gauld & Bolton, 1988). Knowledge of pompilid prey is limited for obvious reasons: most hymenopterists are interested only in pompilids and not so much in their prey. Arachnologists tend to accept prey of Pompilidae gratefully, but without identifying their predators. As a consequence, data on prey hardly exist, are out of date and/or are unreliable because of changed taxonomic views, or do not go beyond generic level (e.g., Day, 1988; Oehlke and Wolf, 1987). However, collectively, all published data suggest some prey specialization, but it is not clear if this is due simply to opportunistic behaviour of pompilids, catching only (or mainly) the most abundant prey. A way to gather more knowledge concerning possible preferences of pompilids, is to catch pompilid predators *with* their prey, and to accurately identify them both. Autecological information on the spiders may give a clue as to whether pompilid species only catch what they can, or prefer, for some reason, some species of prey over others. This paper reports on the first results of such a study which began in 1987.

METHODS AND MATERIALS

Pompilids were studied at several locations, mainly in the southern Netherlands, near of Tilburg. Unless stated otherwise, the second author located pompilids by eye and intercepted prey-transporting females using glass tubes and an insect-net. Prey were collected and preserved in alcohol. Predators were collected only if identification in the field was not possible. Wasps were identified with the aid of Wolf (1972), Day (1988) and Oehlke and Wolf (1987). Identification of spiders was based mainly on Roberts (1985ab, 1987). Not all spiders could be identified to species level, because some were juvenile, thus lacking the genital organs necessary for a proper identification. Autecological data on spiders are derived from Jones (1983) and Maurer and Hänggi (1990). All spiders and wasps collected will be lodged in the National Museum of Natural History, Leiden, The Netherlands.

RESULTS

In total, 56 pompilid prey were collected. Data are summarized below. For each specimen the specific date and collecting site are given because both may have influenced hunting behaviour of the wasps. When more than one prey record is available for a single pompilid species, common characteristics of the prey are given that may point to a preference of the actual wasp.

POMPILINAE:

Anoplius concinnus (Dahlbom): *Pardosa* sp. (1 juv., Thorn, 13.x.1990); *Trochosa ruricola* (Degeer) (1♂, Thorn, 13.x.1990). Both are wolf spiders, Lycosidae. They were excavated from a, supposedly, single burrow between pebbles in a gravelpit, after a female *A. concinnus* had been observed showing nest building activity.

Anoplius infuscatus (Vander Linden): Lycosidae (1 juv., Moergestel, 30.iv.1988); *Alopecosa accentuata* (Latreille) (1 juv. Nieuw-Bergen, 6.ix.1991). Both are wolf spiders.

Anoplius viaticus (Linnaeus): *Agroeca brunnea* (Blackwall) (1♀, Beegden, 12.v.1991); *Trochosa terricola* Thorell (1♀ excavated, Alphen en Riel, 5.v.1989; 1♀+1♂, do., 3.v.1988; 1♀, 15.iv.1989, Apeldoorn; 7♀, Beegden, 12.v.1991; 1♀, Hilvarenbeek, 1.v.1988; 3♀+1♂, Berkel-Enschot, 5.v.1989; 1♀, Drunen, 9.v.1989; 1♀, Loon op Zand, 12.iv.1991; 1♀ excavated, Moergestel, 24.iv.1989; 2♀, do., 27.iv.1989; 2♀, do., Moergestel; 2♀, do., 5.v.1989; 1♀, do., 29.v.1989; 1♀, do., 23.vi.1989; 10♀+1♂, do., 29.iii.1990); *Pardosa monticola* (Clerck) (1♀, Beegden, 18.v.1989). All three species are ground dwelling spiders.

Arachnospila rufa (Haupt): *Alopecosa fabrilis* (Clerck) (1♂, Nieuw-Bergen, 1.ix.1991).

Auplopus carbonarius (Scopoli): *Haplodrassus* sp. (1 juv. found in a beehive in one of a group of barrel-shaped cells typical of *A. carbonarius* (Grandi, 1961: 75; Wahis, 1949: 99), Baarle-Nassau, 1991); *Clubiona brevipes* Blackwall (1♀, Udenhout, 11.viii.1990). Both are nocturnal hunters often hiding in silk retreats during the day.

Episyron rufipes (Linnaeus): *Larinioides cornutus* (Clerck) (1♀, Helvoirt, 16.viii.1991); *Nuctenea umbratica* (Clerck) (1 juv., Moergestel, 26.vi.1990). Both are orbweb building spiders.

Pompilus cinereus (Fabricius): Lycosidae (1 juv., Moergestel, 4.viii.1987).

PEPSINAE:

Caliadurgus fasciatellus (Spinola): *Agelenatea redii* (Scopoli) (1 juv., Moergestel, 4.x.1989).

Dipogon subintermedius (Magretti): *Segestria senoculata* (Linnaeus) (1♀ found in a cavity in an old pollard-willow (*Salix alba*), Tilburg, 23.vii.1991).

Priocnemis fennica Haupt: *Clubiona terrestris* Westring (1♀, Hilvarenbeek, 29.ix.1990).

Priocnemis minuta (Vander Linden): Gnaphosidae (1 juv., Moergestel, 17.viii.1988).

Priocnemis susterai Haupt: *Drassodes cupreus* (Blackwall) (1♀, Boxtel, 21.v.1988).

DISCUSSION

The new observations can be compared to data from the literature on pompilids in The Netherlands (Benno, 1969; Bouwman, 1915ab, 1916; Chrysanthus, 1947; Lefeber and Van Ooijen, 1988; Thijsse, 1907; Walrecht, 1936) and nearby countries (Bristowe, 1948; Day, 1981, 1988; Oehlke and Wolf, 1987; Wahis, 1948, 1955, 1962; Wolf, 1971). A summary with references included is given in Table 1. Comments for each pompilid species follow hereafter.

Anoplius concinnus was found with wolf spiders (Lycosidae) as prey. This is in agreement with the literature, where several genera of Lycosidae are mentioned.

Both in The Netherlands and in other countries, a preference for wolf spiders has been recorded for *Anoplius infuscatus*. Beside these, Thomisidae and Agelenidae are mentioned. Most members of these families are 'sit-and-wait' predators, but there are some exceptions, for instance *Thanatus* species and the males of *Textrix* species. So, the available data may point to a preference for ground dwelling spiders.

Anoplius viaticus appeared to prey almost exclusively on the wolf spider *Trochosa terricola* (Lycosidae). These observations are neither restricted to one locality, nor to a short period. Only in two of 41 cases (5%), *A. viaticus* caught other species: *Pardosa monticola* (Lycosidae) and *Agroeca brunnea* (Clubionidae). This suggests that *A. viaticus* did not simply catch the most abundant wandering spider, but rather searched actively for *T. terricola*. In literature on The Netherlands, the *Lycosa* sp. mentioned by Thijsse (1907) might refer to almost any modern lycosid genus. From data on prey elsewhere, the list given by Bristowe (1948) matches our data very well: he found in only seven of 47 cases (15%) prey that were not *Trochosa terricola*. However, other papers indicate several families and genera. Some are hunters by day like Lycosidae, while others are nocturnal hunters (*Drassodes*) or inhabitants of sheet webs (*Agelena*). Common attributes of the recorded spider genera are their medium to large size (5-13 mm) and the strata they occupy: on or near ground level. Most also prefer rather dry and/or sandy places as does *A. viaticus* (*Thanatus*, *Aelurillus*, *Pardosa monticola*, *Trochosa terricola*), but this is not true for

Predator	Prey
Anoplius concinnus	**Lycosidae** (D2): *Arctosa* (O&W), *Pardosa* sp. (K&P, L&VO, O&V), *Trochosa ruricola* (K&P)

Priocnemis minuta	**Gnaphosidae** (K&P).
Priocnemis susterai	**Gnaphosidae**: *Drassodes* (O&W), *D. cupreus* (K&P).

TABLE 1. Summary of the prey records in the literature for the pompilid species for which this study gives new data. References are abbreviated: B = Bristowe, 1948; Be = Benno, 1969; B1 = Bouwman, 1915b; B2 = Bouwman, 1916; C = Chrysanthus, 1947; D1 = Day, 1981; D2 = Day, 1988; K&P = Koomen & Peeters, this study; L&VO = Lefeber and Van Ooijen, 1988; O&W = Oehlke and Wolf, 1987; T = Thijsse, 1907; Wa = Walrecht, 1936; Wo = Wolf, 1971; W1 = Wahis, 1948; W2 = Wahis, 1955; W3 = Wahis, 1962.

Agroeca brunnea, an inhabitant of wet places. So, although our observations and Bristowe (1948) suggest a strong preference for only one species of Lycosidae, data from other countries show a much broader spectrum of prey. This may point to a preference for *Trochosa terricola*, that is abandoned when the latter species is not available.

Arachnospila rufa is not selective: spiders with various sizes, and from several habitats and strata have been recorded. Our observations support these data.

For *Auplopus carbonarius*, the observations that Segestriidae, *Clubiona brevipes*, Anyphaenidae, and *Dendryphantes* were prey items may point to a preference for spiders that walk along, or hide in crevices in, vertical planes, e.g. walls or tree-trunks. Species with (at least occasionally) similar habits are found in most of the other families and genera recorded (*Zoropsis*, *Aphantaulax*, *Haplodrassus*, *Philodromus*, *Evarcha*, *Sitticus*, *Agelena*, *Meta*), but without species identifications, the hypothesis that *A. carbonarius* is mainly a vertical hunter cannot be supported or falsified. Several authors note that *A. carbonarius* has a habit of amputating the legs of its preys (e.g., Grandi, 1961: fig. 48; Oehlke and Wolf, 1987). This did not occur in the two cases we noted. Both the *Haplodrassus* and the *Clubiona* prey still had all of their legs.

Episyron rufipes was found to prey upon two araneid spiders. Using data from other countries (see Table 1) it can be deduced that *E. rufipes* specializes on orbweb building spiders.

For *Pompilus cinereus* many different prey are known, including burrowing spiders (*Atypus*), orbweb building spiders (*Araneus*), and xerophylic (*Arctosa perita*, *Aelurillus*) and hygrophylic species (*Dolomedes*). This suggests no specificity at all. To date, only one juvenile wolf spider can be added.

Caliadurgus fasciatellus is a second pompilid species that is obviously specialized in capturing orbweb building spiders. The *Araneus redii* prey fits well within these data (Table 1).

The recorded prey of *Dipogon subintermedius*

are in conformity with its observed hunting places: tree-trunks and piles of fences. *Segestria senoculata* is known to build its retreat in these places, and jumping spiders from the genus *Salticus* may also be found there.

For the three species of *Priocnemis*, viz., *P. fennica*, *P. minuta*, and *P. susterai*, reliable data from the literature are few, because formerly these species were not distinguished as separate taxa. Prey recorded so far do not suggest any high degree of selectivity.

ACKNOWLEDGEMENTS

Messrs. Br. V. Lefeber (Maastricht), J. de Rond (Almere), and R. Wahis (Gembloux, Belgium) are thanked for their help in identifying the Pompilidae, and Mrs. J.D. Prinsen (Wageningen) for the identification of *Alopecosa fabrilis*. Messrs. J.E. de Oude (Den Haag) and R. Wahis are acknowledged for translating the summary into French. We thank Mr. J.C. Felton (Brighton, U.K.) for improving the English text.

GROUND-LIVING SPIDERS (ARANEAE) ONE YEAR AFTER FIRE IN THREE SUBARCTIC FOREST TYPES, QUÉBEC (CANADA)

SEPPO KOPONEN

Koponen, S. 1993 11 11: Ground-living spiders (Araneae) one year after fire in three subarctic forest types, Québec (Canada). *Memoirs of the Queensland Museum* **33**(2): 575-578. Brisbane. ISSN 0079-8835.

The ground-living spider fauna was studied one year after fire using pitfall traps in three forest types of subarctic Québec, July-August 1990. About 30 species, of the total 47 found at burned sites, were regarded as pioneer or colonizer species. Spiders captured commonly at burned sites included e.g. *Gnaphosa microps* Holm, *G. muscorum* (L. Koch), *Pardosa hyperborea* (Thorell), *P. uintana* Gertsch, *Trochosa terricola* Thorell, *Alopecosa aculeata* (Clerck), *Diplocentria bidentata* (Emerton), and *Sisis rotundus* (Emerton). Some species were found only or predominantly at unburned sites; e.g. *Pardosa moesta* Banks and *Lepthyphantes complicatus* (Emerton).

En juillet-août 1990, une année après des incendies, la faune des araignées habitant sur le sol des trois types de fôret du Québec subarctique a été étudiée en utilisant des pièges-fosses. Environ 30 espèces, d'un total de 47 trouvées dans les sites brûlés, ont été considerées comme des espèces pionnières ou colonisatrices. Les araignées capturées généralement dans les sites brûlés comprennent par exemple *Gnaphosa microps* Holm, *G. muscorum* (L. Koch), *Pardosa hyperborea* (Thorell), *P. uintana* Gertsch, *Trochosa terricola* Thorell, *Alopecosa aculeata* (Clerck), *Diplocentria bidentata* (Emerton), et *Sisis rotundatus* (Emerton). Quelques espèces ont été trouvées seulement ou principalement dans les sites non brûlés, par exemple, *Pardosa moesta* Banks et *Lepthyphantes complicatus* (Emerton). □*Araneae, forest fire, subarctic, Canada.*

Seppo Koponen, Centre d'études nordiques, Université Laval, Ste-Foy, Québec G1K 7P4, Canada; present address: Zoological Museum, University of Turku, SF-20500 Turku, Finland; 27 October, 1992.

Fire history, effect of fire on forest vegetation, and postfire succession of plant cover have been studied in detail in northern Québec (e.g. Payette *et al.*, 1989). By contrast, very little is known about the effects of fire on spiders in northern forests of North America. In central Alaska, Beckwith and Werner (1979) suggested that the decrease of many arthropod populations after fire can be attributed to increasing spider populations and predation by spiders. Data from temperate forests of North America are also markedly scant (e.g. Pearse, 1943; Buffington, 1967). Pearse (1943) listed about 35 species of spiders from burned pine forests in North Carolina; however, individual numbers were low.

In forests of northern Europe, postfire spider faunas and their succession have been studied both after natural fires and prescribed burning (e.g. Huhta, 1971; Schaefer, 1980; Hauge and Kvamme, 1983; Koponen, 1988, 1989). Data from subarctic forests of Europe are available only from northern Finland (Huhta, 1971; Koponen, 1988, 1989).

This paper deals with the effects of fire on ground-living spiders at the beginning of faunal succession in three forest types in the subarctic zone of Québec, Canada. Forest fires occurred in midsummer 1989; samples were collected in 1990 during the first postfire summer.

MATERIALS AND METHODS

The study areas were situated 1) at Lac Ekomiak (53°23'N, 77°30'W), south of La Grande/Radisson and 2) at Kuujjuarapik (Poste-de-la-Baleine; 55°17'N, 77°48'W) on the eastern coast of Hudson Bay (Fig. 1). Both study areas were near the northern limits of the boreal forest.

1. At Lac Ekomiak, large areas of forest (thousands of sq. km) were burned in midsummer 1989. The study sites situated near the border of this extensive fire area were in dry and mesic forest. The main tree species were *Pinus banksiana* Lamb. and *Picea mariana* (Mill.) B.S.B. at dry sites; *Picea mariana* and *Larix laricina* (Du Roi) K. Koch at mesic sites. The ground layer of the dry sites was characterized by *Cladonia* and *Pleurozium*; that of the mesic sites by *Sphagnum* and *Pleurozium*. The fire had been very intensive and had killed all trees and destroyed field and ground layer vegetation totally. The trapping

TABLE 1 (right). Total number of individuals in major spider families, total number of species, diversity (H) and evenness (E) for pitfall trap material at Lac Ekomiak and Kuujjuarapik, Québec. LDB = Lac Ekomiak dry burned, LDC = Lac Ekomiak dry unburned, LMB = Lac Ekomiak mesic burned, LMC = Lac Ekomiak mesic unburned, KB = Kuujjuarapik burned, KC = Kuujjuarapik unburned site

	LDB	LDC	LMB	LMC	KB	KC
Lycosidae, inds.	59	16	45	32	104	28
Linyphiidae, inds.	44	35	34	22	110	172
Gnaphosidae, inds.	6	8	6	3	11	3
Others, inds.	6	5	6	14	3	0
Total, inds.	115	64	91	71	228	203
Species richness	24	13	15	18	31	20
Shannon H	3.98	3.27	3.50	3.52	3.62	3.31
Evenness E	0.87	0.88	0.90	0.84	0.73	0.77

period was 24 July-20 August 1990; traps were not changed during the period.

2. At Kuujjuarapik, a small area (about 50 x 15m) of *Picea glauca* (Moench) Voss forest was burned in July 1989. The site is in an isolated, small-sized woodland near forestline. Ground layer was dominated by *Pleurozium* and *Empetrum*. The field and ground layer vegetation was destroyed but the intensity of fire had been less than at Lac Ekomiak. The trapping period was 14 July-19 August 1990. The traps were changed once (1 August).

Ten traps were placed at each site (dry burned, dry unburned, mesic burned and mesic unburned) at Lac Ekomiak and five traps at each site (burned and unburned) at Kuujjuarapik. Pitfall traps were plastic cups (diameter 6.5cm, height 7cm) with ethylene glycol (2.5cm) as a preservation liquid. They were provided with covers (12 x 12cm) against rainfall and litter, and there was 2-3cm space between the cover and the ground. Traps were placed in a line at each site, average distance between the traps being 2m.

The indices used are Shannon-Wiener index of diversity:

$$H = -\sum_{i=1}^{s}(p_i)(log_2\, p_i)$$

and evenness: E = H/logS (S = number of species, p_i = proportion of total sample belonging to the ith species). The spider material is deposited in the Zoological Museum, University of Turku, Finland.

	Species	n	%BS	site 'preference'

RESULTS

A total of 772 spiders was collected from 6 study sites (3 burned, 3 unburned) in northern Québec during July-August, 1990. Individuals of two families, Linyphiidae and Lycosidae, clearly dominated all collections; individuals of Gnaphosidae ranked third among trap captures (Table 1).

Both at Lac Ekomiak and at Kuujjuarapik, trap captures were higher at burned sites than at unburned sites. This was mainly due to the great numbers of Lycosidae caught at open burned sites. The figures for the two most abundant families were (Lac Ekomiak and Kuujjuarapik combined): Lycosidae 208 at burned and 76 at unburned sites, Linyphiidae 188 and 229 respectively. In general, at the burned sites, the diversity (H) was higher or equal compared to the unburned controls (Table 1).

Altogether 56 species were caught, 37 species were trapped at Lac Ekomiak and 34 at Kuujjuarapik. Number of species from burned sites was 47; from unburned sites 37; 28 species were common to both burned and unburned sites. Linyphiidae (Erigoninae and Linyphiinae), Lycosidae, and Gnaphosidae were numerically dominant in species number, with 31 (24 and 7), 9 and 6 respectively.

Species that actively colonized the burned sites included, among the lycosids, *Pardosa hyperborea* (Thorell) in both study areas and *Alopecosa aculeata* (Clerck) at Lac Ekomiak (Tables 2, 3). The species group of *Pardosa uintana* Gertsch, *P. mackenziana* (Keyserling) and *P. xerampelina* (Keyserling), including many juveniles, as well as *Arctosa alpigena* (Doleschal) at Kuujjuarapik, and *Trochosa terricola* Thorell at Lac Ekomiak, also were more abundant at burned than unburned sites.

The gnaphosids caught, *Gnaphosa microps* Holm and *G. muscorum* (L.Koch), were slightly more abundant at burned than unburned sites. Of the linyphiids (Erigoninae), *Diplocentria bidentata* (Emerton) and *Pocadicnemis americana* Millidge apparently 'preferred' burnt areas (Tables 2, 3).

Many species were represented by less than 6 individuals captured, and consequently not included in the Tables 2, 3. Several were found only at burned sites. This group included: *Gnaphosa parvula* Banks, *Zelotes fratris* Chamberlin, *Pardosa furcifera* (Thorell), *Neon nelli* Peckham and Peckham, *Sisicus apertus* (Holm), *Ceraticelus atriceps* (O.P.-Cambridge), *Horcotes quadricristatus* (Emerton), *Sciastes truncatus* (Emerton), *Tunagyna debilis* (Banks), *Walckenaeria atrotibialis* O.P.-Cambridge, *W. castanea* (Emerton), *W. directa* (O.P.-Cambridge) and *W. tricornis* (Emerton).

Several species seemed to lack habitat specificity and were equally found in marked numbers at both burned and unburned sites. Such species included the linyphiids, *Sisis rotundus*

(Emerton), *Sisicottus montanus* (Emerton) and *Agyneta olivacea* (Emerton); and the thomisid *Ozyptila gertschi* Kurata. These generalist species must be regarded as colonizer species because of their common occurrence at burned sites. Although only in a few cases (*Pardosa hyperborea* and *P. uintana*) 'preferences' to burned areas were statistically significant, about 30 of the 47 species caught at burned sites can be regarded as potential colonizers in the subarctic postfire forests investigated.

Species that clearly avoided burned sites were the linyphiids *Lepthyphantes complicatus* (Emerton), *L. alpinus* (Emerton), *Hilaira herniosa* (Thorell), *Latithorax obtusus* (Emerton), and *Agyneta allosubtilis* Loksa. Of the lycosids, *Pardosa moesta* Banks was found only at the unburned mesic forest at Lac Ekomiak.

DISCUSSION

The burned areas at Lac Ekomiak and at Kuujjuarapik greatly differed both in the intensity of fire and in the size of area burned. At Kuujjuarapik, spiders easily colonized the burned site from surrounding nearby natural areas. By contrast, at Lac Ekomiak, species colonizing the burned sites came from long distances (i.e., several hundred metres), especially at the dry burned site. The possible survival of spiders in the burnt area during the fire is open to discussion (cf. McKay, 1979: 246); however, at the dry burned site its seems to be improbable due to the intensity of the fire.

The spider community trapped at burned sites one year after fire was rich; the diversity (H) was not lower than at unburned sites. Similar results were found in subarctic Finland during the first postfire summer (Koponen, 1988). This contrasts with some earlier studies (Schaefer, 1980; Metz and Dindal, 1980). However, also Schaefer (1980) observed high diversity values already two years after fire in pine forests of Germany.

Some of the species that colonized burned sites in northern Québec are considered pioneer species in other northern areas, e.g. *Diplocentria bidentata* in burned areas of northern Finland (Koponen, 1988).

ACKNOWLEDGEMENTS

I thank Louise Filion and the staff of Centre d'études nordiques for working facilities and generous help at Kuujjuarapik and Québec City. Luc Sirois provided help at Lac Ekomiak, and Heli Hurme participated in the field work.

DIVERGENT TRANSFORMATION OF CHELICERAE AND ORIGINAL ARRANGEMENT OF EYES IN SPIDERS (ARACHNIDA, ARANEAE)

OTTO KRAUS AND MARGARETE KRAUS

Kraus, O. and Kraus, M. 1993 11 11: Divergent transformation of chelicerae and original arrangement of eyes in spiders (Arachnida, Araneae). *Memoirs of the Queensland Museum* 33(2): 579-584. Brisbane. ISSN 0079-8835.

In various higher taxa of the Araneae (e.g., Mesothelae, Migidae, Hypochilidae), the chelicerae and their fangs show an intermediate position between those commonly called orthognathy and labidognathy. This stage is considered to form part of the ground pattern of spiders; accordingly, it is called plagiognathy (new term). It is concluded that plagiognathy gave rise to orthognathy and labidognathy as divergent adaptational developments. In most instances, plagiognathy is correlated with the maintenance of the original (plesiomorphous) arrangement of the lateral eyes (= ALE + PLE + PME) in triads or semi-triads. The previous assumption that orthognathy and the arrangement of eight eyes in two subparallel rows are characters that were already present in ancestral spiders is refuted.

Bei verschiedenen höheren Taxa der Araneae (z.B. Mesothelae, Migidae, Hypochilidae) weisen die Cheliceren sowie deren Klauen eine intermediäre Position zwischen Orthognathie und Labidognathie im üblichen Sinne auf. Diese Anordnung wird als Teil des Grundmusters der Echten Spinnen angesehen und hierfür die neue Bezeichnung Plagiognathie eingeführt. Von diesem primären plagiognathen Zustand werden sowohl die Orthognathie als auch die Labidognathie als divergente Entwicklungen mit unterschiedlichem Anpassungswert abgeleitet. In den meisten Fällen ist Plagiognathie korreliert mit dem Erhalt der ursprünglichen (plesiomorphen) Anordnung der Seitenaugen (VSA + HSA + HMA) in Form von Triaden oder Semi-Triaden. Die bisherige Annahme ist nicht länger aufrecht zu erhalten, wonach Orthognathie und die Anordnung von 8 Augen in zwei Querreihen als Komponenten des Grundmusters der Spinnen angesehen worden waren. □*Araneae, plagiognathy, orthognathy, labidognathy, lateral eyes, triads.*

Otto Kraus, Margarete Kraus, Abteilung für Phylogenetische Systematik, Zoologisches Institut und Zoologisches Museum, Universität Hamburg, Martin-Luther-King-Platz 3, D-2000 Hamburg 13, Germany; 12 November, 1992.

It is generally believed that the chelicerae in spiders can be arranged in either of two different ways, described by the terms orthognathy and labidognathy. Orthognathy is commonly thought to represent the primitive (plesiomorphic) character stage (Foelix, 1982: 3; Platnick and Gertsch, 1976: 13). At first glance, this view seems to be supported by the fact that a strictly orthognathous arrangement of these mouthparts is also present in the outgroup of the Araneae, i.e., in the Amblypygi. Hence, the idea that orthognathy is a plesiomorphic feature seems to be the most parsimonious explanation. Accordingly, labidognathy is regarded as a derived (apomorphic) feature. Kaestner (e.g., 1952, 1953a, b) presented arguments supporting the assumption that labidognathous, i.e., cooperating chelicerae had various functional advantages. He produced a model (Fig. 1) illustrating the transformation of a 'primitive' orthognathous arrangement into the labidognathous position. However, it is difficult to imagine how this could have happened gradually, and Kaestner did not explain why orthognathy had been maintained in a considerable number of higher taxa.

Simon (1892: 64, 82) pointed out that the Liphistiidae and Migidae had arrangements of the chelicerae that did not fit very well into the generally accepted orthognathy/labidognathy scheme. Later authors ignored such 'deviations', however, and continued to base the distinction of two major subtaxa of spiders–Mygalomorphae (=Orthognatha) and Araneomorphae (=Labidognatha) on different positions of the chelicerae. Kaestner alone remarked on the intermediate arrangement of these mouthparts in Actinopodidae and in *Hypochilus*, but apparently he too continued to adhere to the typological orthognathy/labidognathy concept. One main aspect of his study was therefore to classify the chelicerae in *Hypochilus* as orthognathous *or* labidognathous.

In this paper, we will present relevant facts, most of them already known for decades, and discuss conclusions allowed by alternative concepts.

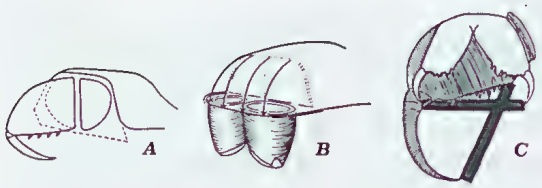

FIG. 1. Transformation of chelicerae as supposed by Kaestner. A, orthognathy, left chelicera omitted, front of prosoma nearly vertical. B, labidognathy, dotted lines and arrows indicate how front of prosoma (with chelicerae) shifted from original vertical to a horizontal position (rotation of basal segments of chelicerae not indicated). C, suggested economy of relatively small cooperating labidognathous chelicerae compared with a single orthognathous chelicera (hatched); both seize objects of same size.–(From Kaestner, 1953b).

This approach leads directly into a critical discussion of another generally accepted dogma in arachnology—that the eight eyes present in the ground pattern in spiders were originally arranged in two more or less parallel rows. In the nearest outgroups (Amblypygi, Uropygi), however, the arrangement of these eight eyes is quite different: the lateral eyes form triads on both sides of the prosoma. Such triads also occur in certain spiders. We therefore also plan to adopt a somewhat unconventional approach, discussing the question as to whether the presence of such triads in various subtaxa of the Araneae could be a persisting plesiomorphic character expression.

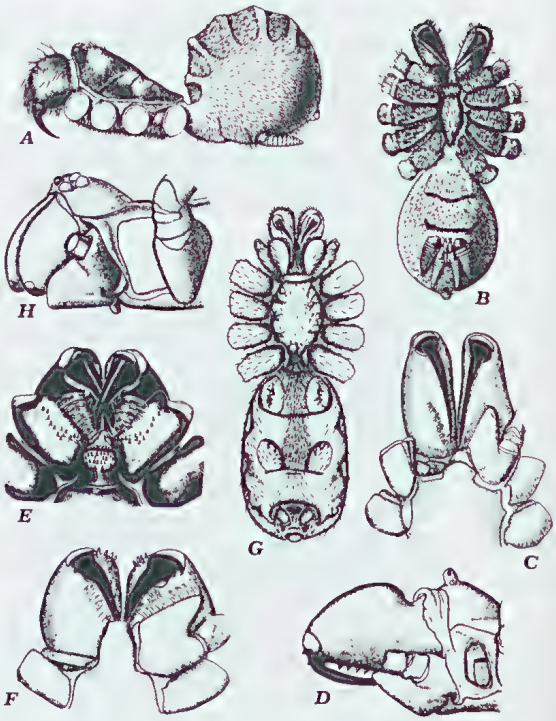

FIG. 2. Position of chelicerae and fangs, lateral and ventral views. A-B, Mesothelae: *Liphistius* sp. C-D, Atypidae: *Atypus affinis*. E, Migidae: *Migas quintus*. F, Actinopodidae: *Missulena occatoria*. G, Hypochilidae: *Hypochilus gertschi*. H, *H. thorelli*.– (A-B from Millot, 1949; C-D, F, H from Kaestner, 1952; E from Wilton, 1968).

RESULTS AND INTERPRETATIONS

Chelicerae

FACTS.

Orthognathy is commonly regarded as plesiomorphic. However, precisely those spiders that have the greatest number of plesiomorphies in common (Platnick and Gertsch, 1976) do not show an orthognathous position of their chelicerae: in the Liphistiidae (Figs 2a-b) the basal segment (paturon) of these mouthparts is relatively short, inflated and obliquely positioned. Further, the longer axis of this basal segment is orientated obliquely downwards, and not horizontally and paraxially as in 'true' Orthognatha (Figs 2c-d). The corresponding position of the fangs is also oblique, and anything but paraxial, in contrast to the position of the fangs in *Atypus*, for example (see Simon, 1892: 64).

The same situation as in *Liphistius* is also found in various subtaxa of the Mygalomorphae. In 1892, Simon (: 82) described similar arrangements in the Migidae, referring to 'chélicères très courtes, convexes à la base, mais ensuite brusquement inclinées, presque verticalement ...' (see Fig. 2e). Kaestner (1952: 118) studied *Sason robustum* (O. P.-Cambridge, 1883) as a representative of the Barychelidae and characterized the chelicerae as short and subvertically inclined. In the same paper, Kaestner demonstrated that obliquely arranged chelicerae were also present in the Actinopodidae (Fig. 2f); he described the situation in *Missulena occatoria* (Walckenaer, 1805) and concluded: 'I cannot see any biological reason for such conditions. But as torsions of this kind play an important role in the origin of labidognathy, it is interesting to see that they [the torsions] may also occur in the Orthognatha' (transl. from German).

It is worth mentioning that the chelicerae even of the oldest known spider, *Attercopus fimbriunguis* (Shear, Selden and Rolfe, 1987) (Middle Devonian), had short basal segments and also fangs (Selden *et al.*, 1991, e.g., plate 1, figs 6-8).

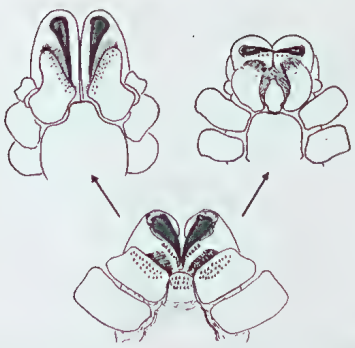

FIG. 3. Orthognathy (left) and labidognathy (right) as apomorphic character states derived from plagiognathy (bottom).

Unfortunately, their original position is unknown.

Chelicerae with an oblique position are also found in a taxon that unquestionably belongs to the Araneomorphae (= Labidognatha *auct.*): the Hypochilidae (Figs 2g-h). Again, it was Kaestner (1952: 132) who studied details. He concluded that the mouthparts in *Hypochilus* were of the orthognathous type in construction and expressed the view (Kaestner, 1952: 114) that 'the majority of important characters present in *Hypochilus* is in accordance with the Orthognatha, whereas the number of features present in Labidognatha only is very low. For this reason, I must remove the genus from the suborder Labidognatha and either place it in the Orthognatha or set it up in a suborder of its own' (transl. from German).

INTERPRETATION

Kaestner maintained that labidognathy was an advanced character state, which had developed from an orthognathous ground pattern by gradual transformation (Kaestner, 1953a: 60; Fig. 1). He felt that *Hypochilus* (and the Hypochilidae) should be regarded as transitory stages and explained the oblique position also present in the Barychelidae and Actinopodidae as a parallel development. Furthermore, he regarded the 'semi-orthognathous' chelicerae in *Dysdera* (Dysderidae) as intermediate. Kaestner thought, then, that various transitory stages still existed, forming a 'phylogenetic link' between the two extreme character states.

We reject this judgement based on typology, and postulate that an oblique position of the chelicerae, including the fangs, really represents the plesiomorphic situation (Fig. 3). As a new term is needed, we would like to suggest 'plagiognathy' to designate this original position of the chelicerae. Accordingly, the plagiognathous position present in the ground pattern of the Araneae has been secondarily transformed in two different directions, both apomorphic character states: orthognathy and labidognathy (Fig. 3). We see various arguments in support of this hypothesis:

a) It explains why orthognathy is not encountered in the Mesothelae (*Liphistius*, *Heptathela*).

b) The absence of orthognathy in representatives of several mygalomorph families is explained.

c) The fact that the Hypochilidae are not labidognathous is explained by the simple assumption that the original plagiognathy has been maintained in this group of the Araneomorphae. Nonetheless, in all other Araneomorphae (this means in the Neocribellatae, the sister taxon to the Hypochilidae) labidognathy has been achieved and is regarded as an apomorphy of this taxon. This conclusion is not invalidated by the fact that superficially orthognathous arrangements originated secondarily in a few sexually dimorphic araneomorph taxa (e.g., in males of the salticid genus *Myrmarachne*).

d) Kaestner's typological and entirely theoretical model suggesting how a supposed transition from orthognathy to labidognathy could come about (Fig. 1) is replaced by a new concept (Fig. 3). This postulates divergent and gradual evolutionary change of the ground pattern, that is to say, of plagiognathy.

e) Kaestner's complicated assumption that obliquely arranged chelicerae originated in parallel both in the Mygalomorphae and the Araneomorphae is replaced by a simple, comprehensive hypothesis.

The only remaining conflict seems to be that reflected in the strictly orthognathous position of the chelicerae in the most closely related outgroups of the Araneae (Amblypygi, Uropygi). If our 'plagiognathy hypothesis' is correct, it must be assumed that orthognathy in the Araneae is a different and thus independent secondary development within the mygalomorph spiders. There is no question but that this contradiction needs some further examination.

Preliminary investigations have already suggested that orthognathy in Amblypygi may be different from orthognathy in spiders: the basal segment in amblypygid chelicerae has a long, stout apodeme at its proximal dorsolateral border, which reaches deeply into the broad, flat prosoma. This peculiarity is lacking in plagio-

gnathous and also in orthognathous chelicerae of spiders. We expect that more detailed studies on the functional morphology, including the musculature, will demonstrate that orthognathy in uropygids and amblypygids differs from orthognathy in spiders. This would support our view and could perhaps constitute point f) in the list of positive arguments above.

EYES

Surprisingly, plagiognathous spiders (for example Mesothelae, Migidae, Hypochilidae) share a special arrangement of the eyes (Figs 4g, e, c): anterior lateral, posterior lateral and posterior median eyes are grouped closely together. This prompts the following remarks on the question as to how the eyes were grouped in the ground pattern of the Araneae.

As designations widely used in taxonomic descriptions (AME, ALE, PME, PLE) disregard the origin of these 'ocelli', some notes on the homolgy of the eyes of spiders may be appropriate to ensure that we understand each other: the anterior median eyes (AME) will be called 'median eyes' by us, as they are homologous with the median eyes of other arthropods (for example those in Xiphosura, 'ocelli' in insects, and the three components of crustacean nauplius eyes). All other eyes, three on each side, will be called 'lateral eyes' (ALE + PLE + PME), as they are homologous with the paired original compound eyes in arthropods, for example, in xiphosurans.

FACTS

It is commonly believed that an arrangement in two transverse rows of eight eyes is plesiomorphic. Only two weak aspects support this view, however: (a) there is no reason at all to doubt that the presence of eight eyes forms part of the araneid ground pattern, and (b) their arrangement in two rows is widely observed both in the Mygalomorphae (for example the Actinopodidae; see Simon, 1892: 79, figs 81-83) and in the Araneomorpha (for example Araneidae, Eusparassidae, Thomisidae).

On the other hand, lateral eyes more or less distinctly grouped in triads occur in various groups of spiders. Mesothelae, Migidae and Hypochilidae have already been mentioned. Almost perfect triads occur in Pholcidae (Fig. 4f). The same is true of Amblypygi (Fig. 4b) and Uropygi, the direct outgroups to spiders!

The arrangement of the eyes in the extinct Trigonotarbida deserves special attention. According to Selden *et al.* (1991: 254), they form the sister group of all other pulmonate taxa (= Araneae + Amblypygi + Uropygi + Schizomida). Devonian trigonotarbids had the usual two median eyes, and the lateral eyes were represented by up to 9 (12 ?) lenses (Fig. 4a). Three of these were major lenses, while the others were minor lenses arranged in the interspace between the major ones (Shear *et al.*, 1987). This kind of transformation of the original compound eyes clearly indicates that a triad of major lateral eyes is a feature of the ground pattern of the pulmonates as a whole; accordingly, the loss of the minor lateral eyes could be regarded as an autapomorphy of all other pulmonates, including spiders. This secondary reduction of the minor lateral eyes may explain why most triads are not perfectly closed, not even in amblypygids (Fig. 4b).

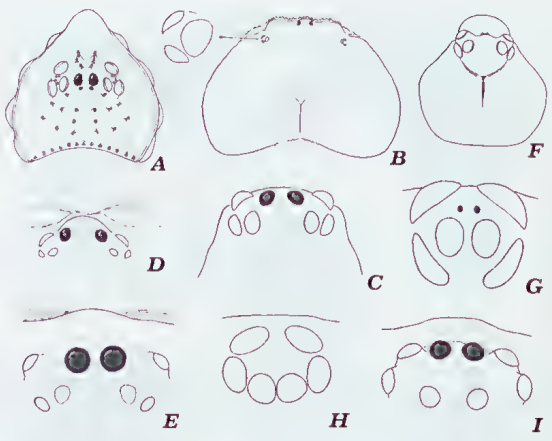

FIG. 4. Position of median (black) and lateral eyes in Trigonotarbida, Amblypygi and Araneae. A, Trigonotarbida: *Gilboarachne grierson*i, reconstruction of prosoma (from Shear *et al.*, 1987). - B, Amblypygi: *Damon* sp. C, Hypochilidae: *Hypochilus gertschi*. D, Atypidae: *Atypus affinis*. E, Migidae: *Poecilomigas* sp. F, Pholcidae: *Pholcus circularis*. G, Mesothelae: *Liphistius* sp. H, Dysderidae: *Dysdera* sp. I, Agelenidae: *Agelena* sp. (Not to scale).

The peculiarity 'lateral eyes in triads' is commonly used as a character in spider identification keys, but as far as we can tell, its potential bearing on phylogeny has never been discussed. Could it be that triads of lateral eyes are part of the ground pattern in the Araneae?

A survey of how the lateral eyes are positioned in representatives of higher taxa of spiders shows that almost perfectly 'closed' triads (as in pholcids) are rare. In most instances, the three lateral eyes on each side are somewhat dissociated. In addition to the Mesothelae and Migidae already mentioned, we should also like to draw attention

to the Atypidae (Fig. 4d) and to the illustrations in Raven's comprehensive study of the Mygalomorphae (1985). In many cases the posterior lateral and the posterior median eyes are closely connected, with some distance between them and the anterior laterals. *Hypochilus* shows slightly dissociated triads (Fig. 4c). The Dysderidae (Fig. 4e) and Oonopidae are six-eyed spiders, having the median eyes completely reduced. In dysderids, the lateral eyes are closely grouped together, resembling the arrangement of the laterals in the Mesothelae. In many groups within the Araneomorphae, diads are present instead of triads. They are formed by the ALE + PLE, with the PME separated. This arrangement can be found in Austrochilidae and especially in most Theridiidae and Linyphiidae, for example. Diads also occur in groups characterized by a secondary loss of the PME, such as Scytodidae.

INTERPRETATION

The assumption that eight eyes arranged in two transverse rows were already present in the ground pattern of the Araneae is not supported by any concrete fact; nor would this at all correspond with the situation in the nearest outgroups. It would mean that triads and triad-like arrangements of the lateral eyes in spiders were classifiable as parallel developments (homoplasies). This is unlikely. In accordance with the position of the eyes in the Amblypygi and Uropygi, we expect that the laterals were primarily grouped as triads (ALE + PLE + PME). This hypothesis is supported by five arguments:

a) Triads of major lateral eyes (lenses) already existed in Devonian Trigonotarbida; hence, triads apparently form part of the ground pattern of all pulmonates among arachnids.

b) The postulated configuration is in good agreement with the arrangement of the eyes in the direct outgroups.

c) Triads and semi-triads present in various groups of the Mygalomorphae and also of the Araneomorphae must no longer be explained by assumed parallel origin.

d) Various types of somewhat dissociated lateral eyes can be explained by a secondary separation of the ALE or of the PME from the others, which frequently remain in contact with each other.

e) Simon's 'oculi laterales utrinque contigui' (e.g., 1894: 517), that is to say, the occurrence of diads can be explained as part of the original triad.

To some extent, the question remains open, as to how it is possible to distinguish between eye positions that can be regarded as more or less modified triads and other positions, with secondarily approximated ALE and PLE.

PERSPECTIVES

Apparently, plagiognathy is part of the ground pattern of the Araneae. Developments in the directions of orthognathy and labidognathy can easily be explained as divergent evolutionary changes (Fig. 3). The question therefore arises of how these might be correlated with functional aspects. As an impetus for further discussion, we propose the following working hypotheses:

a) In the Mygalomorphae, orthognathy may be correlated with the capture of prey on the ground. Under such conditions, the two parallel fangs of the chelicerae can easily penetrate the victim on a substrate like two stabs of a dagger. It seems remarkable that a semi-orthognathous position of the chelicerae has originated secondarily in the Dysderidae: they kill woodlice on the substrate.[1]

b) In the Araneomorphae, the origin of labidognathy may be correlated with the evolution of capture webs (sheet, frame, orb webs etc.). These could make it more efficient to bite the prey with two opposing chelicerae or fangs, whereas plagiognathous and, even more, orthognathous chelicerae might not penetrate but rather push away the victim: there is no longer any substrate 'supporting' prey animals.

c) Plagiognathy and the maintenance of lateral triads or semi-triads of eyes apparently form part of the ground pattern of spiders; these features are confined to more 'primitive' groups. The presence and the various types of transformation of these two characters should be integrated into current concepts on the phylogeny of the Araneae (see, for example, Raven, 1985; Coddington, 1990). At present, our view of features of an araneid ground pattern and succeeding evolutionary changes seems to be somewhat at odds with various published cladograms; they hence could be partially wrong. We feel that this conflict may be due to the possibility that characters assumed to be synapomorphies in various cladograms (see,

[1] But see Kaestner (1953a: 62). He believed that the position of the chelicerae in *Dysdera* was a 'phylogenetic link' between orthognathy and labidognathy. Unfortunately, he was not aware that the first postembryonic stages were nearly labidognathous, with relatively shorter basal segments and only slightly oblique fangs (pers. observ.). In *Dysdera*, the final semi-orthognathous position was gradually acquired in later instars.

e.g., Platnick and Shadab, 1976, fig. 1; Raven, 1985, fig. 1) may well turn out to be symplesiomorphies; e.g., Raven's characters 35 (eyes spread widely across the prosoma; same as Platnick and Shadab's character 1) and 36 (male pedipalps: conductor of bulb present; see Kraus, 1978, figs 12, 14-16).

ACKNOWLEDGEMENTS

We are indebted to Prof. Dr. H.M. Peters, Tübingen, and Prof. Dr. H.W. Levi, Cambridge, Massachussets, for critical advice. We express our thanks to Dr. W.A. Shear, Hampden-Sydney, who draw our attention to the situation in the Trigonotarbida and in other fossil arachnids. Dr. R. Horak, Graz, kindly provided early post-embryonic stages of *Dysdera*.

POLYNESIAN THOMISIDAE - A MEETING OF OLD AND NEW WORLD GROUPS

PEKKA T. LEHTINEN

Lehtinen, P.T. 1993 11 11: Polynesian Thomisidae - a meeting of old and new world groups. *Memoirs of the Queensland Museum* 33(2): 585-591. Brisbane. ISSN 0079-8835.

The Polynesian thomisid fauna is postulated as consisting of an Hawaiian-east Polynesian New World group, living mainly in isolated populations in the mountains and of representatives of two western lowland groups originating from Australia and Southeast Asia. The former group has apparently speciated into numerous endemic species, while the latter groups are represented by a single, widespread species and a rare Tongan species, respectively. The ranges of the eastern and western groups do not overlap. The species of New World origin have been described or previously attributed to *Misumena*, *Misumenops*, or *Synaema*. All such species are included here in *Mecaphesa* Simon, 1900 with the type species from Hawaii. *Misumenops* F.O. Pickard-Cambridge, 1900 has the type species from Eastern Brazil and has no close relatives in Polynesia or in the Old World. A widespread Old World group is also recognized here and tentatively included in *Massuria* which appear to be related to the New Guinean *Loxoporetes*. *Diaea* as currently recognized is polyphyletic and the species occurring in west Polynesia (*Diaea praetexta* (L. Koch, 1865)) is postulated to belong to a group requiring a new generic delimitation and name. *Hedana subtilis* L. Koch, 1874, also of Asian origin is here regarded as having affinity with *Tharrhalea*. The poorly described thomisid species of the isolated, southernmost island group of Polynesia, Rapa Island has not been studied. □*Araneae, Thomisidae, Polynesia, biogeography.*

Pekka T. Lehtinen, Zoological Museum, University of Turku, 20500 Turku, Finland; *11 March, 1993.*

Many zoogeographical discussions, including spiders, are flawed because of poor taxonomy. The zoogeography of the Polynesian spider fauna has been discussed by Berland (1927, 1928, 1929, 1930, 1933, 1934a, b, c, 1935a, b, 1937, 1938a, b, 1942, 1947), but his discussions were based on unrevised taxa. His conclusions were often affected by misidentifications and unevenness of data available. Most spiders for these papers consisted of assorted samples made by non-specialists and many were synanthropic species found near villages.

I have been working towards a zoogeographical synthesis of the Polynesian spider fauna for ten years. Extensive personal field work in mountain tops, but also in the disturbed zone has been the most important method in the elimination of anthropochorous dispersal and distinctly synanthropic species from all speculations on the origin of the fauna of natural habitats.

The taxonomic revision of all families present seems to be necessary for any valid zoogeographical conclusions. As the first step I have carried out a 'generic' revision of Polynesian families which allows the placing of most Polynesian species groups of spiders into named or still unnamed groups of supraspecific taxa instead of zoogeographically useless concepts such as the 'worldwide' *Misumenops*, *Theridion*, *Hahnia*, or *Leucauge*. Some recent papers on Polynesian spiders have been published (e.g. Marples, 1955a, b, 1957, 1959, 1960, 1964; Berry and Beatty, 1987; Beatty and Berry, 1988; Beatty *et al.*, 1991). I have previously discussed some aspects of the spider zoogeography of the Pacific region (Lehtinen, 1980). Polynesian thomisids have also been described by Strand (1913).

The evolution of Polynesian Thomisidae has resulted in the most striking example of local speciation of spiders in Polynesia. The Thomisidae discussed comprise only the subfamily Thomisinae in the sense of Suman (1970) and various other authors. The Philodromidae are not a sister group of Thomisidae, but rather of the Heteropodidae.

The geological history of the Polynesian archipelagoes is now well known (Wilson, 1963; Duncan and McDougall, 1974; Dalrymple *et al.*, 1975). An ancient continent of Pacifica has been proposed (with differing placement and size) marginally affecting to the historical zoogeography of Polynesia (e.g. Nur and Ben-Avraham, 1977; Craw, 1983). Most geophysicists agree that the Polynesian islands are not parts of ancient land masses broken by processes of the plate tectonics, but rather chains of current islands and

seamounts representing former islands (Dalrymple *et al.*, 1975).

The origin of the Polynesian fauna therefore can be explained only by long distance dispersal from different directions (Gressitt and Yoshimoto, 1963) and partly by intrapolynesian speciation processes within the island chains (cf. also Carson, 1984; Fosberg, 1991). The use of the basic principles of the vicariance biogeography (Nelson and Platnick, 1981) will be essential for explaining the origin of groups of biota with complex patterns in their recent ranges. Craw's (1978) variant of panbiogeography, later named spanning-tree biogeography by Platnick and Nelson (1988) is a useful method for comparisons of area including also permanently oceanic island groups and it can be recommended for the analysis of many other groups of spiders. When patterns of distribution are very simple and anthropochorous dispersal in historical time has not thoroughly obscured the original patterns (cf. Stoddart, 1968), conclusions can be made with Craw's method such as have actually long been used by zoogeographers (e.g. Gressitt, 1961) before the concept of 'the most parsimonious area relationship' was defined and named.

In spite of the current taxonomic confusion of the Thomisidae on a global scale some generalisations on the zoogeography of the family are possible in the Pacific area. This paper presents the suggested relationships and zoogeography of the Thomisidae of Polynesia according to rich new material and results of my unpublished revisional work.

TAXONOMIC REMARKS

The nominate subfamily of Thomisidae should be called Thomisinae, although the name Misumeninae has been widely used, also, e.g. recently by Dippenaar-Schoeman (1983). Two groups of greenish or yellowish species without abdominal modifications are easily recognizable, one with conspicuous modifications in the ocular area (*Thomisus*-group), the other without such modifications (*Misumena*-group). The limitation of thomisine groups has been vague. Simon (1895) originally listed *Misumena*, *Heriaeus*, and *Diaea* in different tribes, while at the other extreme, the *Misumena*-group of Dippenaar-Schoeman (1983) includes not only *Thomisus*, but also *Runcinia*.

No phylogeny of thomisine groups is known and detailed discussion is beyond the scope of this study. However, the *Misumena*-group has apparently retained many plesiomorphic characters. Some groups with striking individual adaptive modifications (e.g. *Heriaeus* and *Runcinia*) may be closely related to this group.

There are most probably many other endemic species of Thomisinae in the mountains of French Polynesia, but a revision is excluded here.

The definition and delimitation of thomisine genera has been based traditionally on a few adaptive characters, including number, length, and type of setae on the carapace (Simon, 1895; Mello-Leitão, 1929; Schick, 1965; Tikader, 1980; Dondale and Redner, 1978; Levy 1985; Ono, 1988), but little attention has been paid to general patterns of the genital organs and type of sexual dimorphism. In contrast to conventions in the taxonomy of other spider groups, the naming of individual setae of the thomisid carapace has been used by some recent specialists (Schick, 1965; Dippenaar-Schoeman, 1983). This terminology is widespread in acarine taxonomy.

Some genera have been very obscurely defined and therefore all catalogues list them as being very widespread and species rich, e.g. *Misumena, Misumenops, Diaea*, and *Synaema*. All these generic names appear in thomisids described or listed from Polynesia. Even a superficial comparison of the descriptions or type material from many species of these genera (L. Koch, 1874; Kulczynski, 1911; Chrysanthus, 1964; Tikader, 1980) reveals that they are typical 'waste-basket' groups, where most species are not closely related to the respective type species.

The phylogenetic classification of the west Polynesian '*Diaea*' and the east Polynesian '*Misumenops*' has been time-consuming, as all basic taxonomic work on Indo-Pacific and Neotropical Thomisidae was done before modern taxonomic principles and methods became established. Most structural characters used as generic criteria in Thomisidae seem to be minor convergently evolved adaptations. The type species of all three large widespread genera in question, *Misumenops*, *Diaea*, and *Misumena*, are atypical or 'peripheral' species, not closely related to the Pacific species. Actually the placing of many tropical species in these three genera have been repeatedly changed, depending mainly on emphasis laid on single adaptive characters, e.g. type and pattern of setae on carapace, pattern of leg spines, eye pattern, etc.

The setation of the carapace is variable in the Polynesian groups of Thomisidae. Nevertheless, in *Mecaphesa*, sympatric species may be best identified by differences in length and density of

the carapace setae. The shape of the carapace is variable in *Mecaphesa*, while the shape of the abdomen is variable in both '*Diaea*' and *Mecaphesa*, even within one population.

The colour pattern is variable also, although the 'usual' colouration for most species provides a reasonable guide to identification, if large populations are available.

POLYNESIAN THOMISIDS OF NEW WORLD ORIGIN

Most east Polynesian thomisids have been long included in *Misumenops* F.O. Pickard-Cambridge, 1900 (Berland, 1933, 1934b, 1942; Suman, 1970), although Roewer (1954) transferred all Hawaiian species to *Misumenoides* F.O. Pickard-Cambridge, 1900.

Many Hawaiian and North American species of *Misumenops* sensu Schick (1965) were originally described in *Misumena* or *Diaea*, and Neotropical species also in *Metadiaea* Mello-Leitão, 1929.

The adaptive radiation of Hawaiian Thomisidae indicates that essential changes in the shape of the carapace are possible without other than minor changes in the male palpal structure. The Hawaiian thomisid species were listed by Simon (1900) in *Misumena* (6 spp.), *Diaea* (2 spp.), *Synaema* (4 spp.), and *Mecaphesa* (2 spp.), but by Suman (1970) in *Misumenops* (14 spp), *Synaema* (1) and *Mecaphesa* (3 spp.). I have checked the type material of all Hawaiian thomisids preserved in the Bishop Museum and, in my opinion, both male and female genitalia of *Synaema naevigerum* Simon, 1900 are much closer to the genitalia of all Hawaiian '*Misumenops*' than those of the type of *Synaema, S. globosum* (Fabricius, 1775) from Europe. The relative width of the ocular area is certainly a parallelism in true *Synaema* and the Hawaiian '*Synaema*'. The blunt setae of *Mecaphesa* s. str. have been independently modified, and the three species constitute a sister group of the Hawaiian '*Misumenops*' and '*Synaema*' together. The genital organs of both sexes are again more or less similar and not at all related to *Oxyptila* or *Heriaeus*, as claimed by Simon (1900). Suman (1970) was not familiar with the Palaearctic thomisids and had no opinion on this matter, but be published useful drawings of the genitalia of all Hawaiian thomisids. This group of '*Misumenops*' is also present in Japan, as *Misumenops kumadai* Ono, 1985 and in western North America at least 13 species (*celer*-group), listed by Schick (1965) in *Misumenops (Misumenops). Misumenops inclusus* Banks, 1902 from Galapagos Islands and *M. sjoestedti* Berland, 1924 from Juan Fernandez Islands are

TABLE 1. Hypothesis of generic placement and zoogeographic origins of species groups of Thomisidae represented in Polynesia.

additional members of this genus in the Pacific region.

The generic name *Misumenops* is here reserved for the group of Neotropical species that are unambiguously related to *M. maculissparsa* (Keyserling, 1891), a species with a well developed tutacular process in cymbium and a complex of tibial apophyses that is widely different from any Pacific species. *M. pallens* (Keyserling, 1880) and *M. pallida* (Keyserling, 1880) were recently revised by Rinaldi (1983) without comparison to the type species. These widespread Neotropical species are not close to *M. maculissparsa*, but they may remain in the same genus. On the other hand, the concept of *Mecaphesa* is here widened to also include most Polynesian, some other Pacific and many north American *'Misumenops'*, the more plesiomorphic branch of this genus. *'Misumenops' rapaensis* Berland (Berland, 1934) from the isolated Rapa Island with a terrestrial fauna of peculiar affinities probably belongs elsewhere.

The widespread Holarctic *M. tricuspidatus* (Fabricius, 1775) is removed from this genus, but its final generic placement must wait for a more complete revision of Thomisinae: Misumenini. The structure of the male tibial apophysis, including the microstructure of its tip, is different from all other thomisids known to me. *M. japonicus* (Bösenberg and Strand, 1906) is a relative or even a member of *Diaea*, while the *asperatus* group of *Misumenops* (Schick, 1965) may belong to *Metadiaea* and the *coloradensis* group represents a distinct genus, not close to *Mecaphesa* or *Misumenops.*

The synonymic history of *Metadiaea* is confusing, too, as the authors discussing this problem (Toledo Piza, 1937; Caporiacco, 1954; Rinaldi, 1983) have based their opinions on the data from speices other than the type species, *M. fidelis* Mello- Leitão, 1929 from Minas Gerais, Brazil. I agree with Rinaldi (1983) in transferring the other species to *Misumenops pallida*-group, but not the type of the genus, and *Metadiaea* remains a valid American genus probably including also North American species.

There is a widespread Southeast Asian-New Guinean group with short scutate male abdomen and with genital organs of both sexes close to *Runcinia*. Their male tibial apophysis is similar to *Mecaphesa*, including the characteristic ribbed tip. The New Guinean *Loxoporetes* known only by the female is probably related to, or even congeneric with this group, of which most species have been described as *Misumena.* This group will probably be named *Massuria* Thorell, 1887 and it might be a plesiomorphic sister group of the widespread and widely sympatric *Runcinia.*

POLYNESIAN THOMISIDS OF OLD WORLD OR AUSTRALIAN ORIGIN

The greenish thomisids from Samoa and Tonga islands have been described as different species (L. Koch, 1874; Rainbow, 1902: New Hebrides; Strand, 1913), all referred to *Diaea.* A critical survey of several large populations reveals that there is only one widespread species, *'D.' praetexta* (L. Koch, 1865) with large infrapopulational variation in the colour pattern, but quite small variation in the structure of the genital organs. In contrast to east Polynesian and Hawaiian thomisids this species lives in the vegetation of lowlands and is also common in Fiji and Vanuatu.

At least *D. sticta* and *D. limbata* (Kulczynski, 1911) within the widespread and common Melanesian *Diaea* spp. as well as the east Australian *D. multopunctata* L. Koch, 1874 and *D. prasina* L. Koch, 1876 are congeneric with *D. praetexta.* This group of Australian-Polynesian *'Diaea'* deserves generic status, but until some 'old' thomisine genera from the Indo-Pacific area have been revised the erection of a new genus would be hasty. The type species of *Diaea, Araneus dorsatus* Fabricius, 1775, probably together with some other Palaearctic species has male and female genital organs resembling *Heriaeus* (Loerbroks, 1983). The deviating non-genitalic characters of *Heriaeus* are adaptations to life in the desert.

Hedana subtilis L. Koch, 1874 was described from one male and a juvenile from Tonga, western Polynesia. Most probably it is not congeneric with the Australian type species *H. gracilis* L. Koch, 1874 and several other species

from Southeast Asia to New Zealand. It has not been compared with the type of *Tharrhalea* from N. Australia, but it seems, at least, to belong to the same tribe as *T. maculata* from New Guinea. *H. pallida* Koch, 1876, described from juvenile specimens from Tonga most probably is a synonym of *H. subtilis* or even '*D.*' *praetexta*. In addition to these two very old records there is also a recent record of a subadult female from Tonga. *Hedana* and *Tharrhalea* have been catalogued in Stephanopinae (Simon, 1895; Roewer, 1954; Bonnet, 1957), but '*H.*' *subtilis* belongs to Thomisinae.

I have seen relatives of *H. subtilis* (? *Tharrhalea*) in New Guinea and southeast Asia and the range of this unnamed group is more or less similar, but possibly extending farther northwards, when compared to that of the '*Diaea*' *praetexta*-group.

ZOOGEOGRAPHICAL CONCLUSIONS

The Polynesian thomisid fauna has apparently arrived from two opposite directions, South America and Melanesia. These two elements are not known to be mixed in any part of Polynesia (map in Fig. 1).

New World element (*Mecaphesa*) probably first arrived in Hawaii, where an explosive speciation has taken place, resulting in 17 known species (Suman, 1970: in three genera), most having a small range up in the mountains. Galapagos Islands (1 or several spp.) and Juan Fernandez Islands constitute another possible source of immigration for the East Polynesian *Mecaphesa* spp. They have further evolved to at least six, but probably more local endemics. There are also sympatric montane species, at least in the Marquesas Islands, but most probably also in Tahiti. The majority of East Polynesian species live on mountain tops, but a few species have occassionally been recorded also in lowland.

The Oriental-New Guinean genus of the *Misumena*-group, here tentatively called *Massuria* has not been found in the intervening Melanesian archipelagoes and must be excluded from possible sources of origin of the east Polynesian *Mecaphesa*, although both groups belong to Misumenini, a group probably older than any mid-Pacific archipelagoes.

There are no known thomisids in the Central Polynesian islands (Cook Islands, Tokelau Islands, Niue, etc.) (Marples, 1955b, 1957, 1960, 1964) or in the low coral islands north of Samoa (Rainbow, 1897; Roewer, 1944). In spite of additional collecting both in the lowland as well as in the mountains of Rarotonga by myself, no *Mecaphesa* spp. have been observed. The absence of *Diaea praetexta* in disturbed lowland habitats of Rarotonga seems to show that anthropochorous dispersal of this species is not very effective, although its frequency in the more western archipelagoes can be partly explained by this type of short distance dispersal.

The Australian Thomisidae appear to have arrived through Melanesia, where Fiji and Vanuatu share the same common lowland species, '*Diaea*' *praetexta* and several closely related species are present in New Guinea and Eastern Australia. The other west Polynesian thomisid species, '*Tharrhalea*' *subtilis* belongs to a group that has a wider range including southeast Asia. In spite of intensive field work in Samoa and Tonga during 1991-92, there are still no montane thomisids known in the western archipelagoes of Polynesia.

There are some other Polynesian spiders of Neotropical origin (Anyphaenidae, some Theridiidae, etc.), but most spider families represented in Polynesia are of Melanesian, southeast Asian or New Zealand origin.

ACKNOWLEDGEMENTS

This study is part of a long range programme on Indo-Pacific spiders, including field and museum work during the last 20 years. This work has only been possible through the generous cooperation of numerous persons, who could not be listed separately here. Useful comments were also presented by two referees and an editor. The map was kindly drawn by Ms. Maija Mustonen, and the original English text was checked by Mrs Alice Moore.

SCORPION DISTRIBUTION IN A DUNE AND SWALE MALLEE ENVIRONMENT

N.A. LOCKET

Locket, N.A. 1993 11 11: Scorpion distribution in a dune and swale mallee environment. *Memoirs of the Queensland Museum* 33(2): 593-598. Brisbane. ISSN 0079-8835.

A system of stable and vegetated dunes, separated by occasionally flooded swales, contains populations of six scorpion taxa. *Urodacus yaschenkoi* (Birula) digs deep burrows in the soft soil of the dunes, but the shallower burrows of *U. armatus* Pocock are concentrated at their base, extending onto the swale for ca. 50m. *Lychas jonesae* Glauert, *L. variatus* (Thorell) and *Isometroides angusticaudis* Keyserling occur on the swale but not the dunes. *Cercophonius kershawi* Glauert has occasionally been found in litter beneath mallee trees on the dunes. Soil hardness may account for *U. yaschenkoi* occurring only on the dunes. *Isometroides*, a spider predator, occurs where spider burrows are found. Predation by the larger *Urodacus* may account for the buthids not extending onto the dunes.□ *Scorpions, Australia, ecology, habitat.*

N.A. Locket, Department of Anatomy and Histology, University of Adelaide, Box 498, GPO, Adelaide, South Australia 5001, Australia; 3 November, 1992.

An area of scrub near Berri in the South Australian Riverland consists of a series of stable dunes bearing mallee trees and shrubs interspersed with flat grassy swales, which show signs of occasional flooding. This locality contains a population of *Urodacus yaschenkoi*. Blacklighting on and between the dunes showed that five other scorpion taxa are present in the area but not uniformly distributed. Observations are now presented on these populations and their distribution across the dune- swale system.

Two of the taxa found do not accord with the descriptions given by Koch (1977). One, a *Lychas*, corresponds to Glauert's (1925) unillustrated description of *L. jonesae*, apparently from a single specimen collected near Kalgoorlie, Western Australia. Koch (1977), who examined the holotype, included *L. jonesae* in *L. marmoreus* but did not give reasons for doing so. The present specimens resemble *L. alexandrinus*, widely distributed in arid Australia (Koch, 1977, map 4), but differ significantly from it and from *L. marmoreus*. They agree closely, except in colouration, with the (markedly faded) type of *L. jonesae*. An illustrated redescription of *L. jonesae* is in preparation, and the present specimens referred to that species meanwhile.

The other belongs to the genus *Isometroides*, which Main (1956) suggested was monospecific, all specimens being referable to *I. vescus*, a view supported by Koch (1977). The Berri specimens agree better with the descriptions of Keyserling (1885), Kraepelin (1916) and Glauert (1925, 1963) of *I. angusticaudis*, and are certainly not typical of *I. vescus*. An account of the genus *Isometroides* is in preparation, and the present specimens referred to *I. angusticaudis* in anticipation of that work.

Many factors influence the distribution of scorpions, including latitude and climate, type of terrain and soil hardness. Biotic factors such as intra-guild competition and predation are also important (Polis, 1990). The latitude of the study site, ca 34°, is within the range of maximum scorpion diversity, given by Polis (1990) as 23-38°. Within this belt up to ca 10 species may occur sympatrically in the northern hemisphere, though most locales have only 3-7. Diversity is greatest in desert regions, with 24 of the 28 communities of six or more being in subtropical deserts, where terrain may range from loose sand to hard packed stony ground. Soil hardness was closely related to species distribution in *Opisthophthalmus* by Lamoral (1978). Bradley (1986) showed that populations of the burrowing *Paruroctonus utahensis* were denser on soft soils than hard, and that its burrowing was impaired by the hardening of the soil due to rain. Vegetation patterns correlated both with soil type and scorpion population, but areas with different scorpion densities contained similar biomass of potential prey. Bradley also demonstrated the destruction caused by flooding to a population of *P. utahensis*.

Polis (1990) shows that biotic factors may well affect the composition and balance of a population. He gives strong evidence on the important influence of scorpions on the community in which they live, by competition through predation on other invertebrates or cannibalism of smaller scorpion species, and of smaller conspecific instars. Individual scorpions of different species but similar size may well compete direct-

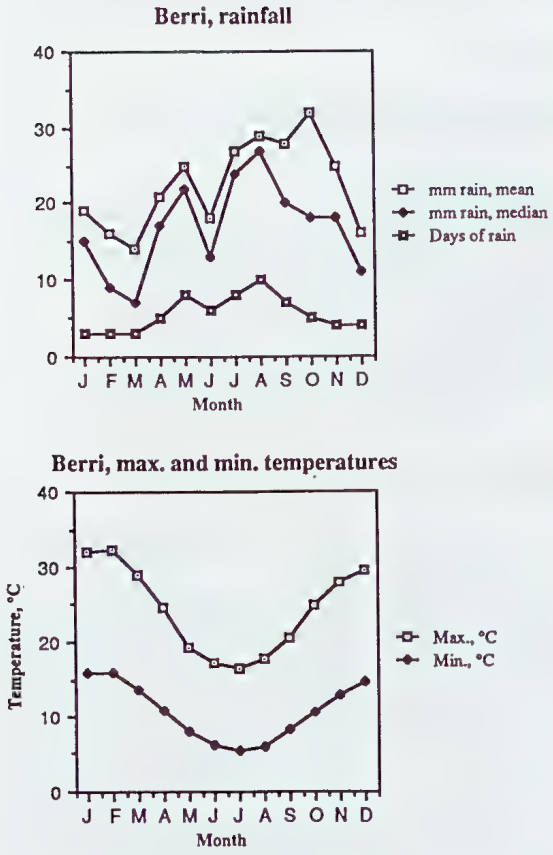

FIG. 1. Temperature and rainfall, Berri (nine year average).

ly for food, since most are generalist predators, perhaps leading to one species becoming dominant. Different sized scorpions may take different groups of prey, based on size, though the young of a large species may compete directly with adults of a smaller when the individuals are of comparable size.

METHODS

The site is about 8 km NNE. of Berri, 140°38'E, 34°13'S, in the South Australian Riverland. The climate at Berri is warm and dry (Fig. 1). A transect 10m wide was laid out from dune to dune across a swale, some 300m. The nature of the soil was noted, and trees and shrubs more than a few cm high plotted to the nearest 1m.

Single-, or on one occasion two-day, visits were made to the study site on fourteen occasions, on moonless nights when possible, between March 1989 and May 1992. On each visit the

TABLE 1. Catches of scorpions, blacklighting only.

parts of the transect containing the characteristic burrows of *Urodacus yaschenkoi* were noted. On one occasion in summer all the burrows within the transect were marked with numbered tags. Burrow identification was confirmed and specimens obtained by trapping burrows away from the transect. The traps were plastic vending machine cups, ca 200cc capacity, dug into place at the burrow mouth, the burrow opening directly at the lip of the cup. The traps were visited at least 1h after sunset, when scorpions had emerged from the burrows and fallen into the cup.

Smaller burrows, without the curved entrance of *U. yaschenkoi*, were identified as those of *U. armatus* by digging out the scorpion. On three occasions *U. armatus* was identified by blacklight at a burrow mouth which was then marked and examined next day.

Blacklighting was carried out, away from the transect but within the dune-swale system, on each visit by two persons, working parallel to each other and approximately 100m apart. Blacklighting, commencing at various times after sunset, on some occasions as soon as it became dark enough and on others up to 1.5h after sunset, was continued for ca 2h.

Urodacus yaschenkoi and *U. armatus* could be distinguished in the field by blacklight. *Isometroides*, except very small individuals, was distinguishable from the *Lychas* species, but the two *Lychas* could not be told apart until the catch was examined indoors. This took place on return from the field, when notes on weather, capture sites and behaviour were written. Detailed plots of specimen location were not made, but it was possible to assign the taxa to dune, dune base or

FIG. 2. View of transect across swale, looking north from southern dune. 1, sandy soil at base of dune. 2, low bank beside old track. 3, track. 4, swale. 5, far dune. See also Figs 3 and 4.

swale. Identifications were confirmed on return to the laboratory.

RESULTS

The transect, running N-S, extends 300m from the top of one dune, ca 6m high, across the flat swale, to the top of the next dune (Fig. 2). The dunes bear scattered mallee trees, *Eucalyptus oleosa* and *E. brachycalyx*, numerous bushes of native hop, *Dodonaea* sp., and clumps of *Spinifex*. The swales are lightly covered with grass and other low plants, with sparse bushes of native hop and of *Cassia nemophila* var. *platypoda* (Fig. 3).

Catch data are summarised in Table 1 and distributions in Fig. 4. *Urodacus yaschenkoi* burrows occur on the dunes, mainly in the open but a few under light cover. In January 1991, 80 burrows were located and marked within the transect, but by October, 56 tags either were not related to a visible burrow or had been disturbed by animals. Of the three *U. armatus* burrows marked while blacklighting, two had been closed by next day, and would have been missed apart from the marker. No further attempts were made to trace the fate of individual burrows. Individual *U. yaschenkoi*, usually adult males, were found by blacklighting in December-February, mainly on the dunes but including one ca. 50m onto the swale. *U. yaschenkoi* were also observed at their burrow mouths by blacklight in summer.

Urodacus armatus burrows were occasionally found on the dunes, but most were at the dune base and for up to 50m onto the swale. *U. armatus*, mostly immature, found by blacklight had a similar distribution , with occasional examples up to ca 100m onto the swale. Immature individuals have sometimes been found clinging to low vegetation within a few cm of the ground. *U. armatus*, recognisable by blacklight from *U. yaschenkoi* by their squat pedipalps, have been seen at the burrow mouth between October and February.

Three species of buthid, *Lychas jonesae*, *L. variatus* and *Isometroides angusticaudis* have been found, only on the swale, by blacklighting. *L. jonesae*, commonest overall, though on occasions outnumbered by *I. angusticaudis*, occurs all across the swale, but often near low vegetation near the dune base. Some have been found clinging to stems within a few cm of the ground,

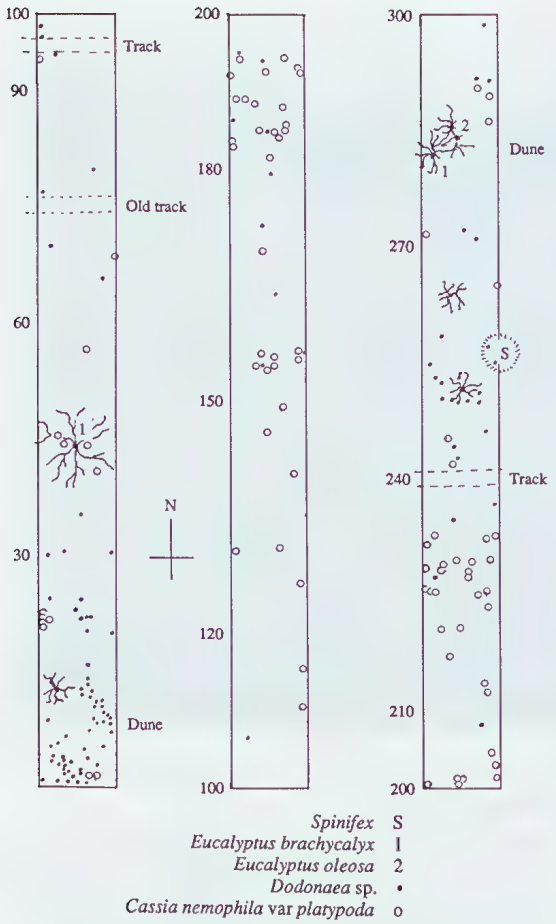

FIG. 3. Plot, to scale, of distribution of major plants across transect. Distances in metres.

mostly head down, but none have been found high in bushes.

Lychas variatus has been taken occasionally, never more than two and frequently none, in an evening. Insufficient have been found to comment on their distribution on the swale.

Isometroides angusticaudis has mostly been found on the surface by blacklight, among low grass rather than taller vegetation and extending up to but not above the dune base. A few have been dug by day from the burrows of lycosid spiders, abundant on the swale but not the dunes.

One *Cercophonius kershawi* (identified from Acosta (1990)) was found in May 1992 by kicking over leaf litter beneath mallee trees while blacklighting. (Two juvenile *Lychas variatus* were caught in the same way on dunes within 1 km of the transect in June 1987).

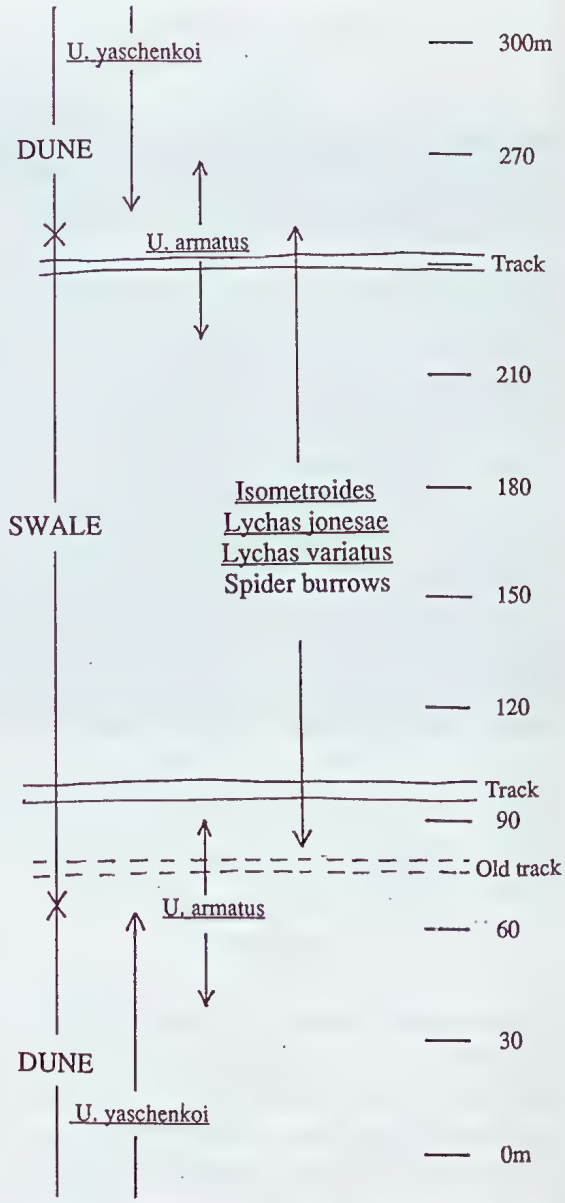

FIG. 4. Distribution of scorpions across dune and swale system. *Urodacus yaschenkoi* occurs on the dunes, *U. armatus* at their bases and the three buthids on the swale.

DISCUSSION

Many labels in collections state a locality, without details of microhabitat. The population disparity now described from localities a few meters apart suggests that it may be helpful to define localities more precisely.

Lamoral (1978), studying two burrowing

species of *Opisthophthalmus*, found clear separation of two otherwise sympatric species, strongly correlated with soil hardness, a factor probably also important in *Urodacus*. Koch (1978) found the depth and tortuosity of *Urodacus* burrows within a species greater with aridity. There is also a species difference: *U. yaschenkoi* and *U. hoplurus* dig deeper and more spiral burrows than *U. armatus*. Koch (1981) noted that *Urodacus* scorpions show little correlation with soil type, but more with softness and the chance of reaching water by burrowing. Shorthouse (1971), Shorthouse and Marples (1980) and Koch (1978) have described the spiral burrows up to 1m deep of *U. yaschenkoi* in loose sandy soil. The dune soil at Berri is of this type. Most burrows of *U. armatus*, seldom more than 30cm deep, are in the firmer soil at the dune base and swale, though some occur up the dunes, in what appears otherwise to be *U. yaschenkoi* territory.

Koch (1981) considered three Australian zones, a moist temperate southern, semi-arid to desert central and humid tropical northern, associating various scorpions with these zones: *Urodacus yaschenkoi* and *U. armatus* he regarded as mainly central forms. He found scorpion distribution not correlated with vegetation type, single species occurring in a wide range of habitats. He suggested that range-determining factors include temperature, precipitation and biotic factors, e.g. competitive exclusion. He also examined morphological characters, suggesting that large size, longer metasomal segments and spines, more granulation, and higher pectine tooth counts are aridity-linked in *Urodacus*, while large size, light colouration, more granulation, higher pectine tooth counts and a less prominent subaculear tooth are aridity- linked traits associated in *Lychas*. He regarded *Isometroides* as showing the culmination of these buthid traits. Of the sympatric species at Berri, both *Urodacus* are pale and smooth, their pectine counts largely overlap, but *U. yaschenkoi* is large and *U. armatus* small. *L. variatus* and *I. angusticaudis* are both pale but mottled though *L. jonesae* is small and dark, with subaculear tooth intermediate between the other two buthids.

The swale, where *Isometroides* has been collected by blacklight, contains numerous lycosid spider burrows, up to 30cm deep in hard soil. *Isometroides* was recognised by Main (1956) as a spider predator and collected by her from their burrows. Four have been so collected in the present study, but no concerted digging has been done.

The habit of clinging to vegetation close to the ground, also observed in immature *U. armatus* by G.T. Smith (personal communication), may enable scorpions to avoid wandering predators. Some scorpions, e.g. *Centruroides exilicauda* in America, are frequently found in bushes well off the ground, but such climbing has not been seen in the present case.

The total catches of buthids suggest that *Lychas jonesae* is dominant on the swale, though on occasions more *Isometroides* have been caught. *L. variatus* is much less common than either. *Isometroides* is known to be a specialist burrowing spider predator. Probably the *Lychas* species are less specialised, though little is known of their diet; one instance of *L. jonesae* eating an immature *U. armatus* was the only act of predation observed. Insufficient is known of the habits of the two *Lychas* to indicate why the smaller should be commoner.

FROM FLOOD AVOIDANCE TO FORAGING: ADAPTIVE SHIFTS IN TRAPDOOR SPIDER BEHAVIOUR

BARBARA YORK MAIN

Main, B.Y. 1993 11 11: From flood avoidance to foraging: adaptive shifts in trapdoor spider behaviour. *Memoirs of the Queensland Museum* 33(2): 599-606. Brisbane. ISSN 0079-8835.

Fossorial habits protect many mygalomorph spiders from both biotic and environmental factors. However burrows in some habitats are vulnerable to sheet flooding. Spiders in diverse habitats counter the hazard of flooding in various ways. A comparative account of adaptive specialisations, particularly of burrows, in flood avoidance is presented. Such primary modifications sometimes lead to new foraging opportunities. Examples are given of modified foraging as a consequence of burrow adaptations. The origins of such constructions are hypothesised in relation to changing climatic regimes and modified habitats. The idiopid genera *Homogona* Rainbow and *Neohomogona* Main are restored from synonymy.
□*Mygalomorphae, Trapdoor spiders, burrows, flood avoidance, foraging, Australia.*

Barbara York Main, Zoology Department, University of Western Australia, Nedlands, Western Australia 6009, Australia; *5 November, 1992.*

Most mygalomorph spiders are terrestrial and either make burrows, silk tubes or webs or combine a web with a burrow. A few are arboreal and either make tubes in the bark of trees or have webs in crevices or under bark; their nests are generally not associated with foliage. Of the 15 currently recognised families of Mygalomorphae (Raven, 1985), 10 occur in Australia and of these, seven have at least some representatives with trapdoors. A burrow provides protection from the physical environment, from weather conditions and from predators and parasites; it provides a brood chamber for eggs and spiderlings. A burrow is also a lair from which a spider perceives and ambushes or intercepts prey; thus it provides a foraging base. All these functions have been commented on many times in the literature over the last century, the earliest comprehensive study possibly being that of Moggridge (1873, 1874).

In its simplest form a burrow has an 'open' entrance from which a spider makes short sorties in pursuit of prey. In extreme habitats, the entrance may be sealed with silk or soil for added protection during certain times of the year, for example during summer drought or winter snow falls. Folding collars and finally hinged doors give maximum security and protection. The protective advantage of a door has been shown to be offset by the hinge-line inhibiting the foraging area of a spider but nevertheless many door builders have overcome this disadvantage by various modifications to the burrow (Coyle, 1981; Main, 1986).

This paper discusses the adaptive behavioural responses associated with nest structure and site, of Australian mygalomorph spiders, to the hazard of flooding and shows that these primary adaptations have sometimes secondarily created new foraging opportunities for spiders. In particular the previously unreported nest of an undescribed species of *Aname* which exhibits both 'primary' and 'secondary' responses in its flood-avoidance tactics is described also.

FLOOD AVOIDANCE BEHAVIOUR

In certain terrestrial habitats, burrows and silk tubes and webs face the physical hazard of flooding. Generally the complexity of habitats in rainforest and mesophyll forest provides some sort of buffer against flooding; there is greater capacity for absorption of rainfall in the vegetation and litter of a forest floor than there is for example in desert or semi-arid country where sheet flooding on bare ground is a common phenomenon. Even so some rainforest situations are subject to water logging and flooding associated with torrential downpours. Likewise where rain is markedly seasonal as in monsoon rainforests the alternation of wet and dry conditions means that some habitats experience sudden saturation or inundation. Main (1976, 1982b) and Cloudsley-Thompson (1982, 1983) discussed some of the burrow modifications of mygalomorphs which prevent flooding. Avoidance of flooding is different to behaviours whereby spiders withstand immersion by enclosing the body in a bubble of air.

In summary, in avoiding flooding of nest sites, mygalomorph spiders have adapted behaviourally in several ways:

(1) By moving the nest site–behaviour prior to, during or after the event.

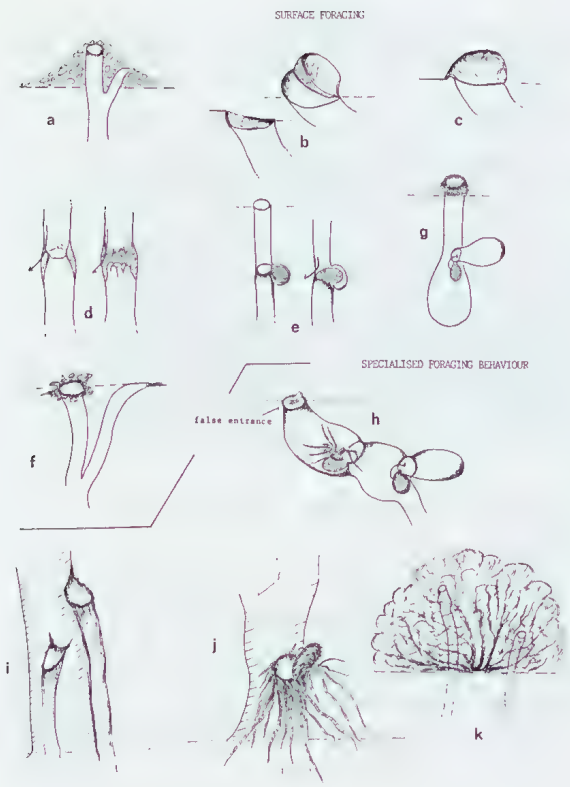

FIG. 1. Flood avoidance specialisations of mygalomorph burrows: (a) soil and pebble levee of *Kwonkan wonganensis*; (b) bath plug door (Idiopidae); (c) dome or 'cap' of an *Aganippe* species (Idiopidae); (d) 'sock' of *Anidiops* (Idiopidae); (e) 'pebble' and collar closure of burrow of *Stanwellia nebulosa* (Nemesiidae); (f) side shaft and escape 'hatch' of burrow of *Aname diversicolor* (Nemesiidae); (g) side shaft with door in nest of *Idiommata* sp. (Barychelidae); (h) profile of nest of a *Teyl* sp. (Nemesiidae) with entrance atrium and subterranean doors (and sideshaft); (i) aerial tube of *Misgolas robertsi* (Idiopidae) supported on tree trunk; (j) extended tube with trapdoor of *Aganippe castellum* (Idiopidae) supported against stem of shrub; (k) silk and soil tube of 'turret-building' *Aname* sp. (Nemesiidae) in foliage of shrub.

(2) By permanently reinforcing the nest e.g. burrow (and/or opening) against inundation–prevention.

(3) By modifying the nest structure so that part of it is safeguarded against inundation–prevention.

(4) By modifying the nest so that it is (in part) sited beyond the reach of intermittent flooding–prevention.

(5) By adopting an arboreal instead of terrestrial habitat.

Examples of these adaptations will now be given.

(1) Mygalomorphs elsewhere have been recorded as moving nest sites prior to inundation. The Amazonian web-weaving diplurid *Ischnothele guianensis* makes webs on tree trunks in the rainforest which is seasonally inundated. Spiders move their web sites higher up the trunks as the water level rises (Hofer, 1991). The Australian diplurid genus *Cethegus* (curtain web spiders), which makes copious webs sometimes associated with a burrow retreat, amongst stones, or against logs or shrub stems, is widespread across tropical Australia, the interior and southwestern Western Australia (Main, 1960, 1991a and unpublished; Raven, 1984). A study on a species at Durokoppin in the Western Australian wheatbelt showed that the spiders move their web sites after rain damage (Main, unpublished). Another species which occurs amongst the rocks of water courses in the Kimberley rainforest patches (Main, 1991a) presumably moves web sites during the 'wet' when the habitat is inundated. Although dependent on a web for prey capture these spiders are remarkably agile on the ground, and thus could readily decamp if flooded out of their nest sites, following which a web could be readily reconstructed (unlike some architecturally complex burrows of other mygalomorph families).

(2) Even 'open' burrows, if lined with silk frequently have collapsible or folding collars which can prevent flooding, for example as in many nemesiids and some *Misgolas* species, e.g. *M. pulchellus* (Rainbow & Pulleine) (pers. obs.). Collars are sometimes strengthened with litter or by a surrounding pile of soil or silk-bound pebbles (Fig. 1a) e.g. the levees of some nemesiids including *Kwonkan wonganensis* (Main) (originally described as *Dekana* (Main, 1977, plate 15)) (see also Main (1981, plate 1, fig. d) with reference to the levee of a 'diplurine' burrow). The ctenizid *Conothele*, the actinopodid *Missulena* and some barychelids have secure doors and parchment or canvas-like, silk linings which are more-or-less impermeable. Most idiopid species construct well defined burrows and all except some species of *Homogona*[1], *Neohomogona*[1] and *Misgolas* have a trapdoor. Many idiopid species which have adapted to flood-prone habitats, ranging from rainforest to desert

[1]The idiopid genera *Homogona* Rainbow and *Neohomogona* Main were synonymised with *Cataxia* Rainbow by Raven (1985). They are here formally restored from synonymy and diagnosed in Main (1985).

and particularly in bare ground or sloping creek banks, frequently have permanently reinforced burrows including thick plaster walls coated with dense silk, and thick, close fitting bath-plug like doors or tightly fitting caps (Figs 1b, c). Such secure nests also provide protection against predators, parasites and adverse physical conditions, including dessication.

(3) Some species of Idiopidae, Nemesiidae, Barychelidae and Hexathelidae safeguard particular areas of their burrows against inundation. Such safeguards include (a) special blocks in the lumen or (b) sideshafts with 'escape' hatches or (c) one or more sidechambers with 'internal' trapdoors. Examples of the above are:

(a) Some species which have either an open entrance (e.g., *Misgolas* spp.) or a flimsy door (e.g., *Anidiops*) have a collapsible collar ('sock', see Main, 1957, 1976, plate 9 and 1985, figs 209, 210) consisting of a detachable section of the silk lining which can be pulled downwards by the spider thus blocking the burrow (Fig. 1d). Water seeping down the walls or flowing into the burrow is deflected by the infolded 'neck' of the sock and soaks into the surrounding soil leaving the lower section of the silk lined burrow unflooded. A similar structure in *Stanwellia nebulosa* (Rainbow & Pulleine) (Fig. 1e) is further reinforced by an attached, artificial pebble which seals the lower silk lined part of the burrow (Rainbow & Pulleine, 1918, pl. 20; Main, 1964, 1972 figs 22a, b, 1976). Although these devices are generally considered a protection against predators (see Main, 1956a regarding *Anidiops* (=*Gaius*) their original function was probably prevention against flooding (see Main, 1976 regarding *Stanwellia*).

(b) Nests of some species have silk sideshafts with 'escape' hatches at the surface (see Fig. 1f) which probably enable the spiders to escape flooding as well as intrusive predators. Examples are the burrows of 'wishbone' spiders of the genus *Aname* (Main, 1982a, fig. 1; 1976, pl. 10) and *Misgolas ornata* (Rainbow) (Main, 1985: 33).

(c) Sideshafts with 'internal' trapdoors are constructed by several undescribed species of *Teyl* (Nemesiidae) (earlier attributed to *Ixamatus*, see Main (1976, pp. 86-88, fig. 21)), by *Hadronyche* (Hexathelidae) (see Main, 1964:40, fig. j; 1976, fig. 18c; Gray, 1984, fig. 31 (described as *Atrax*)), *Idiommata* (Barychelidae) (Main, 1976, fig. 19d; Raven & Churchill, 1991: 35) and *Missulena* (Actinopodidae) (Main, 1956b). While the sideshafts of all species studied are known to function as brood chambers and also sometimes as protection from predators it is probable that the original function was that they offset flooding of the main shaft of the burrow (see Fig. 1g). Considering the habitat of *Teyl* species this is unequivocal.

(4) Burrows of some species are continued as tubes above the ground or litter surface and may be strengthened into free standing palisades (by the attachment of leaves, twigs and debris) which deflect sheet flooding in bare ground or prevent immersion in water-soaked litter. Examples include the tubes of *Homogona cunicularius* Main (Main, 1983, fig. 15), *Misgolas hirsutus* (Rainbow & Pulleine) (pers. obs.) and *Neohomogona stirlingi* and *N. bolganupensis* Main (Main, 1985, fig. 219). Tubes that extend a considerable distance above the substrate are attached to rocks, tree buttresses, exposed roots e.g. *Misgolas robertsi* (Main and Mascord) and related species (Main and Mascord, 1974, pl. 1a, b; Mascord, 1970 pl. 2 fig. 4), logs e.g. *Cataxia maculata* Rainbow (Main, 1969, figs 30, 31) or stems of shrubs e.g. *Aganippe castellum* Main (Main, 1986, figs 2, 4i; 1987, fig. 6). The first examples have open tubes, sometimes with flanged, collapsible collars but *A. castellum* has a trapdoor (Figs 1i, j). All are effective in flood avoidance by having the entrance above the 'flood level' following a deluge.

The previously undescribed but remarkable burrow/tube of an undescribed species of *Aname* extends as a turret-like tube amongst supporting foliage of shrubs. The genus *Aname* which is widespread but endemic in Australia and Tasmania, occurs in varied habitats, is taxonomically diverse and includes many undescribed species.

The turret-building species occurs in semi-arid country in southeastern Western Australia and Eyre Peninsula in South Australia. Nests have been observed in mallee/spinifex associations (*Eucalyptus/Triodia*) (Figs 2a, b, c) but also in mulga and amongst chenopod shrubs in seasonally swampy habitats. The spiders make shallow burrows lined with silk which extend as tubes into the foliage of supporting tussocks or shrubs and open either within the foliage or above the canopy (Fig. 1k). The outside of the tube is heavily but irregularly coated with soil. During and after rain, sheet flooding occurs in such sites, and particularly in the sandy loam of mallee/spinifex associations, water flows in a slurry around the spinifex hummocks. Burrows appear to be deepened (and/or remade) after rain and the sodden spoil dumped on the lip of the tube and outside the

Siting of burrow opening		PRIMARY ADAPTATION		SECONDARY ADAPTATION
		Flood avoidance through modified burrow structures	Unmodified foraging	Specialised foraging in response to 'new' opportunities
FOSSORIAL	Ground	—open* burrows: collars& folding collars & levees	surface

		—extension of closed burrow (with door) against plant stem		arboreal
		extension of open tube into foliage		foliage canopy
CORTICOLOUS		— open or closed tubes in bark		arboreal

TABLE 1. Siting of mygalomorph burrows primarily modified in flood avoidance and those secondarily resulting in specialised foraging methods. * open = without door; closed = with trapdoor.

entrance. Thus the turret is heightened progressively while much of the paste-like spoil pours down the outside wall, solidifying into a kind of stucco as it does so. Tubes up to 25cm have been observed within the supporting scaffolding of spinifex hummocks. The sometimes bulky structures belie the relatively small size of the artificers (up to 4.5mm carapace length). Occasionally free-standing tubes (but small and only up to 10cm high), away from shrubs, are found (see Main, 1982b, fig. 2). Most unsupported tubes may collapse (at ground level) and be destroyed during flooding while at least the aerial section of those amongst the tussocks remain relatively intact.

(5) Mygalomorphs which have their nests sited completely on the trunks of trees are found only in very wet forests. Their nests in such situations appear well protected against inundation. Australian examples include theraphosids which make silk retreats under bark in north Queensland (pers. observation), the nemesiid, *Chenistonia villosa* Rainbow and Pulleine which makes defined silk tubes in crevices of *Casuarina* bark in the karri forest of southwest Western Australia (pers. observation), species of the ctenizid, *Conothele*, in tropical Queensland (Main, 1976) illustrated in McKeown (1963), the barychelid *Sason* in north Queensland (Raven, 1986) and migids e.g. *Moggridgea tingle* Main (Main, 1991b). *C. villosa* and *M. tingle* both make nests in the ground also, in sites not vulnerable to water logging. This is probably a secondary habitat adopted in response to gradual drying of the climate and environment where the bark of trees would be subject to dessication.

NEW FORAGING OPPORTUNITIES

Foraging 'techniques' of mygalomorphs are closely associated with burrow structure. Burrows of some species are constructed with special adjuncts that enhance foraging, such as silk trip threads or attached twiglines. Main (1957, 1982b, 1987) described some combinations of burrow structure, morphology and foraging behaviour in relation to the habitats occupied and noted the relative efficiency of the various foraging strategies.

In modifying behaviour and burrow structure in flood avoidance, some species have as a consequence been exposed to 'new' foraging opportunities. Table 1 summarises the categories of 'primary' burrow modifications and sitings associated with flood avoidance and any 'secondary' changes of foraging behaviour. Reinforcement to burrows and doors which do not involve alteration of siting of the entrance, do not generally result in modification of foraging method. However, any modifications which alter the siting of burrow entrances away from the surface of the ground do result in specialised (predatory) foraging behaviour.

A striking example of a subterranean entrance is that constructed by a group of *Teyl* species. Although most species of *Teyl* have open burrows, a few build doors in flood avoidance. Several species have surface doors in bare open ground but the foraging method is similar to that of species with open holes (Main, 1986). Several species which occur in deep litter in seasonally flood-prone, braided creeks and the flats around salt lakes in southern Western Australia have evolved a further specialisation. An open 'false entrance' leads into a cup-like pouch or atrium which has on its inner wall a trapdoor (entrance

FIG. 2. *Aname* sp. Habitat and turrets (a) mallee/spinifex shrubland on sandy loam soil west of Balladonia, Western Australia; (b) spinifex shrubs with 'turrets'; (c) turret in spinifex, note open entrance.

proper) which leads into the main shaft of the burrow; a second trapdoor leads from the main shaft into a blind sideshaft (Fig. 1h). These doors provide a double safety valve in the event of flooding (Main, 1976). The false entrance/atrium functions like a pit-fall trap which 'catches'

crawling insects that are then seized by the spider as it straddles the open door inside (Fig. 1h) (Main, 1982b fig. 7d). The pit-trap also provides a clear foraging area for the subterranean entrance-proper, unencumbered by the litter which would otherwise impede the plug-like door. Notable examples of elevated nests (supported against tree trunks), the primary adaptation of which has been flood avoidance but which has secondarily resulted in arboreal foraging, are those of *Misgolas robertsi* (see Mascord, 1970 p.12; Main 1976, plate B5) and *Aganippe castellum* (Main, 1986, 1987 p. 34 and fig. 6).

Spiders, the nests of which are sited on the trunks of trees but which have no contact with the ground and are thus corticolous, similarly have adopted an arboreal foraging behaviour. *Conothele* (possibly *Conothele arboricola* Pocock), *Sason* and *Chenistonia villosa* and *Moggridgea tingle* are thus all arboreal foragers although the latter two are recognised as being facultative in their behaviour. Even *Idioctis* species which extend their tubes above the tide level (or are sealed against tidal rise), sometimes against mangrove stems (Abraham, 1924), are probably in effect arboreal foragers.

However, until recently there was no known example of an Australian mygalomorph which fed in the foliage or canopy of vegetation. Therefore, the turret-building species of *Aname* is of interest. The tubes open either in gaps amongst the foliage or above the canopy of tussocks and shrubs. The spiders presumably do not venture far, if at all, away from the entrance (and are unlikely to crawl down the outside of the tube to the ground) and thus are dependent on insects creeping amongst and on the foliage and flying insects as they alight. This would mean that they are a truly foliage or canopy forager as distinct from arboreal spiders which forage on the trunks of trees and shrubs.

BURROW MODIFICATIONS AS A RESPONSE TO HISTORICAL ENVIRONMENTAL CHANGES

The arboreal tubes and most corticolous nests in mesophytic and rainforest habitats have evolved *in situ* in continuously humid habitats (but where some sites may experience extreme flooding). In contrast, of those flood-adapted nests which occur now in semi-arid and arid habitats most have evolved (*in situ*) from mesophytic denizens but as a result of a general drying of the habitat associated with climatic aridification. Paradoxically while probably making simple tubes and burrows in a "primitive", uniformly wet habitat the spiders have been exposed to the the hazard of sheet flooding as a result of periodic deluges associated with a dryer, but seasonal climate. Nevertheless, clearly a few such species do belong to taxonomic groups which already had burrows and doors well adapted to sudden deluges in rainforest and mesophytic habitats, e.g., species of *Arbanitis*.

Much of the semi-arid woodland, shrubland and saltbush steppe of southern Australia enjoyed a consistently wet climate and supported mesophytic forest and rainforest interspersed with swampland during the early Tertiary (Cookson, 1973; Cookson & Pike, 1953, 1954; Truswell, 1990). With progressive drying of the climate and development of a markedly seasonal weather pattern the vegetation was altered, leaving some relictual, moist microhabitats in juxtaposition with other seasonally alternating wet/dry microhabitats some of which now experience periodic, sudden inundation.

Certain species of trapdoor spiders whose taxonomic relatives in rainforest and mesophytic habitats lack specialised burrow structures have responded to seasonal sheet flooding in arid habitats by modifying burrow structures in flood avoidance. Notable types of burrow modification in the western part of the continent, which are hypothesised as having evolved in direct response to (geologically) historical changes in the environment are the burrows of *Aganippe castellum*, *Teyl* species with both surface and subterranean doors and the aerial tubes of the *Aname* species. Main (1986) discussed the probable origin of the semi-arboreal nest of *A. castellum*, its anti-flooding function and adoption of a 'new' foraging behaviour. This dual adaptation probably evolved during the late Miocene/Pliocene in response to fluctuating wet/dry seasons and fragmentation of the landscape into a mosaic of wet and dry microhabitats. It also has been postulated earlier (Main, 1976) that the single surface door of some *Teyl* species evolved in response to climatic/habitat changes towards a seasonal weather regime and more open habitat. The turret nest of the *Aname* species has probably, similarly developed contemporaneously, in response to the drying of the climate, in different geographic habitats but which also occur in areas subjected to some seasonal, torrential or at least very heavy rain which causes flash flooding.

INTRASPECIFIC PREDATION IN *CLUBIONA CORTICALIS* (ARANEAE: CLUBIONIDAE)

P. MARC

Marc, P. 1993 11 11: Intraspecific predation in *Clubiona corticalis* (Araneae: Clubionidae). *Memoirs of the Queensland Museum* 33(2): 607-614. Brisbane. ISSN 0079-8835.

Clubiona corticalis is supposed to be a useful biological control agent of lepidopteran larvae (e.g. Tortricidae) in orchards. Thus, the levels of its intraspecific predation especially when bred in captivity must be determined. Predation is a risk at mating and dispersal. Cannibalism during mating, studied at 13°C, 20°C and 27°C and without prey in cages, remains low (1.5%) during the first 24 hours at all temperatures. After 24 hours cannibalism increased and was significantly higher at 27°C than at 13°C after one week. Males were 72% of the victims. Males can mate twice with different without increasing the risk of cannibalism. The spiders were studied for 12 days after dispersal. Until Day 3, no intraspecific predation occured, whatever the availability of prey for juveniles. Intraspecific predation is very much reduced by the availability of sufficient prey, and a female given prey did not feed on its own progeny. *Clubiona corticalis* pourrait être utilisée en verger pour lutter contre des larves de lépidoptères (Tortricidae). Il était donc important de connaître les niveaux de prédation intraspécifique chez cette espèce, lorsqu'elle est élevée en captivité. Il est montré qu'il y a des risques de prédation à deux moments du développement: l'accouplement et la dispersion. Le cannibalisme durant l'accouplement, étudié à 13°C, 20°C et 27°C sans proie dans les enceintes, reste faible à toutes les températures (1.5%) pendant les premières 24 heures. Après 24 heures, le cannibalisme augmente. Il est significativement plus fort à 27°C qu'à 13°C après une semaine. Les mâles sont les victimes dans 72% des cas et peuvent s'accoupler deux fois avec des femelles différentes sans augmenter les risques de cannibalisme. Les jeunes araignées sont étudiées pendant douze jours après la dispersion. Quelle que soit la disponibilité en proies, aucun cas de prédation intraspécifique n'intervient jusqu'au troisième jour. Ensuite, la disponibilité en proies dimunue de façon très significative le niveau de canabalisme. A noter qu'une femelle disposant de proies, n'exerce aucune prédation sur sa progéniture.□*Biology, Europe, laboratory, Araneae, France, breeding, auxiliary, intraspecific predation, Clubiona corticalis, dispersal, mating.*

P. Marc, Laboratoire de Zoologie et d'Ecophysiologie, L.A. INRA, Université de Rennes I, Campus de Beaulieu, 35042 Rennes Cédex; *19 January, 1993.*

Clubionids are wandering, nocturnal spiders (Marc, 1990a), and certain species are efficient in caterpillar control in orchards (Mansour *et al.*, 1980; Marc and Canard, 1989). The study of the arachnofauna in apple orchards led us to take an active interest in whether *Clubiona corticalis* (Walckenaer) can be used in biological control of pest caterpillars. In the laboratory, all instars of *C. corticalis* can consume large quantities of lepidopteran larvae, especially tortricids, harmful to orchards (Marc, unpublished data). However, the efficacy of using *C. corticalis* in biological control remains uncertain. Spiders are generally envisaged as having high rates of intraspecific and interspecific predation (Bristowe, 1958; Greenstone, 1978). If this is true for *C. corticalis*, then its effectiveness in biological control would be reduced, i.e., an increase in spider densities in the field would increase cannibalism. Thus, data on rates of cannibalism in *C. corticalis* are needed.

In *Anyphaena accentuata* (Walckenaer), *Philodromus cespitum* (Walckenaer) and *Diaea dorsata* (Fabricius) (the most abundant non-web spinning spiders in apple orchards), intraspecific and interspecific recognition minimizes cannibalism (Marc, 1992). Whether this is true of *C. corticalis* is not known. *C. corticalis* occurs in very high densities on pines (Marc, 1990b) where they build silk nests under bark for refuge during the day (Marc, 1990a). Partially flaking bark are favoured shelters on which concentrations of 6-12 nests can be found in 10-15cm^2 (often the clustered nests are stuck together). Furthermore, nests of other clubionids, *Clubiona brevipes* Blackwall, *C. leucaspis* Simon and *Ceto laticeps* (Canestrini), often adjoin those of *C. corticalis*. These aggregations suggest low intraspecific and interspecific predation in nature. However, laboratory bred spiders for use as auxiliaries may present special problems. In captivity, intraspecific predation at critical moments of develop-

ment may be artificially high because contact between individuals is more frequent. Mating and dispersal are likely to be critical periods (Fig. 1). This work determines levels of cannibalism in *C. corticalis* when bred in captivity.

MATERIALS AND METHODS

Subadult spiders (one instar before maturity) were collected in winter, in a forest under the bark of *Pinus sylvestris*. Removed from the field in Ependorff micro-tubes, they were separated into males (recognisable at this instar by a bulging palpal tarsus) and females. Each individual was then placed in Petri dishes (9 cm in diameter and 1.5 cm high) for breeding. Damp cotton wool kept humidity high in cages. Individuals were fed with two flies (*Lucilia*, Diptera) three times per week. Unless otherwise specified all procedures and observations where carried out in the laboratory. All enclosures are here referred to as 'cages'.

Cannibalism during Mating

In each of 135 Petri dishes, one male was placed with a virgin female, and no food was added for the week of the experiment. Breeding cages were kept at 13°C, 20°C and 27°C under long photoperiod (L-D=16-8), and were observed several times a day. Males and females used for mating had all moulted to adults at least two weeks before.

Cannibalism After Dispersal

Dispersal, in this species, is when the juveniles at instar 2 leave the female's breeding-nest. Cannibalism, from dispersal (when the first juvenile leaves the breeding-nest) for 12 days was observed on eight egg masses from mating carried out. The egg masses were inside the female's cages (25ml Petri dishes). These observations were carried out at 20°C and in a L:D photoperiod of 16:8. Two groups of 4 egg masses each were set up:

- no prey for the juveniles. In two cages the female had been separated from her progeny.
- *Drosophila* provided for juveniles. The female was taken out of one dish.

Lucilia were given to the females left in the cages every day from the second day after the dispersal of the first of the juveniles. The caged spiders were observed 2-3 times a day for 12 days and the status–alive, death by cannibalism, or death by other causes, or still inside the nest–recorded.

RESULTS AND DISCUSSION

Cannibalism during Mating

In the final moult the reproductive organs are completely formed. Trophic, and locomotory activities and very different behaviour in two sexes of the *C. corticalis* species also appear (Marc, 1992). In the field, males become adults about 10 days before females (Marc, unpublished data). Males then seek females, inside whose nests mating takes place. Because of this asynchrony of maturity, males frequently mate with females soon after the latter moult and at which time females do not feed; they remain in their nest without feeding for 1-2 days after moulting (Marc, 1990a). These two days appear, therefore, to be an especially favourable time for the male to mate because, during this time, the female is only slightly aggressive. Males may also build a nest adjoining those of the subadult females and thus fertilise them soon after the final moult. This was also observed by Austin (1984) in *C. robusta* L. Koch and by Wolf (1990) in *Cheiracanthium pennyi* Cambridge and *Cheiracanthium punctorium* (Villers). The mating of many other species takes place just after the final moult of females. Jackson (1980a) reported that 161 species use tactics of cohabitation (the male stays with the immature female to mate with her after she has undergone her adult moult).

Here, successful mating could be obtained several weeks after the final moult of both sexes. The male approaches the female by tapping on her nest. Copulation, which takes place inside the female's nest, lasts for about 3 hours. The male, mounted on the female's back and facing the same direction, forms an angle of about 45° to her. From this position, he applies each palp consecutively into her epigyne. One male can fertilize the eggs of at least 3-4 females. Mating can also take place outside the female's nest without cannibalism. On the other hand, in other species, intraspecific interactions outside the nest were more 'lethal' (Jackson, 1988a; Jackson and Macnab, 1989).

Intraspecific predation was observed in 13% of the cases for all matings (Fig. 2). The most favourable conditions to reduce the risks of cannibalism during mating would have been to place the males in the female's cages just after the female's moulted, or, at least, in the presence of prey. Yet, here, males were brought to females which had moulted at least 15 days before. Furthermore, no food was provided. Because, to be practicable for production of auxiliary popula-

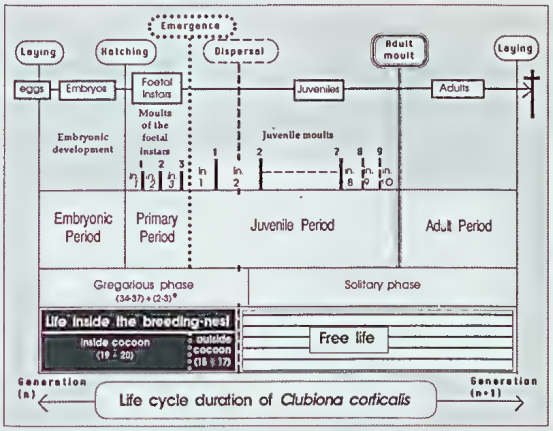

FIG. 1. Life cycle of *Clubiona corticalis*. Terminology in Canard (1987). *In.1*, *in.2* and *in.3* indicate the foetal instars, and in.1 to in.10 the juvenile ones (last juvenile instars, 9 and 10, not present in every individual). Numbers in parentheses indicate duration in days. * (2-3) refer to Time spent by juveniles close to breeding-nest just after dispersal.

tions for biological control, the time needed for care during laboratory breeding must be minimal. Synchronized mating was more practicable. Likewise, the absence of prey in the mating cages simplifies the work. Cannibalism observed after one week (13%) was very much higher than that in the field.

Predation before 24 hours, whatever the temperature, were rare (1.5%) (Fig. 2), but thereafter increased with time and after one week the rate of cannibalism was significantly lower (p) at a lower temperature (7.5% at 13°C and 18.5% at 27°C).

The spider's activity is probably related to the temperature. Indeed, locomotory activity increases with temperature and greatly increases the probability of interindividual encounters and, therefore, the risks of aggressiveness, especially in the absence of prey.

Cannibalism in 24 hours was rare, whatever the temperature, even though the trophic needs of females, especifically after adult moulting, must be high considering ovule production. This can be explained simply by the smaller need for food after only one day of fasting, when this time is sufficient to guarantee mating. Indeed, the pairing time was quite short. Within 5 hours of the individuals being brought together, 75% of the matings had begun, and mating itself lasted 3 hours. We observed, however, that one male could mate several times with the same female which lengthens the interaction, but it seems that this has no effect on the number of egg masses or on the descendants produced by the female. At 13°C no intraspecific predation occurred before 48 hours, and the females were fertilized normally and laid fertile eggs in the same way as at 20°C and 27°C.

In all pairs where intraspecific predation occurred once in the week after the start of the experiment, males are more often (72%) the victim. We did not observe a relation between weight and the individuals eaten, and sometimes smaller individuals ate larger ones. There is no significant sexual dimorphism in *C. corticalis*.

In contrast, even though size is not important, males do move more than females (Marc, 1990a). Conceivably, this weakens males relative to similar sized females. Furthermore, males who have smaller trophic needs and mate several times with different females display less aggressiveness towards their partners. This may partly explain why males were more often the victims of cannibalism.

A male can mate once or twice without significantly increasing the rate of cannibalism after one week (9% for one mating and 14% for two matings; $p>0.05$). However, after two further matings (3 or 4), intraspecific predation increases significantly to 33% ($p<0.05$) if compared to a male which mated only once. However, the male is not always the victim.

In *C. reichlini* Schenkel, males and females can mate several times without cannibalism (Hengmei and Hongquan, 1987). Equally, in interactions of *C. cambridgei* L. Koch, no cannibalism occurred between virgin males and females during the 38 interactions studied (Pollard and Jackson, 1982). Generally, species of *Clubiona* do not seem to be very aggressive

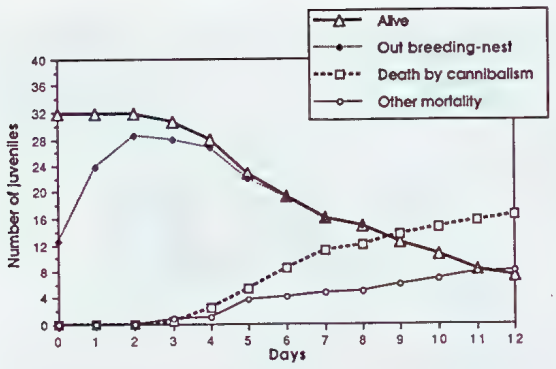

FIG. 3. Survival of juveniles (2nd instar) of *C. corticalis* during 12 days after dispersal, without prey.

toward each other during mating. Apparently, to eliminate cannibalism in *C. corticalis*, males and females should be brought together at about 13°C and individuals should be kept paired for about 24 hours. Furthermore, the presence of prey at 13°C should make the cohabitation of males and females perfectly feasible for several days without intraspecific predation occurring. Such conditions during mating should minimize the manpower needed and lower production costs.

Cannibalism After Dispersal

Juveniles leave the breeding-nest, built by the female, after 1-4 days. Then, they remain grouped around the nest for about 2-3 days before dispersal. This gregarious phase lasts 17-20 days at 20°C (15-17 days in the breeding-nest and 2-3 days around the nest) (Fig. 1). It is only from the juvenile instar 2 (as defined by Canard, 1987), that juveniles begin to hunt. Until leaving the breeding-nest juveniles use on their vitelline reserves and, some attack the undeveloped eggs in the nest. Indeed, weight differences between juveniles leaving the breeding-nest indicate the existence of trophic activity in some individuals, as there are no significant weight differences known to occur between eggs in the same batch in the spider (Lecaillon, 1905). Furthermore, this trophic activity does not seem linked to the female feeding her juveniles by regurgitation or the consumption by the juveniles of a trophic egg-mass as, for example, in *Amaurobius* (Amaurobiidae) (Tahiri *et al.*, 1989). At this point, mortality is the highest in many species (Austin, 1984). It may be even more delicate in a captive breeding situation as the juveniles, in large numbers in the cages, would devour each other.

The dispersal of the juveniles given prey can spread over 4 days (Fig. 3). There was no significant difference between the cages with a female and those with one removed ($p>0.05$). Thus, females did not attack their own progeny after dispersal for at least the first 12 days and on the condition that prey was available. Cannibalism between the juveniles first began 3-4 days after the first dispersal and coincided with the expression of the first agonistic behaviour observed. Next, the number of juveniles decreased until there are about 10 individuals per cage towards the eleventh day.

When the juveniles were fed *Drosophila* (Fig. 4), the female's influence on this period of her progeny's development was similar. On the other hand, intraspecific predation was almost non-existant in the first 6 days and continued to be minimal afterwards, being about 5% after 10 days. There is a highly significant difference between the two groups after the 12 days of study ($p<0.001$). Thus, with prey in the breeding cage, cannibalism decreased and was almost eliminated. Rypstra (1983), likewise, found in several spider species that intra-individual tolerance increased and cannibalism decreased when maintained at extremely high prey levels. Also, Krafft *et al.* (1986) were able to prolong the juvenile social period by giving juveniles abundant food. Austin (1984) recorded a high mortality in the breeding of *C. robusta*, cannibalism being one of the two major causes of mortality. On the other hand, in nature, spiders, which are potential prey of the highest density in the environment, only represented only 3% of prey actually consumed (Austin, 1984). Austin suggested that the highest mortality occurs at the dispersal instar.

The rest of the development presents fewer

problems of cannibalism. Six groups of juveniles were bred together with 5 per Petri dish from instar 2-6 and no cannibalism was noted. Furthermore, the periodic absence of prey during a few days (3-5) in the cages did not result in intraspecific predation, but behaviour of escape and avoidance was observed. Similar observations had been made on sub-adults and adult females bred at 25-30 individuals per cage (30×20×20 cm) over 2 months.

Therefore, in breeding *C. corticalis*, the provision of *Drosophila* to juveniles at the dispersal stage should be sufficient to eliminate intraspecific predation. Then, 5 days after dispersal when all juveniles are out of the breeding-nest and no cannibalism has occured, the division of these juveniles at instar 2 with about 5 per Petri dish, should prevent cannibalism later.

CONCLUSIONS

Intraspecific predation in *C. corticalis* during two especially susceptible periods of development (mating and dispersal) involves limited risks of cannibalism which can be eliminated. Mating must be at 13°C. Males in the enclosures with females must be limited to 24 hours, and dispersing juveniles must have sufficient prey. Cannibalism should not, therefore, be an obstacle to the mass breeding of this species for biological control.

Rates of intraspecific and interspecific predation have often been considered very high in spiders. The main enemies of spiders are often other spiders (Bristowe, 1941; Foelix, 1982). Certain species partially practice araneophagy (e.g. *Pardosa lugubris* (Walck-enaer), *Lycosa annulata* Thorell), and a few make it their speciality (e.g. *Mimetus*, *Ero*, *Portia*) (Table 1). In fact, the species most studied for cannibalism are araneophagic in nature. In contrast, in other species, araneophagy appears to be almost non-existant (Table 2) even without prey (e.g. *Anyphaena accentuata*, *C. corticalis*, *Diaea dor-*

sata, Philodromus cespitum) and it is absent in social spiders such as *Mallos gregalis* (Simon) (Jackson, 1979, 1980). Behaviour of a few spider species cannot be applied to all. The degree of araneophagy of a species must be based on only that one. Therefore, the levels of intraspecific and interspecific predation amongst the more abundant species in agrosystems in which a spider is a possible biological control agent must be studied. A simple method has been finalised for spiders which do not spin a web (Marc, 1992).

ACKNOWLEDGEMENTS

Thanks to Didier Capdeville for his help in breeding the species studied.

COMPARATIVE MORPHOLOGY OF THE SEXUALLY DIMORPHIC ORB-WEAVING SPIDER *ARGIOPE BRUENNICHI* (ARANEAE: ARANEIDAE)

MONIKA C. MÜLLER AND WILFRIED WESTHEIDE

Müller, M.C. and Westheide, W. 1993 11 11: Comparative morphology of the sexually dimorphic orb-weaving spider *Argiope bruennichi* (Araneae: Araneidae). *Memoirs of the Queensland Museum* 33(2): 615-620. Brisbane. ISSN 0079-8835.

Although the web building spigots of the glandulae aggregatae and the glandulae flagelliformes are not functional in mature males, adult *Argiope bruennichi* and *A. lobata* males are able to build webs. The structure of these webs is described. The aciniform spigots on the intermediate spinnerets of *A. bruennichi* males have degenerated to a great extent. Culture experiments with *A. bruennichi* enabled us to follow differences in the development of female and male morphology. The presence of the tubuliform spigots in the sixth instar suggests one possible evolutionary hypothesis concerning sexual dimorphism in spiders.
Nach der Reifehäutung sind die aggregaten und flagelliformen Spulen–welche als Triade die Fangfäden sezernieren–auf den hinteren Spinnwarzen der Männchen nur rudimentär ausgebildet. Trotz dieser Reduktion spannen adulte *Argiope bruennichi* und *A. lobata* Männchen Radnetze, deren Struktur beschrieben wird. Auf den mittleren Spinnwarzen subadulter und adulter *A. bruennichi* Männchen ist ein hoher Prozentsatz der aciniformen Spulen unvollständig ausgebildet. Durch Aufzucht der Wespenspinne war es möglich, morphologische geschlechtsspezifische Unterschiede in der Postembryonalentwicklung festzustellen. Das frühe Auftreten der tubuliformen Spulen im weiblichen Spinnapparat kann als Argument für eine Hypothese zur Evolution des Sexualdimorphismus interpretiert werden. □% *Development, sexual size dimorphism, spinning apparatus, male orb-webs, tubuliform spigot.*

Monika C. Müller and Wilfried Westheide, Universität Osnabrück, Fachbereich Biologie/Chemie, Spezielle Zoologie, D-49069, Osnabrück, Germany; 28 October, 1992.

Sexual dimorphism varies across taxa, but the question of whether highly dimorphic species occur as a result of selection for large female or small male size remains controversial.

Gerhardt (1924) observed that both carnivorous feeding habits and cannibalism endanger male spiders before, during and after copulation (Elgar and Nash, 1988). Darwin (1890) and Bristowe (1929) suggested that their small size protects the males from the females which do not recognize males of reduced size as prey. In contrast, Gerhardt (1924) and Vollrath (1980) argue that 'the females have evolved to be larger, allowing greater egg production' (Vollrath, 1980: 165).

Morphological investigations of sexual size dimorphism are rare; for example Sekiguchi (1955a, b) compared the spinning apparatus in male and female spiders. The present investigation examines whether or not there are morphological data that could be used to assess these different ideas, by analysing the spinning apparatus in different instars of *Argiope bruennichi*.

MATERIALS AND METHODS

Adult males and females of *Argiope bruennichi* (Scopoli, 1772) were collected from Dabas (Hungary), and subadult males and cocoons from Wittenberg-Lutherstadt (Germany).

Specimens of *A. bruennichi* were raised individually from the third instar. Some individuals from each instar were fixed in Carnoy's fluid immediately after moulting. The lengths and widths of the prosoma were measured. For SEM studies the spinning apparatus was removed and the spinnerets were dehydrated in ethanol and critical point dried with carbon dioxide. After sputtering with gold, they were analysed with a Cambridge Stereoscan 250. For light microscopy the spinnerets were separated into smaller pieces and embedded in Swann-fluid.

Subadult males of *A. bruennichi* were kept in plexiglass frames from the penultimate stadium until they died.

Early instars were fed with greenflies (Aphidina) and *Drosophila melanogaster* while older stages were provided with various insects captured in the field.

RESULTS

ADULT *ARGIOPE* MALES CAN SPIN WEBS

The posterior spinnerets of adult males are

equipped only with rudimentary projections of the triad spigots (Fig. 1). These aggregate and flagelliform spigots–which usually furnish the capture threads–obviously do not function. Nevertheless, adult males of *A. bruennichi* and *A. lobata* spun rudimentary orb-webs (Fig. 2). These webs were destroyed every day during our study and the spiders renewed them almost daily. Subadult males spun normal orb-webs with the typical stabilimentum until the last moult. Webs spun after the terminal moult were smaller than subadult webs. They showed an irregular structure; but radia and a spiral were present. This spiral consisted of a few turns with remarkably increasing space outwards thus showing a closer resemblance to the auxiliary spiral than to the capture spiral. No droplets adhered to the spiral threads when the spiders were sprayed with water using an atomiser. They seemed to be thinner than capture threads and were not sticky. Prey thrown into the webs did not adhere to the spiral threads. A microscopical investigation revealed that their structure also strongly resembled auxiliary threads (Figs 5-7). The auxiliary nature of the web was confirmed by comparing the connection points of different types of threads with the radia (Figs 8-9).

Intermediate Spinnerets of Adult Males

The number of piriform and aciniform spigots for each sex were counted under the light microscope. There were fewer bases than apical parts of the aciniform spigots in the intermediate spinnerets of males. SEM examinations showed that a surprisingly high number of apical parts were degenerated (Figs 3-4). Only 19.2% (6 individuals) of the aciniform spigots on the intermediate spinnerets were fully developed. This degeneration was less in subadult males.

Postembryonic Development of Body Size

The shape of the opisthosoma changed during the development of *A. bruennichi*. The spherical form changed into an elongated one, reaching the proportion of adult spiders at the sixth instar. This pattern is clearly shown by the length/width-quotient of the opisthosoma in each instar (see Table 1). The development of both prosoma and opisthosoma was nearly uniform for all individuals until the sixth instar, although the intervals between the moults varied (instar III to IV: 17-73 days; instar IV to V: 11-52 days). Following the sixth instar (when subadult males could be first determined) the sexes developed differently (Fig. 15). This pattern of development of sexual dimorphism is less apparent in the prosoma.

TABLE 1. *Argiope bruennichi*. Length/width-quotients and standard deviation of the opisthosoma for different instars (II-VIII) and adults (n = 62).

Postembryonic Development of the Spinning Apparatus

The development of the spinnerets was documented by counting the piriform and aciniform spigots. None of these fusules was found in the second instar (Fig. 10). Six piriform (anterior spinnerets), two aciniform (intermediate spinnerets) and three aciniform spigots (posterior spinnerets) were counted for third instar individuals (Figs 11-13). The development of the spigot number was uniform until the sixth instar. From that stadium on, the sexes developed differently as shown for the aciniform spigots on the posterior spinnerets (Fig. 16). Although the anterior and intermediate spinnerets develop in the same way (Fig. 16), the differentiation of the sexes is less obvious.

Tubuliform spigots were also first observed in the sixth instar of female spiderlings (Fig. 14).

DISCUSSION

The degeneration of the triad spigots on male posterior spinnerets during the terminal moult was first described by Sekiguchi (1955b) and subsequently documented for other species. These morphological reductions in males were explained by changes in their behaviour: adult males cease spinning webs and instead search for females. Emerton (1878) and McCook (1890) mentioned that small webs were spun by *Argiope aurantia* males, but no information about the structure of these webs was provided. This study shows that *A. bruennichi* and *A. lobata* males are capable of spinning webs. The spiral threads of

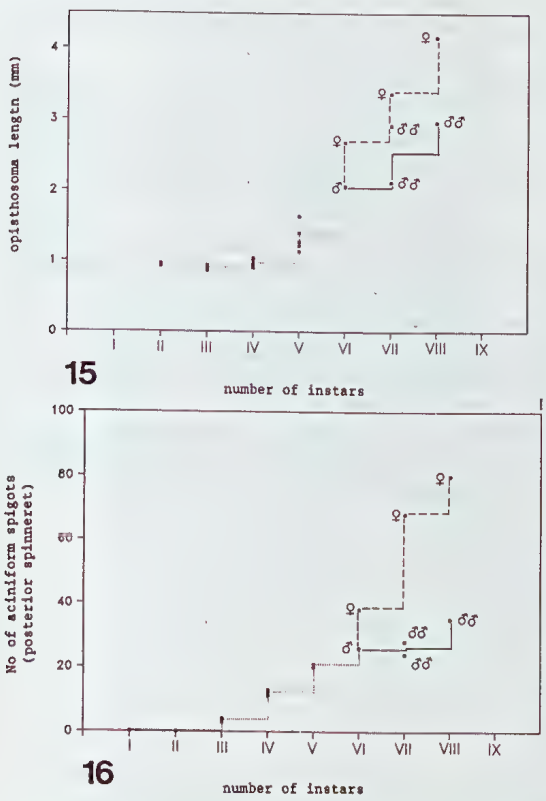
Developmental stages of spinning apparatus. 10: Second instar; anterior (A), intermediate (I) and posterior spinnerets (P) are undeveloped; 11-13: Third instar; 11: Anterior spinneret with six piriform (ps) and two ampullate (ams) spigots; 12: Intermediate spinneret with two aciniform (acs) and two ampullate (ams) spigots; 13: Posterior spinneret with three aciniform spigots (acs) and the triad (consisting of two aggregate (ags) and one flagelliform (fs) spigots; 14: Detail of posterior spinneret of ♀spiderling at sixth instar. Tubuliform spigot (ts) is clearly to differentiate from aciniform spigots (acs). Note arrangement of triad: aggregate (ags) and flagelliform (fs) spigots stay apart from each other, typical for subadults.

these webs resemble auxiliary threads, and therefore are not furnished by the triad glands which still exist immediately after the last moult (see Sekiguchi, 1955b). The auxiliary thread type was recognized because the threads were not covered with glue droplets. However, it is possible that these threads are not auxillaries: Vollrath and Edmonds (1989) found that the glue is soluble in



FIGS 15-16. Postembryonic development of *Argiope bruennichi*: 15: Opisthosoma length; 16: Number of aciniform spigots at posterior spinneret.

water and Peters and Kovoor (1991) argue that the glue does not necessarily fall into droplets.

It is not clear why adult males produce these rudimentary webs, but their poor design suggests that it is unlikely that they function to catch prey. That adult males rejected food offered with tweezers can support this assumption.

The females in spider genera that exhibit extreme size dimorphism are usually hemisessile. Thus courtship and mating is achieved by male mobility. Male mobility is achieved by using bridging lines and ballooning (Peters, 1990). McCook (1890) described these balloon lines as consisting of quite a number of threads that remain separated from one another, which suggests that they are furnished by the aciniform spigots. The degeneration of these aciniform spigots on the intermediate spinnerets of adult *Argiope bruennichi* males may occur because the remaining spigots are sufficient to produce the balloon lines. Alternatively, these threads may originate from other spigots. If the aciniform spigots of the posterior spinnerets furnish the balloon lines, then their degeneration on the intermediate spinnerets would not disadvantage the males. Since adult males do not depend on the additional function of the aciniform threads (in terms of prey wrapping) their degeneration may be interpreted as a morphological adaptation to an altered style of life.

These results suggest that the development of sexual dimorphism takes place in the sixth instar.

Townley *et al.* (1991) reported tubuliform spigots in *Araneus cavaticus* in the fourth instar, which is equivalent to the sixth instar of *Argiope*. Townley *et al.* (1991) suggested that the tubuliform spigots are present that early in order to 'stake out sites for the functioning spigots of mature females, because the tubuliform glands are poorly developed and do not serve any function at that time'. This explanation seems unlikely because the spinnerets are reorganized and the number of fusules increases with each moult.

In contrast, we consider the existence of the tubuliform spigots already at the sixth instar in female spiderlings to be an indication for the hypothesis that phylogenetically earlier females reached maturity at this developmental stage.

In females the tubuliform spigots may indicate the penultimate stadium as do the swollen palpi in males. While the males become mature, females undergo another series of moults (3-4) to reach maturity. During their phylogenetic history, the females in the subadult stage–more exactly in the penultimate stadium–undergo a prolongation of their development resulting in a larger body size, directly correlated with higher egg production. Therefore, sexual size dimorphism may have evolved to produce larger females, a hypothesis as especially presented by Gerhardt (1924) and Vollrath (1980).

ACKNOWLEDGEMENTS

We wish to thank Dr. Peter Sacher (Wittenberg-Lutherstadt, Germany) for valuable discussions and for the *Argiope* material.

A METHOD TO DEVELOP AN 'INDICATOR VALUE' SYSTEM FOR SPIDERS USING CANONICAL CORRESPONDENCE ANALYSIS (CCA)

RALPH PLATEN

Platen, R. 1993 11 11: A method to develop an 'indicator value' system for spiders using Canonical Correspondence Analysis (CCA). *Memoirs of the Queensland Museum* 33(2): 621-627. Brisbane. ISSN 0079-8835.

Multivariate Canonical Correspondence Analysis (CCA) is used to derive 'indicator values' for spiders, similar to those used for plants. The data set consists of activity abundance values of spiders, sampled by pitfall trapping in various habitat types (mires, woods, dry grassland) in the Berlin area. Light exposure, soil moisture and temperature were also measured at the sites. Species scores are plotted as a function of environmental factors within an ordination diagram. The method used to determine the indicator value from this ordination diagram is presented. The system of indicator values is regarded as a suitable method to evaluate sites and areas easily. Advantages and limitations are discussed.

Mit Hilfe der multivariaten statistischen Methode Kanonische Korrespondenz Analyse (CCA) werden Zeigerwerte für Webspinnen, ähnlich denen für Pflanzen ermittelt. Die Entwicklung dieses Zeigerwertsystems und dessen Anwendung wird im Prinzip beschrieben. Der verwendete Datensatz besteht aus Aktivitätsabundanzwerten von Spinnen, die mit Bodenfallen in unterschiedlichen Biotoptypen (Mooren, Wäldern und Trockenrasen) im Gebiet von Berlin gefangen wurden. Die an den Standorten gemessenen abiotischen Faktoren Licht, Temperatur und Bodenfeuchte werden mit in die CCA einbezogen. An Hand von Beispielen wird der Weg erläutert, Zeigerwerte aus Ordinationsdiagrammen zu ermitteln. Mit Hilfe einiger Arten werden Anwendungsbereich und Beschränkungen des Zeigerwertsystems aufgezeigt und diskutiert. Das Zeigerwertsystem wird als eine brauchbare Methode betrachtet, um Standorte und Untersuchungsgebiete relativ leicht mit Hilfe der Spinnen zu bewerten. □ *Araneae, indicator value, multivariate analysis.*

Ralph Platen, Institut für Bodenzoologie und Ökologie, Freie Universität Berlin, Tietzenweg 85-87, W-1000 Berlin-45, Germany; 12 January, 1993.

Ecosystems change under anthropogenic influences faster than their structures and functions can be analysed. It is therefore difficult to make well-founded comments about their ability to withstand external pressure, or about possibilities for their protection or renaturalisation. The complex ecological questions this deficit poses will require field work involving as many environmental factors and groups of organisms as possible.

GOALS

A first step is the description of the ecological behaviour of species in the field. A further step is to derive evaluations for the sites, biotopes or areas of study from the ecological behaviour of the species. For example when establishing whether an area should be protected, for purposes of planning and biotope-management as well as when studying the changes at the sites under anthropogenic influence, an efficient evaluation system which beyond that is easy to handle will be necessary.

A number of evaluation systems have recently been developed, e.g. for soil organisms by Wodarz *et al.* (1992), for epigaeic predatory arthropods (spiders and ground beetles) by Haenggi (1987) and Platen (1989, 1992), for spiders by Martin (1991) and for ground beetles by Mossakowski and Paje (1985). Some of these evaluation systems describe the ecological behaviour of the species in the field very precisely (Martin, 1991), or allow a differentiated evaluation of sitse or areas of study (Mossakowski and Paje, 1985; Haenggi, 1987; Platen, 1989). Some evaluation systems, however, have the disadvantage that lengthy calculations are necessary for synoptic evaluation for different sites or areas (Wodarz *et al.*, 1992; Haenggi, 1987). In other cases parameters are used in the calculations which are not stable for time and/or locality, such as a low local abundance of a species, or the numbers of individuals of a species caught in a year (Mossakowski and Paje, 1985). The evaluation systems mentioned can also only be applied locally where, as a result of intensive field work, the ecological behaviour of species along abiotic gradients is known.

A much simpler method would be the applica-

tion of an indicator value system similar to that for plants of Ellenberg *et al.* (1991). It would then no longer be necessary to redetermine and re-evaluate the ecological behaviour of a species for each local investigation, since this would already be contained in the key values. Nor would the evaluation involve complicated calculations.

My aim has been to develop just such an indicator value system for spiders.

MATERIAL AND METHODS

Data

The data consisted of the activity abundances of spider species. These were determined using ground traps in the Berlin area for open and wooded sites in moors, in various types of forest and for heathland and semi-dry and dry meadows. The investigation period was a full year in each case. Activity abundance is defined by Heydemann (1953) as the number of individuals, which has been trespassed a borderline (which is represented by the diameter of the pitfall trap) within a certain period of time. Parallel to the trap catches the following abiotic factors were also measured:

The soil water content (measured as the percentage by volume of water in the upper soil layer), the light exposure using the method described by Friend (1961), and the effective temperature after Pallmannn *et al.* (1940). The sites are described in detail in Platen (1989).

General

The activity abundance of the spider species and the measurements of the abiotic factors are analysed using Canonical Correspondence Analysis (CCA; Jongman *et al.*, 1987), using the program CANOCO Version 3.10 (Braak, 1988, 1991). The results of this analysis are displayed as ordination diagrams using CANODRAW (Smilauer, 1990).

Before running CCA the spider data had been masked according to dominance in a formal way: species which did not have an activity abundance of at least 1% at a site were removed from the data set. This meant that of the original 281 spider species only 111 remained for the further analysis.

Furthermore a transformation of the raw data was carried out. Instead of the abundance values their square roots were used.

RESULTS

Ordination Diagrams

The CCA results with abiotic factors light exposure and temperature, as well as soil water content, are shown graphically (Figs 1, 2). The horizontal axis corresponds to the first CCA axis and the vertical to the second CCA axis. The 111 species of spider are represented by an 'x', together with an abbreviation of the name as far as possible. Using CANOPLOT it was also possible to determine the coordinates and the name of a species which could not be presented unambiguously in the diagram.

Initially the axes of the site factors light exposure and soil water content are extended beyond the origin (Fig. 1). The factor along the 'environmental axes' increases in the direction of the arrow. The origin marks the mean value for the entire data set. Species whose position lies between the arrowhead of an environmental axis and the origin have a larger weighted mean. Where the origin is between the arrowhead and the position of the species, its weighted mean is smaller than the overall mean. For interpretation a perpendicular is projected for each species in turn onto the environmental axis according to their sequence (cf. Jongman *et al.*, 1987). *Xysticus ninnii* and *Thanatus arenarius* occupy the brightest sites, and *Pardosa agrestis* and *Baryphyma pratense* the warmest sites (Fig. 1). Species at extremes of the axes represent limits of the area for a two-factor system, and thus form the start and end points of the indicator value scale. The distance between these points is measured and divided into five equal parts. The species are then noted for each class with the appropriate indicator value.

The determination of indicator values for three factors requires at least two ordination diagrams. Initially an indicator value is assigned for all three individual factors, then for all combinations of two factors. The result always remained the same. For the representation of all three factors in an ordination diagram the class of a species can, however, change, in some cases considerably, since the relative spatial distances of the species in three-factor constellations cannot be represented in a two-dimensional coordinate system without distortion. For the determination of indicator values from the data of individual environmental variables the solution (Figs 1 , 2) is an optimum.

Moisture is strongly negative correlated with the 1st CCA-Axis (Inter-set correlation: -0.919)

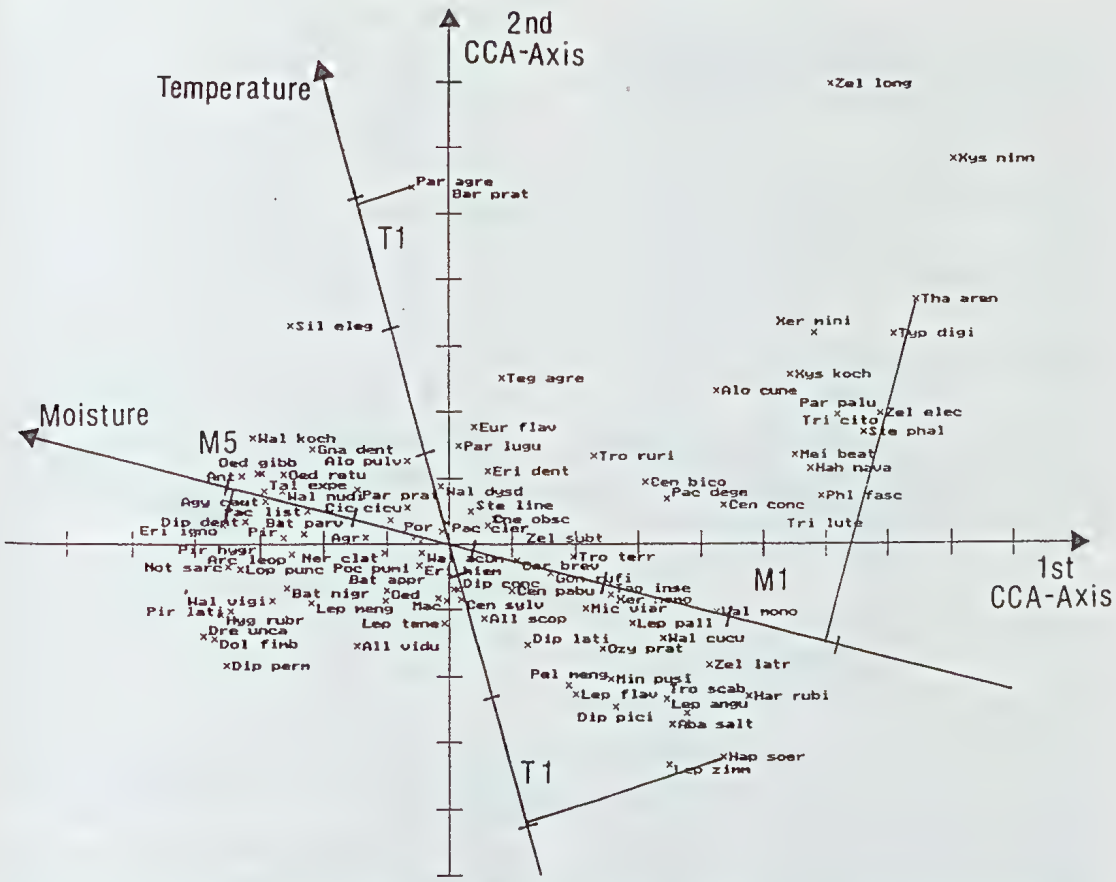

FIG. 1. CCA ordination diagram with 111 spider species represented by an 'x' and environmental variables moisture and temperature represented by arrows. The part of the arrows to derive indicator values are devided into five parts (M1-M5 and T1-T5 respectively). For further explanation see text.

(Fig. 1) which means that the horizontal species distribution is best explained by light and less by temperature (Inter-set correlation with 1st CCA-Axis: 0.26, with 2nd CCA-Axis: 0.538). Hence, the vertical species distribution is best explained along the 2nd CCA-Axis.

The Inter-set correlation between light and 1st CCA-Axis is 0.955 which means that the data set again is best explained by this abiotic factor. Temperature is strongly correlated with 2nd CCA-Axis (Inter-set correlation with 1st CCA-Axis: 0.0367, with 2nd CCA-Axis: 0.6177).

Indicator Values (Table 1)

The last two columns contain details of the ecological type and habitat type in which the species predominantly occurs in the Berlin area (after Platen *et al.*, 1991). The data are intended only to demonstrate the principle of this method. In view of the limited data set the indicator values cannot claim to be comprehensive or generally valid. Some examples will show the similarities and differences between the indicator values and other methods of determining ecological behaviour.

The distribution of *Xysticus ninnii* is centered exclusively on dry meadows. F1, L5, and T4 reflect this ecological behaviour well.

Diplocephalus permixtus: Occurring mostly in wet alder forest-habitats characterised by high soil water content, low light exposure and low temperatures. This is expressed with adequate precision by the indicator values F5, L1 and T2.

Diplocephalus picinus: F2, L1 and T1 characterise its habitat preferences, namely shadowy sites with low pH in dry mixed forests.

Pardosa agrestis: In this case the indicator value does not reflect the ecological behaviour, as a result of the inadequacy of the data set. The species occurs mostly on arable farmland and

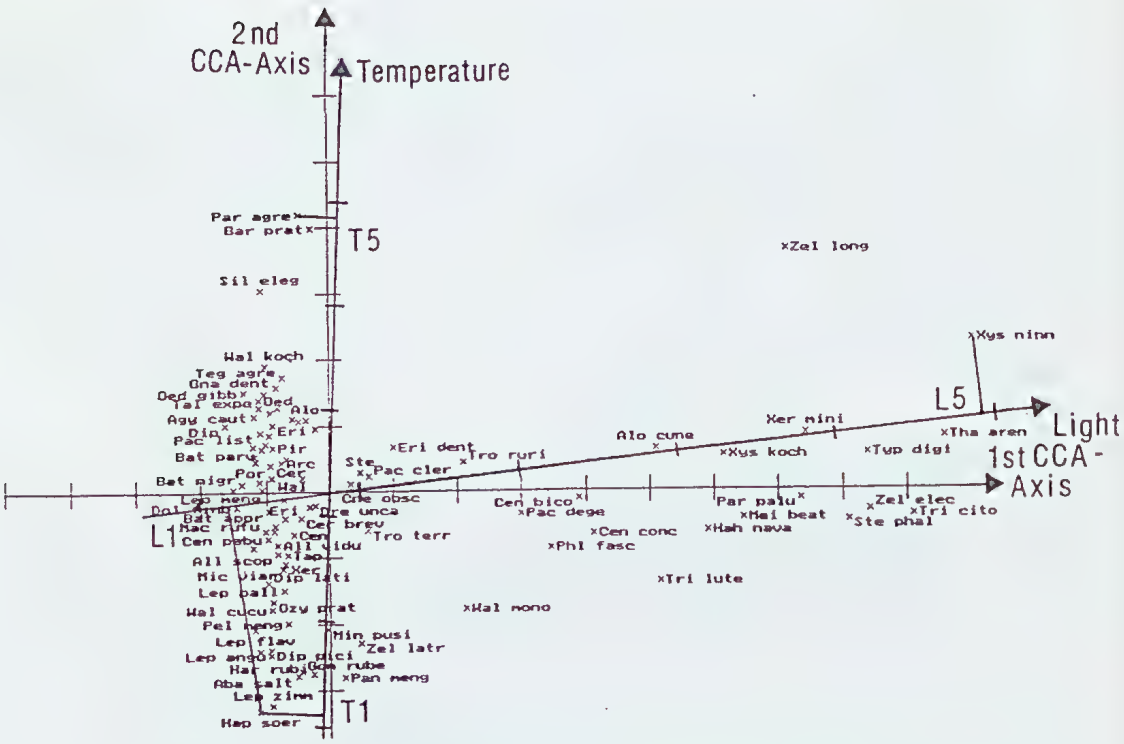

FIG. 2. CCA ordination diagram with 111 spider species represented by an 'x' and environmental variables light and temperature represented by arrows. The part of the arrows to derive indicator values are divided into five parts (L1-L5 and T1-T5 respectively). For further explanation see text.

other open, rather dry habitat types (Platen *et al.*, 1991). While T5 describes the behaviour in terms of temperature, the indicated soil water content (F5) is too high and the light exposure too low (L1). This is because in the data set it only occurred on one site (a former moor which was still wet in comparison to the sites on mineral soils), so that as an outsider it had an extreme position in the ordination diagram. The data set did not include arable farmland sites.

Comments

This method is a relatively easy one to determine indicator values for spiders and other soil arthropods (cf. Platen, 1992).

Indicator values have the advantage that with only a few values the ecological behaviour of a species can be characterised. Mean indicator values can be calculated, and in the absence of the measurements or vegetation surveys they allow a rough quantitative assessment of environmental variables for a investigation site, habitat type or an area of study. The use of indicator values obviates the need for complicated calculations for the evaluation of sites, as required by some evaluation systems (Mossakowski and Paje, 1985; Haenggi, 1987; Platen, 1989).

Some reservations concerning the applications of indicator values are necessary. As already emphasised by Ellenberg *et al.* (1991), indicator values describe the ecological behaviour of species in a multiple system of biotic and abiotic factors, from which those chosen in this paper are regarded as the key abiotic factors for the spiders. They do not, however, describe their physiological optima.

Indicator values for animals underlie more restrictions as those for plants because animals are mobile and often change their habitat for overwintering (Schaefer, 1976). Therefore in the strict sense they are valid only for Adults which does not change their habitat within their period of maturity. As juvenile animals were not included in the data set this holds true for this investigation.

Indicator values should never be used in the same way as measurements. They are ordinal, and are not suited for use in statistical (including multivariate) methods requiring higher scale data.

The indicator values determined above are al-

ways valid only for the data set used. Since they were limited to only a few types of biotope the results above can only be regarded as being a first approximation. The results of the analysis are greatly dependent on the type and number of habitats types and of the frequency with which various species occur there. The combination of a wet, light site (F5, L5) is not represented by an indicator value, although it is relevant for a number of species (*Drepanotylus uncatus*, *Antistea elegans*) (Table 1). However, since almost 2/3 of the 30 sites investigated were wet, and most species occurred with almost the same frequency in wet habitats, these species grouped close to the origin. Species which occur frequently, but only at one or two dry sites with very high light exposure are far from the origin, so that there is a higher differentiation of the axis over the bright range.

A generally valid indicator value system would need to analyse all known spider species of Germany or Central Europe for all existing types of biotope (abiotic factor combinations) in one data set, from which the indicator values could then be derived. The scale could then be expanded, or other environmental factors, such as the biotope structure, could be included. A problem would be the large number of measurements required.

A further problem is that the CCA only depicts species correctly in the ordination diagram if they have an unimodal response curve along a factor gradient (Jongman *et al.*, 1987). By plotting the frequencies of species at all habitat types sorted according to the levels of a factor, it is possible to determine bi-modal, multi-modal or continuous responses. The coordinates of all the habitats where the species occurs with high frequency can be entered in the ordination diagram, making it possible to recognise a corresponding range of occurrence on the environmental axis. For this species, as is the case with some plant species, an indifferent response to this factor for the species or to give a range of the indicator value (cf. Ellenberg *et al.*, 1991) may be possible.

ACKNOWLEDGEMENTS

THE SPIDERS OF THE HIGH-ALTITUDE MEADOWS OF MONT NIMBA (WEST AFRICA): A PRELIMINARY REPORT

C. ROLLARD

Rollard, C. 1993 11 11: The spiders of the high-altitude meadows of Mont Nimba (West Africa): a preliminary report. *Memoirs of the Queensland Museum* **33**(2): 629-634. Brisbane. ISSN 0079-8835.

Spiders are abundant in the high-altitude meadows of the Nimba mountains, in Guinea. Collections have been carried out in this ecosystem where grass ground cover is dominant: this preliminary study at the family level concerns specimens collected in March 1991. It already gives some data on the localisation of the spiders. More than 20 families are represented along the mountain tops. A provisional list of these spiders has been drawn up. Most specimens were Araneidae, Gnaphosidae, Hersiliidae, or Salticidae. Their distribution in the herbaceous stratum as well as along an altitude gradient between 800-1700m is being analysed.

Les araignées sont abondantes dans les prairies de haute altitude des Monts Nimba, en Guinée. Des récoltes ont été effectuées dans cet écosystème où la couverture herbacée est dominante. Cette étude préliminaire au niveau des familles concerne les spécimens collectés en mars 1991. Elle apporte déjà quelques éléments sur la localisation des araignées. Plus de 20 familles sont représentées sur ces sommets et une liste provisoire en a été établie. La plupart de ces araignées sont des Araneidae, des Gnaphosidae, des Hersiliidae ou des Salticidae. Leur distribution est analysée dans la strate herbacée ansi que selon un gradient altitudinal entre 800 et 1700m. □*Spiders, biogeography, Africa, montane.*

Christine Rollard, Museum National d'Histoire Naturelle, Laboratoire de Zoologie (Arthropodes), 61 rue de Buffon, 75005 Paris, France; 14 January, 1993.

The Mont Nimba biosphere reserve, located in West Africa, is the subject of a multidisciplinary study as part of a UNESCO pilot project. These mountains have been classified as an Integral Natural Reserve since 1944. Over the past 50 years, many more animals have been collected during several scientific expeditions directed by Professor Maxime Lamotte (Lamotte, 1943). Many papers have been published on the Nimba mountain range. However works on the spider fauna are non- existent. Hence the organization of the spider populations are still little known. Especially in this tropical region, no work deals with the ecology of spiders except for the research initiatives in the Ivory Coast, in the savanna of Lamto (Lamotte, 1943, 1967; Blandin, 1974; Blandin and Célérier, 1981).

With this subject of research in mind, another field trip was made to Guinea in March 1991. The new collection of spiders made there compliments those of Mr Lamotte and his associates. This abundant material is in the process of being classified. An attempt is being made to describe the structure and function of the spider community in this tropical ecosystem.

The programme focuses on the spiders of the high-altitude meadow, relatively less-frequently collected than those of the savanna or the head of ravines (Lamotte, 1958). This environment is characterized by the strong contrast between the dry and rainy seasons. It presents a characteristic fauna with several endemic species.

In this paper, preliminary data dealing with the localisation of the different families of spiders collected in March 1991 are presented. The overall study will lead to a more detailed inventory of the spiders along the mountain ridges, as well as a better knowledge of their distribution with altitude and the relative abundance of the different species.

ENVIRONMENT AND CLIMATE

Mont Nimba is situated in High Guinea, near the borders of Liberia and the Ivory Coast (Fig. 1). It extends from SW to NE for about 30 km into guinean territory. All the crests stand over 1000m. The mountainside is steep and notched by valleys with sheer slopes. No trees or shrubs are present on the crests. Only some small trees of the inferior savanna grow at lower altitude on the slopes (Schnell, 1966). Above 900-1000m, the forest is confined particularly to the ravines. The mountain range is covered by herbaceous plants with a grassland structure. The term of montane or sub-montane has been given to this

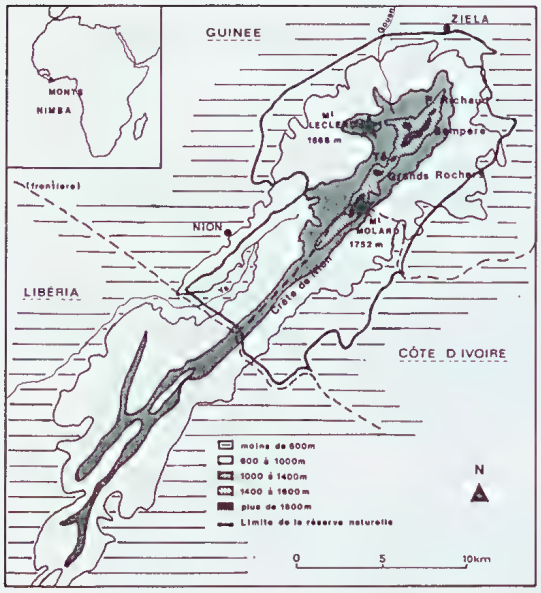

FIG. 1. Map of Mont Nimba, West Africa. Situation of the various sample zones along the Mont Nimba crest.

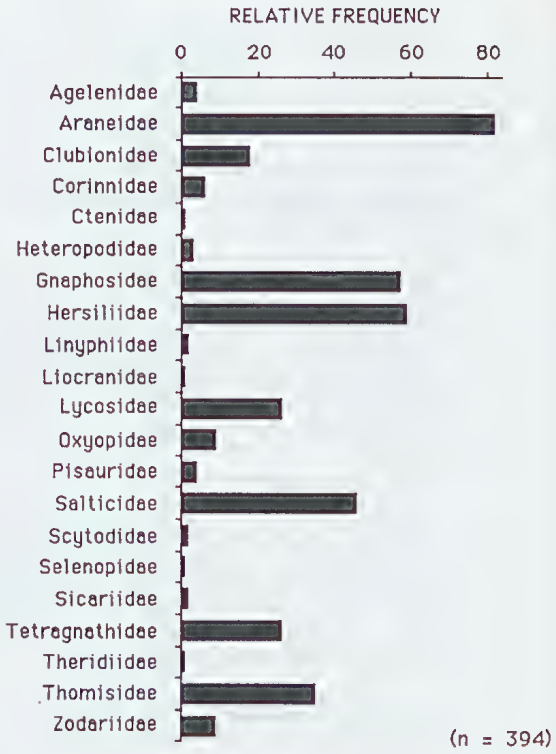

FIG. 2. Total no. spiders taken during March 1991.

crest vegetation (Schnell, 1987). In this type of meadow, located in the guinean part of Nimba, the low (about 20-30cm or less) graminaceous species *Loudetia kagerensis* is abundant and constant. This grass forms a predominant group associated with other tall or short species, varying from site to site.

Mont Nimba receives abundant rainfall and a dry season not exceeding three and a half months. Generally, high-altitude meadows are often covered in fog during the rainy season, from May to November. Precipitation is fine and stable. During the other periods of the year, clouds scale the slopes and progressively cover the crest. Thus the humidity, which is closely bound to the degree of precipitation and nebulosity, varies with altitude and also along the crest. For example, the crest of Nion, spreading upwards to Mont R. Molard in the NE, is wetter than either Mont P. Richaud or the region of Sempéré (Leclerc *et al.*, 1955). Nevertheless, seasonal variations do exist. In the meadow, this factor does not seem to be very important to the ecological cycle of the fauna.

The spiders listed here were collected in March 1991, during the transition period just before the rainy season. Sudden storms or regular strong precipitations occur in the late afternoon from April onwards.

METHODS

Up until now, the high-altitude meadows of Mont Nimba have rarely been sampled. The present study lasted 20 days (8-27 March) with only 14 days of sampling. The first phase consisted in obtaining an overall idea of the spider communities over the whole crest. The collecting program was prepared as follows: 4 days in Sempéré, Grands Rochers; 4 days on the Nion crest, 2 days in Grands Rochers, R. Mollard; 3 days on Mont Leclerc and 1 day in Ziela, P. Richaud.

No strictly quantitative sampling methods were used. Several gathering squares (1m x 1m) were made but the results are insufficient. In addition, these quadrats have not been well materialized because the transport of materials was not easy. Only the sizes were marked by various elements found on the ground. Furthermore, this type of analysis is rare in these environments. Some information on the vertical distribution of the spiders was obtained by the use of beating and ground sweeping methods. A few specimens found on the high sections of the grass were captured, but this is certainly not a representative

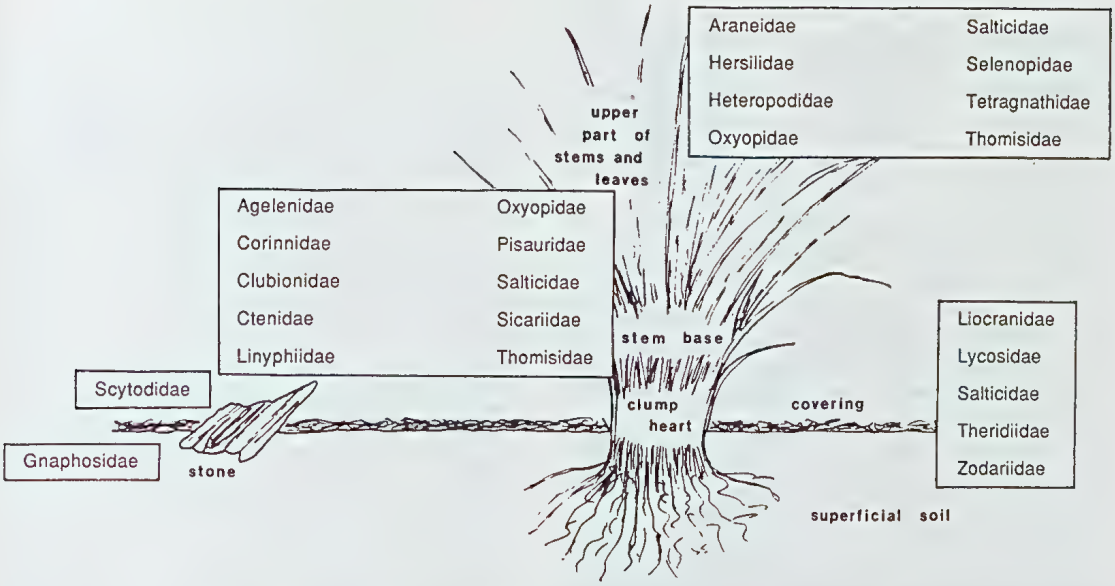

FIG. 3. Distribution of families in epigean environment.

sample of the spider fauna of the herbaceous stratum.

So, in the low herbaceous stratum, samples were made by visual searching in vegetation and under stones, using forceps and pooters. Collecting was only carried out during the daytime and was therefore not exhaustive. The time spent on Mont Nimba was rather short: the researchers stopped collecting at the end of an hour at each site.

A mean of 40 individuals was collected per day, by one to three collectors depending on the days and the availability of the expedition members.

RESULTS

Families Identified

For each sample, the spiders were sorted and enumerated by family. Young and adult spiders were counted together. Immature spiders represent about 54% of all specimens found.

Mygalomorphs were collected, but not in great numbers: 0.5% (2/435). For the moment, the inventory of this suborder has not been established at the family level. Similarly, about 9% (39/435) of the collection is still at the level of indeterminate araneomorph. Therefore, we are only able to present results of the determinate araneomorph families, which correspond to 394 specimens. The names used follow Brignoli (1983) and Platnick (1989).

At least 21 families have been recorded along this crest, of the roughly 100 families known worldwide (Table 1). This relatively high number provides a good idea of the diversity of this environment. The high-altitude meadow-like plateau savanna characterized by the grass species *Loudetia*, is usually considered to be one of the poorest habitats. However, this type of environment clearly possesses an important variety of spiders.

Furthermore, the relative frequencies of these spiders gives another indication of their diversity (Fig. 2). The physionomy of the araneological community is characterized by the predominance of Araneidae which represent around 21% of determined spider families. Four other families were common: Gnaphosidae (57/394), Hersiliidae (59/394), Salticidae (46/394) and Thomisidae (35/394). We note that these spiders are generally large and therefore easier to find. The same observation can be applied to other families which are more easily collected, especially for a certain size. However, the fewer Clubionidae, Lycosidae, Oxyopidae, Pisauridae, Selenopidae and Tetragnathidae in the collections could indicate that they are less abundant in the meadow during this period of the year. The specimens belonging to most other families are generally small and consequently poorly collected. In addition, Liocranidae and Zodariidae are active and move quickly on the soil, so they frequently evaded capture.

Gnaphosidae	Salticidae	Zodariidae

TABLE 1. List of spider families on Mont Nimba

sideration the biology and the size of the spiders. All families are represented, in spite of the small number of specimens. Around two-thirds of these families frequent the herbaceous stratum and most are diurnal (Fig. 3).

On the upper part of the stems and leaves of plants, the spider community is composed of eight families of which the Araneidae, Tetragnathidae, Hersiliidae and Thomisidae are the most common. The former two build their webs about 20 cm above the soil. Of all Araneidae, Oxyopidae and Salticidae, 25, 2 and 1 specimens respectively were collected by beating and sweeping of the ground. Ten families are present at the base of the stems or in the center of the clumps, Clubionidae being the most abundant. The clubionids are nocturnal hunters and easily found in nests among the vegetation. Five families occur in the superficial soil layer. The Lycosidae constitute most of the collections. Gnaphosidae are mostly nocturnal hunters found in nests among stones. Scytodidae are also found nocturnally active around stones.

Thus, each level of this epigean environment seems to possess its own spider community, characterized by its family composition. Nevertheless, some of them such as the Salticidae, Thomisidae and Oxyopidae are present at all levels of the vegetation and the soil surface. Only analysis at the species level will permit the clarification of the distribution of the spiders in each stratum.

Altitudinal Distribution

The spiders were collected along the crest, mainly situated above an altitude of 1200m. The results are presented by altitudinal classes of 200m, principally because of the small numbers of spiders, and the various sampling zones are indicated in Fig. 1.

An overall view indicates that some families appear to be better represented at the highest altitudes, from 1200m to around 1700m (Table 2). The numbers of Gnaphosidae and Clubionidae regularly increase. Most other families did not

provide many specimens, with the exception of Tetragnathidae. These spiders are perhaps rare or difficult to observe, but it is all the more interesting to note that their distribution is limited to a certain altitude. In the same way, Eusparassidae and Pisauridae are found only up to 1200m, in low vegetation. The lack of data, between 1000 and 1200m altitude, for the Araneidae and Hersiliidae is probably due to sampling problems. Spiders of these families as well as the Salticidae, Thomisidae and Lycosidae, are certainly present at the different altitudes, and it is likely that the same is the case for the Zodariidae. The family diversity seems to increase slightly with altitude.

The collections made on slopes from 800m upwards concentrated particularly on Mont Leclerc (Table 3). Here too, we note the diversity of the spider fauna, with 14 families present of the 21 listed for Mont Nimba. The same families are found at the highest altitudes. Only Zodariidae and Clubionidae are not encountered below 1400m. Salticidae, Hersiliidae, Thomisidae and Lycosidae can be found from 800 to 1600m.

We also compared the spider families found at three points along the crest: P. Richaud, Grands Rochers and Nion crest, between 1200 to 1600-

1700m altitude (Table 4). Seven families are present on the Nion crest, clearly a lower diversity than on P. Richaud with eleven families. Six families were observed at all three places. Only Tetragnathidae were found south of the crest. This place seems to be more humid than the others at different periods of the year. The spiders found there are generally hygrophilous species.

For the moment, we cannot provide definitive results on the ecological requirements of the families present only on P. Richaud and Grands Rochers. However, more precise information, at the species level will, hopefully, be available in the future.

COMMENTS

Spiders occupy an important place among the invertebrate fauna of Mont Nimba. They are represented by about twenty families which is a relatively large number for this type of highland meadow. This study is only a first approach; the diversity of the spider community according to stratum and altitudinal level will certainly prove to be rewarding, both quantitatively and qualitatively, with the determination of species. Publication of the final results will probably be delayed because of taxonomic difficulties.

Nevertheless, this study already gives some results at the family level. Prudence in the interpretation of these results is necessary, because the families do not always form homogenous ecological units. The sampling methods used must also be taken into consideration. In the tables and figures, we see that the distributions found are dependent on the collecting effort. In this study we used mostly visual-hunting, with no collecting at night. So we only have a partial sample of the spider families, mainly representing those with diurnal activities. As yet, pitfall traps have not been used to intercept nocturnal spiders. Nevertheless, an estimation of the spiders present along the Mont Nimba crest and their spatial distribution has been made.

We observe several components of this spider

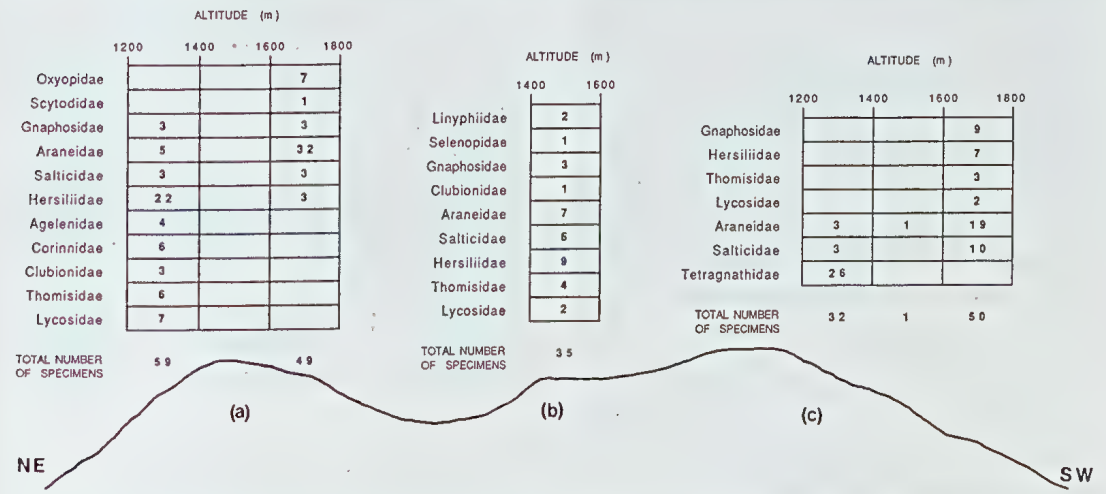

TABLE 4. Altitudinal distribution of spider families along Nimba crest, from SW to NE: (a) Pierré Richaud; (b) Grands Rochers; (c) Nion crest before Richard-Molard.

community, not forgetting the movements of wandering spiders. There are groups on the soil surface principally characterized by Lycosidae and Salticidae; three other families, Liocranidae, Zodariidae and Theridiidae exist in smaller numbers. Groups in the lower part of the vegetation includes ten families, the most with few representatives; Clubionidae, Thomisidae and Salticidae exist in great numbers. A last group exist of the upper part of the herbaceous stratum where Araneidae, Hersiliidae and Tetragnathidae are found in a great numbers; the five other families are less well represented.

The comparison between the northern and southern parts of the crest indicates a possible tendency of one family (Tetragnathidae) to prefer greater humidity. The altitudinal distribution shows that some families, such as Araneidae, Salticidae, Hersiliidae, Thomisidae and Lycosidae, are present from 800 to 1752m. On the contrary, other families are preferentially localised at the highest or lowest altitudes. The spider families found between the altitudes 800 and 1000m, can be considered as being roughly comparable with those present in typical savanna with *Loudetia*. In this environment, there are a great number of spider families (Gillon and Gillon, 1974). More data will be required to confirm these tendencies, as well as their presence on the slopes according to a greater altitudinal gradient and along the whole of the Mont Nimba crest. In addition, some comparisons among sites, including absence of families, might be artefacts, due to relative rareness of representatives.

The study of all spiders collected during the previous expeditions directed by Prof. Lamotte will certainly provide supplementary elements to the various points mentioned in this paper. It will be necessary to characterize, with more precision, the araneological fauna of Mont Nimba. Blandin and Célérier (1981) already noted the misreading of this fauna in West Africa. In addition the well-collected environments are essentially savanna rather than high-altitude meadow.

ACKNOWLEDGEMENTS

I thank Professor M. Lamotte for allowing me to participate in this project, for providing me with the opportunity of undertaking the mission in Guinea, and for all his advice; Denise Palczewski and Mark Judson for reviewing the manuscript.

VISUALLY MEDIATED RESPONSES IN THE LYCOSID SPIDER *RABIDOSA RABIDA*: THE ROLES OF DIFFERENT PAIRS OF EYES

J.S. ROVNER

Rovner, J.S. 1993 11 11: Visually mediated responses in the lycosid spider *Rabidosa rabida*: the roles of different pairs of eyes. *Memoirs of the Queensland Museum* **33**(2):635-638. Brisbane. ISSN 0079-8835.

Video images of conspecifics were presented to *Rabidosa rabida* (Walckenaer) (Araneae: Lycosidae) to study the roles of different pairs of eyes in a wolf spider. Four groups of spiders had one pair of eyes occluded, and four had all but one pair occluded. Various control groups were also tested. The PLE were essential for sizeable orientation turns of up to about 160°. The PME served for rapid, long distance approaches toward the stimulus; they also initiated orientation turns of up to about 50°. If close to the stimulus, the ALE initiated small turns of up to about 20° and mediated small approaches. The AME did not mediate any responses. Courtship could be triggered in males via the PLE or the PME. In females, only the PME mediated receptive display responses to temporally patterned leg I movements seen in anterior or lateral views of a courting male. □*Araneae, Lycosidae, eyes, vision, communication.*

Jerome S. Rovner, Department of Biological Sciences, Irvine Hall, Ohio University, Athens, Ohio 45701, U.S.A.; 3 July, 1992.

Very little behavioural research has been carried out on vision in lycosid spiders, compared to the extensive studies on salticid spiders (reviewed in Forster, 1985). In lycosid spiders, occlusion of the eyes has been used to test for differences in the roles of the main vs. secondary eyes (Homann, 1931) as well as the anterior vs. posterior eyes (Acosta *et al.*, 1982); however, the results of both of these studies were confounded by the lack of controls for vibratory stimuli. The only successful behavioural investigation of the role of particular eyes in lycosids (Magni *et al.*, 1964) demonstrated the importance of the AME in astronomical orientation and was accomplished by covering all but a single pair of eyes in each group tested. Occlusion of only one pair of eyes at a time has proven useful in several behavioural studies of salticid vision (e.g., Forster, 1979).

In the present study of the lycosid spider *Rabidosa rabida* (Walckenaer), I used both methods of occlusion to examine the roles of different pairs of eyes in detecting visual stimuli and mediating appropriate responses. By using video images as stimuli (Clark and Uetz, 1990), I eliminated the possibility that vibrations or chemicals from conspecifics could confound the results.

METHODS AND MATERIALS

Penultimate *Rabidosa rabida* (formerly *Lycosa rabida*) were collected in late June (1990 and 1991) in Athens County, Ohio, USA. The methods of maintenance and the laboratory conditions during testing have been described previously (Rovner, 1989). Spiders were not used in testing until 1 week after the final moult. Tests were conducted between 1000 and 2200 hours.

For each test the spider's home cage, with its resident within, was placed with its narrow front side facing a small television set (black and white Magnavox BH-3907; screen = 9.2cm wide, 6.6cm high), which received a playback signal from a Sony recorder (SL-HFR70). The clear front side of the plastic cage (the other sides were opaque) was 7cm wide and was located 3cm from the screen. I removed the cage cover and, if necessary, gently positioned the spider with an artist brush to insure that the screen would be within the visual field of the spider's useable eyes. (I used separate brushes for males and females). Then, a glass cover (one for each sex) was placed on top of the cage. A front-silvered mirror fixed at 45° to the floor was 0.5m above the cage. A video camera (JVC GX-8NU) was aimed at both the mirror and an adjacent, second, identical television set receiving the same signal from the playback recorder as the first set. This yielded (on a second, identical recorder) a kind of split-screen recording. On the left was a dorsal view of the spider, which facilitated the measurement of turning angles (accurate to the nearest 5°) and speeds of locomotion. On the right was a view of the video image concurrently being presented to the spider. Thus, the relationship of

the video stimulus to the spider's response could later be analyzed.

Subjects used for video presentations were recorded against a plain, pale background and illuminated evenly by a 32-W, circular fluorescent bulb 0.5m above the arena. The camera was located at a distance yielding a screen image the size of the actual subject (average body lengths: female=18mm; male=12mm). The 15-min video playback for females was a pheromone-stimulated, courting male; his occasional position changes provided nearly equal proportions of anterior and lateral views of his display (total number of courtship bouts = 51). The 10-min video playback for males was a lateral view of a female walking to and fro in an elongate glass arena (passes across the screen =15 leftward and 15 rightward). Some preliminary tests made use of prey images provided by a 10-min video of three crickets (*Acheta domesticus*, 10mm body length) walking to and fro.

To cover the eyes of spiders, I painted them with two coats of water-based enamel (Top Color Hobbylack, Pelikan AG). That this insured complete occlusion had been established previously (Rovner, 1989). Spiders were tested one or more days later.

I ran two preliminary tests to see if painting or its related procedures lowered responsiveness. All the eyes of five females were covered with two separately applied coats of clear paint. Five other females were briefly anaesthetised (carbon dioxide) and then restrained for 6 hr, thereby duplicating the procedure used when painting the eyes. However, at the two times that paint would have been applied (0 hr and +3 hr), I used water instead. The next day, when exposed to video images of crickets, the clear-painted spiders were less responsive than were the water-brushed spiders. The latter seemed as responsive as untreated spiders.

There were three control groups, each with 10 females and 10 males; these 60 individuals were given two trials apiece. One group consisted of untreated spiders exposed to the conspecific video playback, to determine how readily fully sighted spiders respond. A second group, also untreated, was exposed to a 10-min video of an empty arena, to determine if that alone had a stimulating effect. (Light from the screen = about 800 lux; incident light from above = about 350 lux.). The third group consisted of fully blinded spiders exposed to the conspecific playback, to see if such spiders would perform behaviours (orientation, rapid approach, or display) that I assumed would only occur in this study as visual responses.

There were eight experimental groups, each having 10 spiders of each sex. In four experimental groups a single pair of eyes was occluded; in four others, all but one pair was occluded. Since one of the untreated control spiders had failed to respond to video playback within two trials and since the preliminary tests had indicated that painting the eyes can reduce responsiveness, I gave unresponsive experimental spiders additional opportunities to respond, up to a limit of five trials. One or more days separated consecutive trials undergone by any individual spider.

RESULTS

During testing of control groups, all of the untreated females and all but one of the untreated males showed 'orientation' and/or 'long-range approach.' Most (16/20) did so in the first trial. 'Orientation' involved a single, rapid pivot that resulted in the spider facing the image. This pivot had a mean speed (SD) of 121 ± 51.7°/s ($N = 12$), about eight times faster than turns that occurred during wandering, 16 ± 12.4°/s ($N = 11$). A 'long-range approach' covered a distance of up to 10cm, the maximum being limited by cage depth (12.5cm). The speed of an approach, 5.9 ± 3.32 cm/s ($N = 22$), was about ten times faster than walking during wandering, 0.6 ± 0.31cm/s ($N = 36$). (The above speeds are not the maxima attained, since I included the acceleration and deceleration phases in each bout of locomotion.) No orientation or approach responses occurred in the empty arena or fully blind controls.

Results of the eye occlusion experiments are summarized in Table 1. Spiders with any one of the four pairs of eyes occluded were still capable of orientation; those with occluded PME did not show approach. When all but one pair of eyes was occluded, the only group failing to show orientation was the one limited to use of the AME; and the only group that still showed long-range approach was the one with useable PME. When close to the cage front, a few spiders having only useable ALE did perform a near-field approach response, edging forward less than one body length. For all the responding experimental groups, the mean number of trials (± SD) needed to obtain either an orientation or a long-range approach to the image was 1.2 ± 0.53 ($N = 63$) for females and 2.4 ± 1.24 ($N = 55$) for males (Mann-Whitney *U*-test, $Z = -6.545$, $P < 0.0001$).

Spiders with useable PLE showed orientation

Condition	Orientation		Long range approach		Display

Only PLEs	10	7	0	0	0	5
Only PMEs	9	6	10	5	5	2
Only ALEs	3	1	0	0	0	0
Only AMEs	0	0	0	0	0	0

TABLE 1. Number of ♀ and ♂ spiders responding to video playback. $N = 10$ spiders/sex/condition. Each spider was allowed more than one trial to respond: controls, up to two trials; experimentals, up to five trials. Only ♂♂ that also performed orientation or approach are included under 'Display'.

turns of up to about 160°. Those with only the PME useable performed orientation turns of up to about 50°. If near the stimulus, those with only the ALE useable showed orientation turns of up to about 20°.

During playback of male courtship, only those females with non-occluded PME performed leg-waving receptive displays (Table 1). This brief display occurred 3.0 ± 1.9s ($N = 30$) after the abrupt termination of the male's courtship bout. The receptive display was sometimes performed unimpeded, this being the case in females which had not yet reached the front of the cage. However, it was usually constrained, since most females quickly approached the cage front and rested their anterior legs against the wall. Still, the timing of their response remained precise. Females showed this display while seeing anterior or lateral views of the courting male.

Up to 6/10 of the males tested in each condition performed courtship display, which occurred in every group. It even occurred in two males during the empty arena playback and in three of the fully blinded males, such data reflecting a previously noted readiness of *R. rabida* to sometimes court in response to subnormal stimuli (Rovner, 1968). Perhaps these non-visually stimulated courtships were triggered by mechanical cues resulting from my moving the cage to the testing site or from my positioning the spider with a brush (to duplicate the procedure used on experimental spiders). For this reason, only courtships occurring during trials in which orientation or approach also occurred were scored as visually initiated displays. (This may have prevented some visually stimulated males that were facing the stimulus at the outset from being included in the courtship total for some experimental groups.) Only males with useable PLE or PME showed courtship accompanied by orientation, and only males with non-occluded PME showed courtship accompanied by approach (Table 1).

DISCUSSION

Data presented here indicate that *R. rabida*'s posterior eyes play major roles in mediating responses to important visual stimuli, as was earlier predicted for lycosids on anatomical grounds (Homann, 1931; Land, 1981). The PLE serve the same function that they do in salticid spiders, that of detecting stimuli in an extensive visual field and initiating the largest orientation turns. They cannot mediate approach behaviour. On the other hand, the PME are essential for mediating rapid, long-range approaches to stimuli. They can also initiate orientation turns of up to 50°.

As to the anterior eyes, at close range the ALE can play small roles in orientation and approach. This contradicts Land's (1981) suggestion that only the large posterior eyes are involved in prey capture. As predicted for lycosids by Land (*ibid.*), the AME of *R. rabida* play no role by themselves in mediating turns or approaches toward a target. Whether they serve for other than polarized light detection (Magni *et al.*, 1964) remains to be explored.

The present findings on the anterior eyes of *R. rabida* may not apply to all lycosids. For example, unlike *R. rabida*, in *Arctosa variana* the AME are larger than the ALE (*ibid.*). Also, local tiering is found in the retinae of the AME of *Geolycosa godeffroyi* but not in the type genus *Lycosa* (Blest and O'Carroll, 1989). Furthermore, the finding of high nocturnal sensitivity in the anterior eyes of *Lycosa tarentula* (Carricaburu *et al.*, 1990) suggests that an understanding of the capabilities of the anterior eyes of lycosids will require examining different species under various illumination conditions. Finally, I must point out that I did not test for any possible collaboration between different pairs of eyes. Collaborative visual mechanisms were revealed in salticid spiders by ipsilateral blinding (Forster, 1979).

As in the salticids (Forster, 1985), orientation and approach are the initial behavioural responses of lycosid spiders to moving images, whether prey or mating partners. Thus, the performance of such behaviours does not specify the spider's

motivational state. However, the fact that twice as many trials were needed to obtain these behaviours in males as in females suggests that such initial responses relate primarily to predation, i.e., that adult females, on average being hungrier than males, are more responsive to visual stimulation. A subsequent occurrence of display behaviour indicates a switch to sexual motivation.

For display to occur in females the PME have to be useable, and they are sufficient by themselves for mediating this response. The fact that lateral as well as anterior views of the courting male elicited responses suggests that the cue is movement of the male's black leg I: it extends forward in a pumping-like motion of increasing frequency and then abruptly flexes back. Unlike salticid face-to-face courtship, in which the perceived form of the male may be as important for the female as his behaviour (*ibid.*), female *R. rabida* need not view the male's anterior. Apparently, detection of a temporal pattern of movement suffices for recognition.

As to visually-triggered courtship display, male *R. rabida* differ from male salticids, which require one particular pair of eyes, the AME (*ibid.*). Stimulation of either pair of a male *R. rabida*'s posterior eyes suffices for triggering courtship. If the PLE are involved, orientation precedes display. If the PME are involved, approach can precede display, although it need not do so.

Given that the movement-detecting PLE are sufficient for courtship onset in *R. rabida*, an adequate stimulus in this species may be any object of an appropriate size, speed, and perhaps movement pattern entering the extensive visual field of the PLE. Since the other three pairs of lycosid eyes are also assumed to be movement detectors (Land, 1981), there may be no need to require their involvement in additional visual analysis before initiating courtship. However, this may not be true for all lycosids. In particular, female *Pardosa laura* have been hypothesized to use form vision for species discrimination (Suwa, 1984). If male *P. laura* likewise do so, eyes other than the PLE would be have to be used for such form analysis in order to inititate courtship.

THE SPATIAL DYNAMICS OF LINYPHIID SPIDERS IN WINTER WHEAT

K.D. SUNDERLAND AND C.J. TOPPING[†]

Sunderland, K.D. and Topping, C.J. 1993 11 11: The spatial dynamics of linyphiid spiders in winter wheat. *Memoirs of the Queensland Museum* **33** (2): 639-644. Brisbane. ISSN 0079-8835.

The density of linyphiid spiders was monitored accurately throughout the growing season in a field of winter wheat in southeast England in 1990 and 1991. Numbers increased until harvest in 1991, but declined before harvest in 1990, possibly due to drought conditions. The pattern of natality in 1991 closely mirrored the pattern of change in density, suggesting that reproduction, rather than immigration, was the predominant factor underlying the increase in density. Aerial activity, as measured by deposition traps and a rotary trap in the field, and a suction trap at the edge of the field, increased progressively during the growing season. Results from a short-term field caging technique, used to measure net migration rates, indicated that there was little immigration before July (thereafter high sampling variance, caused by aggregation in weedy patches, precluded meaningful analysis).□*Araneae, Linyphiidae, spatial dynamics, winter wheat, density, natality, migration.*

Keith Sunderland and Chris Topping, Horticulture Research International, Littlehampton, West Sussex BN17 6LP, England; [†]current address, Scottish Agricultural College, Craibstone, Bucksburn, Aberdeen AB2 9TR, Scotland, UK; *8 September, 1991.*

There are few studies of the population dynamics of predators. For example, Stiling (1988), in an examination of the incidence of density-dependence in invertebrate populations, quotes 62 population dynamics studies; of these 60 relate to phytophages, 2 to parasitoids and none to predators. There are also few population dynamics studies of migratory species, because of the methodological problems involved in quantifying migration. The present study, of the population dynamics of linyphiid spiders (the species concerned are all migratory predators), was undertaken to collect some basic data in this neglected area, and also because these species are known to be valuable predators of crop pests (Sunderland *et al.*, 1986). This paper summarises the main trends for total linyphiids; consideration will be given to individual linyphiid species in later publications.

METHODS AND MATERIALS

Total spider density was measured throughout most of the growing season of 1990 in a 17ha field of winter wheat (c.v. Pastiche) in southeast England. In 1991, density, natality and migration were measured in a 3ha field of winter wheat (c.v. Riband), 24km from the 1990 study field. The fields were treated with agrochemical applications, following normal farm practice; insecticides were not required in either year.

Density Sampling

Twenty-five 144m^2 squares were marked out inside a 60 x 60m area (adjacent to one edge of the field in 1990 and 30m from the nearest edge in 1991). Fifteen density samples were taken at each sampling interval (approximately weekly) following a Latin Square design. The sample unit consisted of a randomly-selected 0.5m^2 area of ground delimited by a metal ring and sampled using a vacuum insect net (D-vac). Vegetation and the top 1cm of ground, within the 0.5m^2 sampled by D-vac, were then immediately hand-searched for spiders. The suction catch was kept at 10°C and returned to the laboratory for live-sorting. Therefore spiders were collected from 7.5m^2 of habitat (crop, ground surface and immediate sub-surface) on each occasion (Topping and Sunderland, 1992). The D-vac collected only about 50% of the total number of spiders present in a sample unit, the other 50% were uncovered by hand-searching (see also Sunderland *et al.*, 1987).

Natality

Adult female linyphiids were collected from the field, adjacent to the 60 x 60m area, at weekly intervals and incarcerated individually in 9cm diameter plastic Petri dishes lined with moist filter paper. The dishes were returned immediately to a ventilated box in the study field and examined at weekly intervals. Mean daily temperatures in the Petri dishes did not diverge from field temperatures (measured on the ground

surface, under weed cover) by more than 1°C (warmer in spring, cooler in summer). The dishes were inspected at weekly intervals and the following statistics recorded (i) proportion of spiders producing eggsacs in the first week of incarceration, (ii) time (days) to emergence of spiderlings, (iii) number of spiderlings emerging, and (iv) number of undeveloped eggs (by dissection of the eggsac). These results were used, in conjunction with information on the density of adult females, to calculate daily natality rates for each species and then combined to give a composite spider natality curve.

Net Migration Rate

Migration to and from small areas of the crop was suppressed by the use of ten stainless steel spider-proof cages. The cages were circular, $0.5m^2$ by 1m tall, and made of mesh with 3 x 2.5 perforations mm^{-2} (too small to allow passage of first instar linyphiid spiders). The bases of the cages were sealed with sufficient compacted soil to prevent entry or exit of any spiders. Total spider density inside the cages was assessed as above. Because the cages were moved to a new location within the Latin Square each week, there was assumed to be insufficient time for the processes of natality and mortality to be significantly affected by the changed microclimate inside the cages; therefore differences in the change in density from one week to the next between caged and uncaged parts of the crop were considered to be a measure of net migration.

Aerial Density of Spiders

A 46cm Propeller Suction Trap (Taylor, 1955), with an air throughput of $70m^3$ min^{-1} and a sampling height of 142cm above the ground surface, located at the edge of the study field, was emptied daily. In addition, a rotary insect net was used to collect spiders within the field, 25cm above the top of the crop canopy. The 10m long rotor arm travelled at 6.3m sec^{-1} and the 56 x 25cm net at the end of the rotor arm (which was designed to sample air isokinetically, (Taylor, 1962)) processed $53.8m^3$ min^{-1} and was also emptied daily. To measure rates of input of spiders into the field, a set of seven deposition traps were deployed at 15m intervals between the rotor and the 60 x 60m area. Each trap consisted of a 10cm deep, $1m^2$, fibreglass tray, filled with water and ethylene glycol (20:1) plus 1% detergent, fitting inside a $1.6m^2$ metal tray containing the same fluid. The outer tray acted as a barrier to prevent spiders walking from the crop into the inner tray, which therefore received only aerial immigrants. As the crop grew, the deposition traps were progressively raised on wooden supports to maintain the level of the fluid surface constantly at *ca.* 5cm above the top of the crop canopy. The traps were emptied at approximately weekly intervals.

Nomenclature follows Roberts (1987).

RESULTS

The study was based on data from more than 39,000 individuals belonging to 53 species. 12 species were dominant (Table 1). All species belong to the family Linyphiidae, with the exception of the tetragnathid *Pachygnatha degeeri*. *Lepthyphantes tenuis* was the most abundant species in 1991 and the second most abundant in 1990. Species composition was similar in the two years, the only notable differences being that *Meioneta rurestris* was relatively more abundant in 1990, the reverse being true for *Oedothorax* spp. Here, all spiders are treated as a group.

In 1990, density of total spiders increased in spring to reach a peak of $78m^{-2}$ on 18 June and thereafter declined, apart from a short-lasting peak (made up entirely of immature spiders) just before harvest (Fig. 1). The pattern was different in 1991 (Fig. 2); spider density built up in two steps (the first in May/June, the second in August) to reach a peak of $123m^{-2}$ just before harvest. Mean air temperatures in June and July were slightly higher in 1990 (15.1°C) than 1991 (14.9°C), but rainfall was considerably lower (68mm in 1990 cf 191mm in 1991). The semi-drought conditions in the summer of 1990 may have had a deleterious effect on spider survival.

Species	1990	1991
Meioneta rurestris (C.L. Koch)	32.5	5.4
Lepthyphantes tenuis (Blackwall)	27.8	31.3
Erigone atra (Blackwall)	9.8	13.3

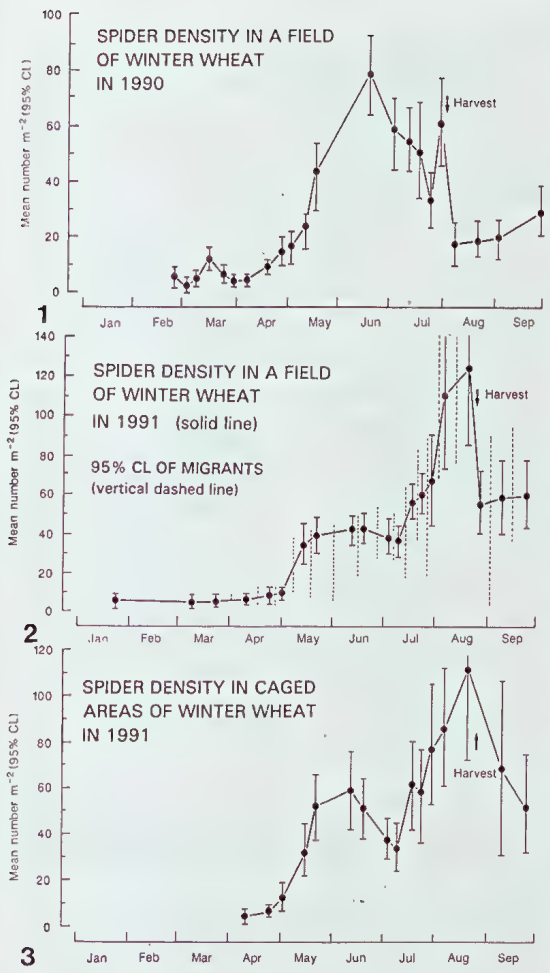
TABLE 1. Species composition of adult spiders in density samples in 1990 (n=1562) and 1991 (n= 1457).



FIGS. 1-3. Total spider density in a field of winter wheat: 1990 (Fig. 1); 1991 (solid line) and 95% CL of number of migrants m^{-2} (vertical dashed lines) (Fig. 2); in caged areas, 1991 (Fig. 3).

Density in the caged areas of the crop in 1991 followed a similar pattern to that in uncaged areas (Fig. 3). 95% confidence limits increased during July and August (Figs 2, 3) due to aggregation of spiders in weedy patches of the crop (significantly more spiders in weedy than bare areas; paired t-test, n = 5 dates, p = 0.05).

The pattern of change in density with respect to time is examined, below, in relation to natality and migration for 1991.

Natality rates were *c.* $4m^{-2}$ day^{-1} in the spring, briefly 10-$15m^{-2}$ day^{-1} in late July, then $8m^{-2}$ day^{-1} in August. The pattern of daily natality was similar to the patterns for immature spider density (Fig. 4) and total spider density (Fig. 2); this is

24 September	7.1	(-19.6-33.8)

TABLE 2. Indices of net aerial migration, M (95% CL), in 1991.

circumstantial evidence that reproduction (as opposed to immigration) is the predominant process driving increase in density of spiders in the field. Data on migration can be examined in the light of this hypothesis. Aerial activity of spiders, as measured by catches in the 1.4m suction trap at the edge of the field, tended to increase steadily from March to August, and this was followed by a much larger increase in September (Fig. 5). A similar pattern of aerial activity was evident inside the field, as indicated by the catch in deposition traps and in the rotary trap (Fig. 6). To assess whether there had been a a net gain or loss of spiders from the field over a particular period, the density of spiders inside caged areas was compared with the density outside,to give an index of net migration (M);

$$M = (F2-F1)-(C2-F1) = F2-C2$$

where F1 and F2 are densities in the uncaged part of the field in weeks 1 and 2 respectively, and C2 is the density in the caged part of the field in week 2. (F2-F1 represents change in numbers due to natality, mortality and migration, whereas C2-F1 represents change in numbers due to natality and mortality alone, because migration was suppressed by caging). The standard error of M is calculated as the square root of [$SE\ F2^2$ + $SE\ C2^2$]; the 95% CL's on M are therefore large because they are compounded of two standard errors. Values of M are shown in Table 2. Positive values indicate immigration and negative values indicate emigration. However, all 95% CL's span the range from negative to positive and therefore no significant net migration can be demonstrated.

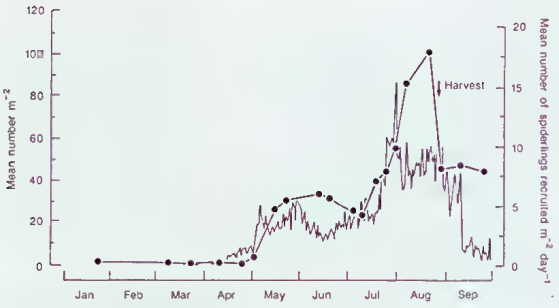

FIG. 4. Total immature spider density (●) and total spider natality (continuous line) in a field of winter wheat in 1991.

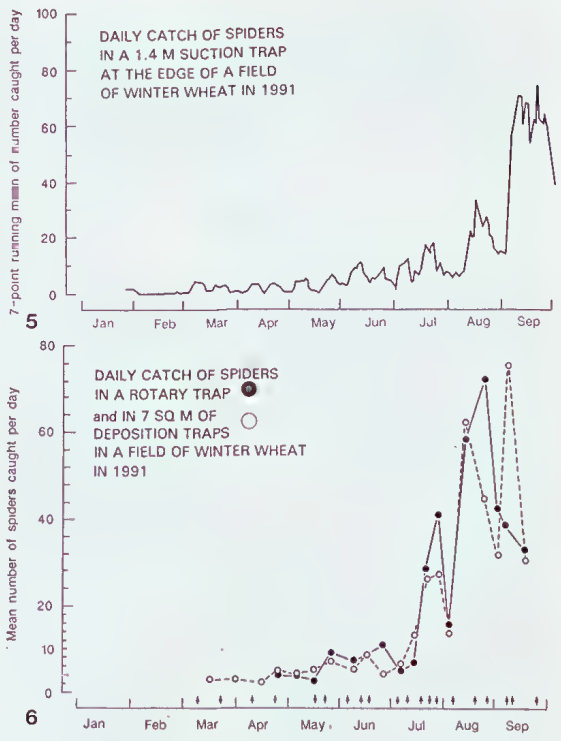

FIGS. 5, 6. Daily catch of total spiders in winter wheat field in 1991. 5. In 1.4m suction trap at edge of field; 6. In rotary trap (●) and in $7m^2$ of deposition traps .

These 95% CL's are plotted on the curve of total spider density (Fig. 2); the extent of the dotted line above and below the density curve shows the amount of immigration and emigration, respectively, that could have occurred between any two dates. The following conclusions can be drawn; (i) any migration that may have occurred in April was small (i.e. on a similar scale to density sampling variance), (ii) if immigration occurred in May and June it must also have been on a small scale, but there could have been a large emigration, and (iii) in July, August and September 95% CL's were very large (due to spider aggregation, see above), with no obvious bias in favour of either immigration or emigration.

DISCUSSION

There appear to be no previous quantitative arachnological studies in which the seasonal patterns of natality and migration are compared with the seasonal pattern of density using consistent units. Examples of other arachnological studies involving density or natality estimation are given below. The majority of investigations where density has been measured are for grassland; peak densities of lycosid and linyphiid spiders vary greatly according to location (Table 3). Densities are often lower in graminaceous crops (Table 3). The peak spider density of $123m^{-2}$ in the present study is comparable with, if somewhat greater than, densities recorded in cereals by other authors (Table 3). In common with the present investigation, nearly all the studies in Table 3 reported large confidence limits due to aggrega-

TABLE 3. Maximum density estimates (number m^{-2}) in a range of arachnological studies.

tion of spiders. There seem to be no previous publications describing the seasonal pattern of spider natality, but a few authors (eg Steigen, 1975; Workman, 1978) have recorded natality at specific times of year. Schaefer (1978) estimated the egg density of the linyphiid *Floronia bucculenta* in grassland during the spring to be 98-151m^{-2} depending on location. The maximum spring natality of the linyphiid *Erigone arctica* in coastal grassland was claimed to be 2584m^{-2} (van Wingerden, 1977), which is considerably greater than the total natality (8 dominant linyphiids) of 789m^{-2} between March and October in the present study; this difference may underly the relative sparseness of spiders in crops compared with natural grassland (Table 3). Although the intensity of aeronautic activity has been measured using sticky traps (Duffey, 1956, van Wingerden, 1977, Greenstone *et al.*, 1985), window traps (Meijer, 1976; De Keer and Maelfait, 1987, 1988) and suction traps (Dean and Sterling, 1985; Sunderland, 1987, 1991), there appear to be no previous attempts to directly quantify the impact of migration on population density. The use of short-term field cages in the present study provided useful estimates of the upper limits to migration (except when sampling variance became very large) and it is expected that this technique will yield better results when data are analysed for individual species. In addition, when the rotary trap has been calibrated, it should be possible to estimate rates of aerial immigration and emigration from a comparison of deposition and rotor catches.

ACKNOWLEDGEMENTS

We thank Mr Bewsey and Mr Reeves (HRI) for constructing the rotary trap, Mr Fenlon (HRI) for statistical advice, and Dr Jepson and Mr Thomas (Southampton University) for useful discussions. The work was funded by the Natural Environment Research Council (Joint Agriculture and Environment Programme) and the Ministry of Agriculture, Fisheries and Food. The first author is grateful to the British Council for the opportunity to deliver this paper in Australia.

MORPHOLOGY OF THE EMBRYOS AT GERM DISK STAGE IN *ACHAEARANEA JAPONICA* (THERIDIIDAE) AND *NEOSCONA NAUTICA* (ARANEIDAE)

HIROHUMI SUZUKI AND AKIO KONDO

Suzuki, H. and Kondo, A. 1993 11 11: Morphology of the embryos at germ disk stage in *Achaearanea japonica* (Theridiidae) and *Neoscona nautica* (Araneidae). *Memoirs of the Queensland Museum* 33(2): 645-649. Brisbane. ISSN 0079-8835.

Embryos at the germ disk stage were investigated by electron microscopy in *Achaearanea japonica* (Theridiidae) and *Neoscona nautica* (Araneidae). In both spiders, the germ disk was composed of spherical cells, which had almost no large yolk granules. In the inner part of the embryo, several large yolk granules were packed by cell membrane with various organelles and glycogen granules similarly to lycosid spiders. In *Achaearanea japonica* there were very flat cells which possessed several large yolk granules in the surface region where the germ disk was not formed. In *Neoscona nautica* cells were not observed in that region at all, so the packages of large yolk granules were exposed directly to perivitelline space. The araneid type can be distinguished from the agelenid and theridiid type.

Die Embryonen von *Achaearanea japonica* (Theridiidae) und *Neoscona nautica* (Araneidae) im Stadium der Keimscheibe wurden mittels des Elektronenmikroskops untersucht. Die Keimscheiben der beiden Spinnen bestanden aus sphärischen Zellen, die große Dotterkörnchen nur selten hatten. In dem inneren Teil von dem Embryo wurden manche großen Dotterkörnchen mit verschiedenen Organellen und Glykogenkörnchen von der Zellmembran gepackt, wie im Falle von den lycosiden Spinnen. Im Falle von *Achaearanea japonica* gab es sehr flache Zellen, die manche großen Dotterkörnchen hatten, in dem oberflächlichen Bezirk, wo die Keimscheibe nicht gebildet wurde. Im Falle von *Neoscona nautica* wurden die Zellen in dem Bezirk schließlich nicht beobacht, also waren die Packe von großen Dotterkörnchen direkt in der Perivitellinhöhle entblößt. Der araneide Typus soll sich von dem ageleniden Typus und dem theridiiden Typus unterscheiden. □*Spider, Achaearanea, Neoscona, embryo, germ disk, morphology.*

Hirohumi Suzuki and Akio Kondo, Department of Biology, Faculty of Science, Toho University, 2-1, Miyama 2 chome, Funabashi-shi, Chiba 274, Japan; 29 October, 1992.

Three types of germ disk formation are known in the embryos of spiders. In the most common type known in Agelenidae, the germ disk is formed on a hemisphere of the egg as the result of transformation of squamous blastoderm cells in this region into spherical cells. Egg surface of the other hemisphere is covered with squamous cells (Holm, 1952). In the second type known in Theridiidae, the most blastoderm cells converge on the germ disk region and few cells remain on the other hemisphere (Montgomery, 1909). In the third type found in many Araneidae, a rip appears in the blastoderm, so the yolk mass is exposed (Sekiguchi, 1957). Then all blastoderm cells take part in germ disk formation, and any cells are not observed in the region where the germ disk is not formed. A comparative study of the spider embryos at germ disk stage was carried out under light microscope (Kondo and Yamamoto, 1975). The study of germ disk formation under electron microscope was executed in lycosid spiders, whose germ disk formation is the agelenid type (Kondo, 1969, 1970). We had to examine whether remaining cells connect each other or not in theridiid type and whether extreme thin cells exist or not at the superficial region where the germ disk is not formed in araneid type. In present study, electron microscopic investigation of the embryos at germ disk stage was carried out in *Achaearanea japonica* and *Neoscona nautica*.

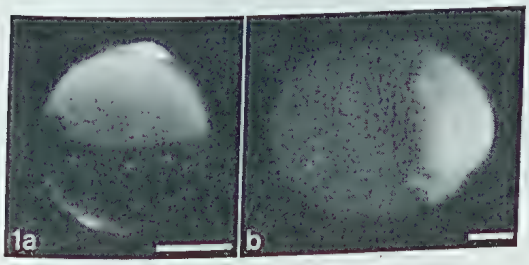

FIG. 1. The embryo at germ disk stage in *Achaearanea japonica* (a) and *Neoscona nautica* (b). In *A. japonica*, a few cells are found on region where germ disk is not formed. In *N. nautica*, exposed yolk mass is found on that region. Scale=0.2mm.

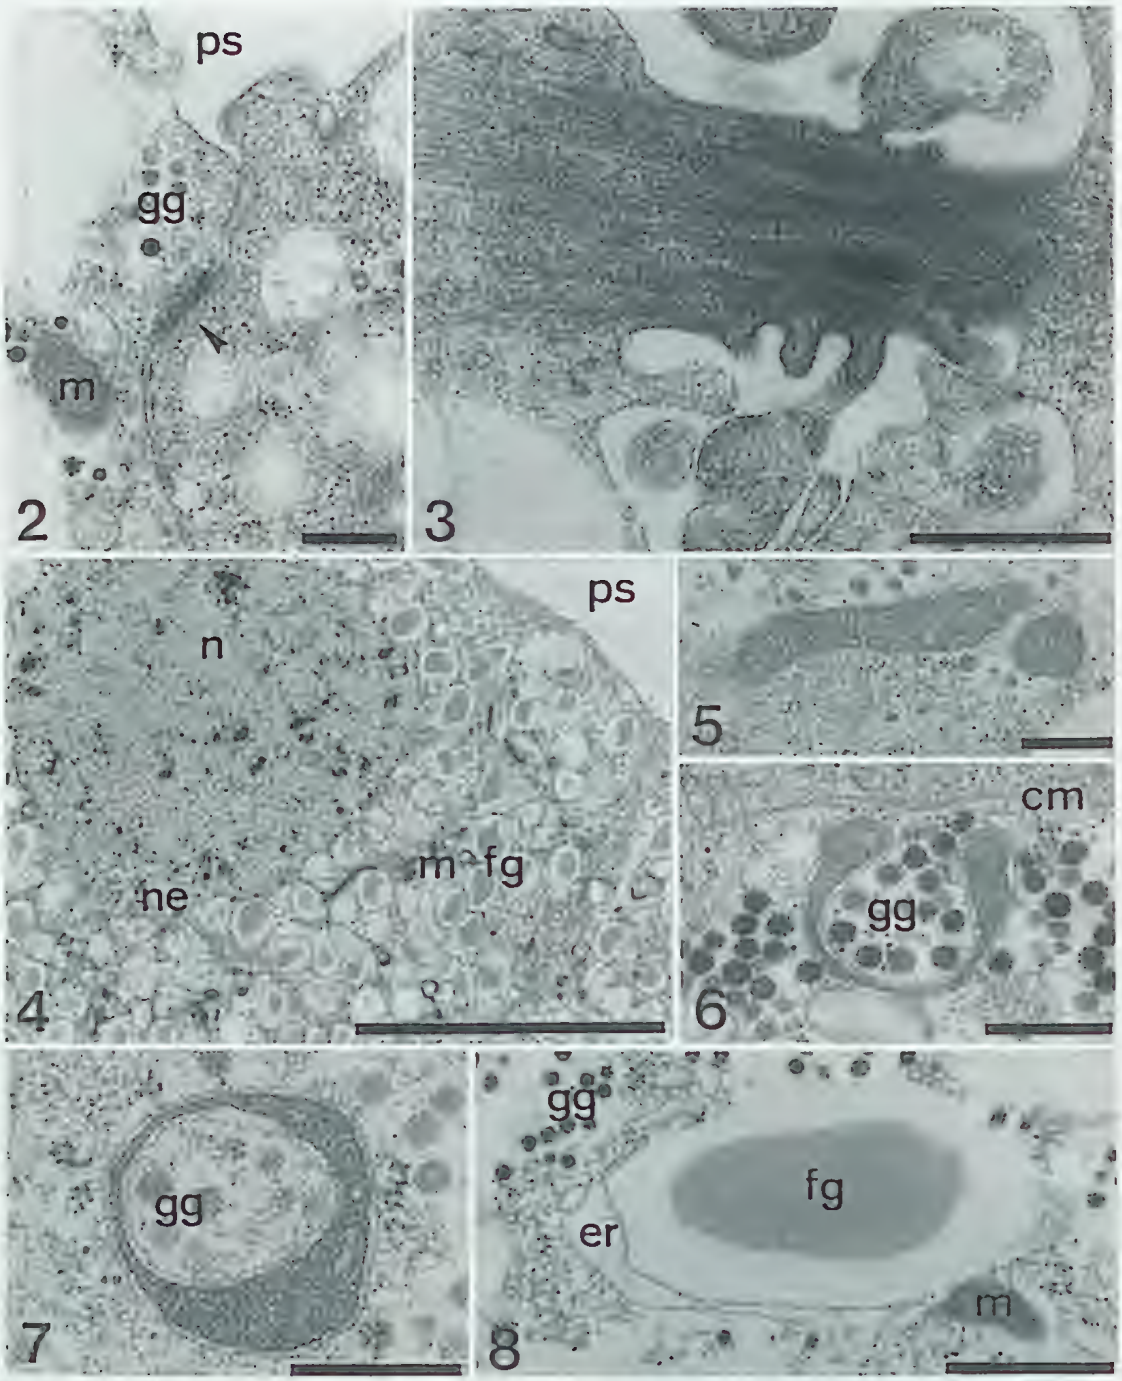


FIGS. 2-8. 2. *A. japonica.* Peripheral region of two germ disk cells. (0.5μm.) Arrowhead: Desmosome-like structure, 3. A mid-body. Many microtubules. (1μm.) 4. A germ disk cell. Main components of cytoplasm are fatty granules (fg) with medium electron dense matrix, and no large yolk granules. (10μm.) n: nucleus, ne: nuclear envelope. 5. Mitochondria have high electron dense matrix and the cristae are found faintly. (0.5μm.) 6. Cup-shaped mitochondrion. (0.5μm). cm: cell membrane. 7. Ring-shaped mitochondrion. (0.5μm.) 8. Scales in parentheses.

MATERIALS AND METHODS

Achaearanea japonica (Bösenberg and Strand) (Theridiidae) and *Neoscona nautica* (L. Koch) (Araneidae) were used here. In *A. japonica*, the eggs collected in August were used. In *N. nautica*, the eggs laid in glass tubes at laboratory were used. The observation of the live eggs was carried out in liquid paraffin, where the opaque chorion became transparent. The eggs were fixed for 3 hours at 4°C in 2% paraformaldehyde and 2.5% glutaraldehyde solution in 0.1M phosphate buffer, pH 7.4, containing 0.2M sucrose. Through fixation, the eggs were cut in half with a tungsten needle. After rinsing more than one hour with the same buffer containing 0.2M sucrose, the samples were postfixed for one hour at 4°C in 2% osmic acid in 0.1M phosphate buffer, pH 7.4, without sucrose. After rinsing with the same buffer without sucrose, samples were dehydrated in ethanol series, transferred to propylene oxide, and embedded in Quetol-812. Ultrathin sections were cut on a ultra-microtome, LKB-4800, stained with uranyl acetate and lead citrate, and examined under Hitachi HU-12A electron microscope. Thick sections were prepared simultaneously, and stained with methylene blue for light microscopy.

RESULTS

Achaearanea japonica

The eggs were spherical and 0.5mm in diameter. Typical theridiid type germ disk formation was observed (Fig. 1a). At 25°C, the eggs took 24 hours to the germ disk stage after oviposition.

The germ disk was formed as a single layer composed of spherical cells, but the cells piled up in its central region. The diameter of germ disk cells was about 30μm, and that of nuclei was about 15μm. Desmosome-like structures were observed between germ disk cells at the superficial region (Fig. 2), but interdigitations were not observed. Mid-bodies were observed rarely (Fig. 3). Narrow cytoplasmic bridge connected cells adjacent to each other, and contained many microtubules.

The main components of cytoplasm were fatty granules, 1- 3μm in diameter, with a matrix of a medium electron density (Figs 4, 8). The limiting membrane was often obscure. The germ disk cell had almost no large yolk granules. Fine yolk granules, less than 5μm in diameter, were observed.

Mitochondria had a high electron dense matrix, and the cristae were found faintly (Fig. 5). Many figures of mitochondria showed oval or curved bars, and several showed cups (Fig. 6) or rings (Fig. 7).

Smooth-surfaced endoplasmic reticula were often found enclosing fatty granules (Fig. 8). Rough-surfaced endoplasmic reticula were not observed.

Typical Golgi bodies were rare. Vesicles were generally observed in the cytoplasm. The glycogen granules, 0.1μm in diameter, were very high electron dense, and scattered.

The superficial region where the germ disk was not formed was occupied by remaining flat cells. These cells were about 100μm in length, about 25μm in thickness at the central part, but often less than 1μm near the peripheral one (Fig. 9). The diameter of nuclei was about 13μm. Desmosome-like structures were observed between remaining cells (Fig. 9).

Several large yolk granules occurred in these remaining cells. The largest yolk granule was 20μm in diameter. Vesicles were sometimes arranged along the large yolk granules (Fig. 10).

The interior of the embryo was filled with yolk packages composed of several large yolk granules, various organelles and glycogen granules, and enclosed by cell membrane (Fig. 11).

Neoscona nautica

Ellipsoidal eggs of *N. nautica* had longer axis measuring 1.2mm and shorter axis measuring 1mm. At 23°C, 45 hours were needed from oviposition to establish the germ disk (Fig. 1b).

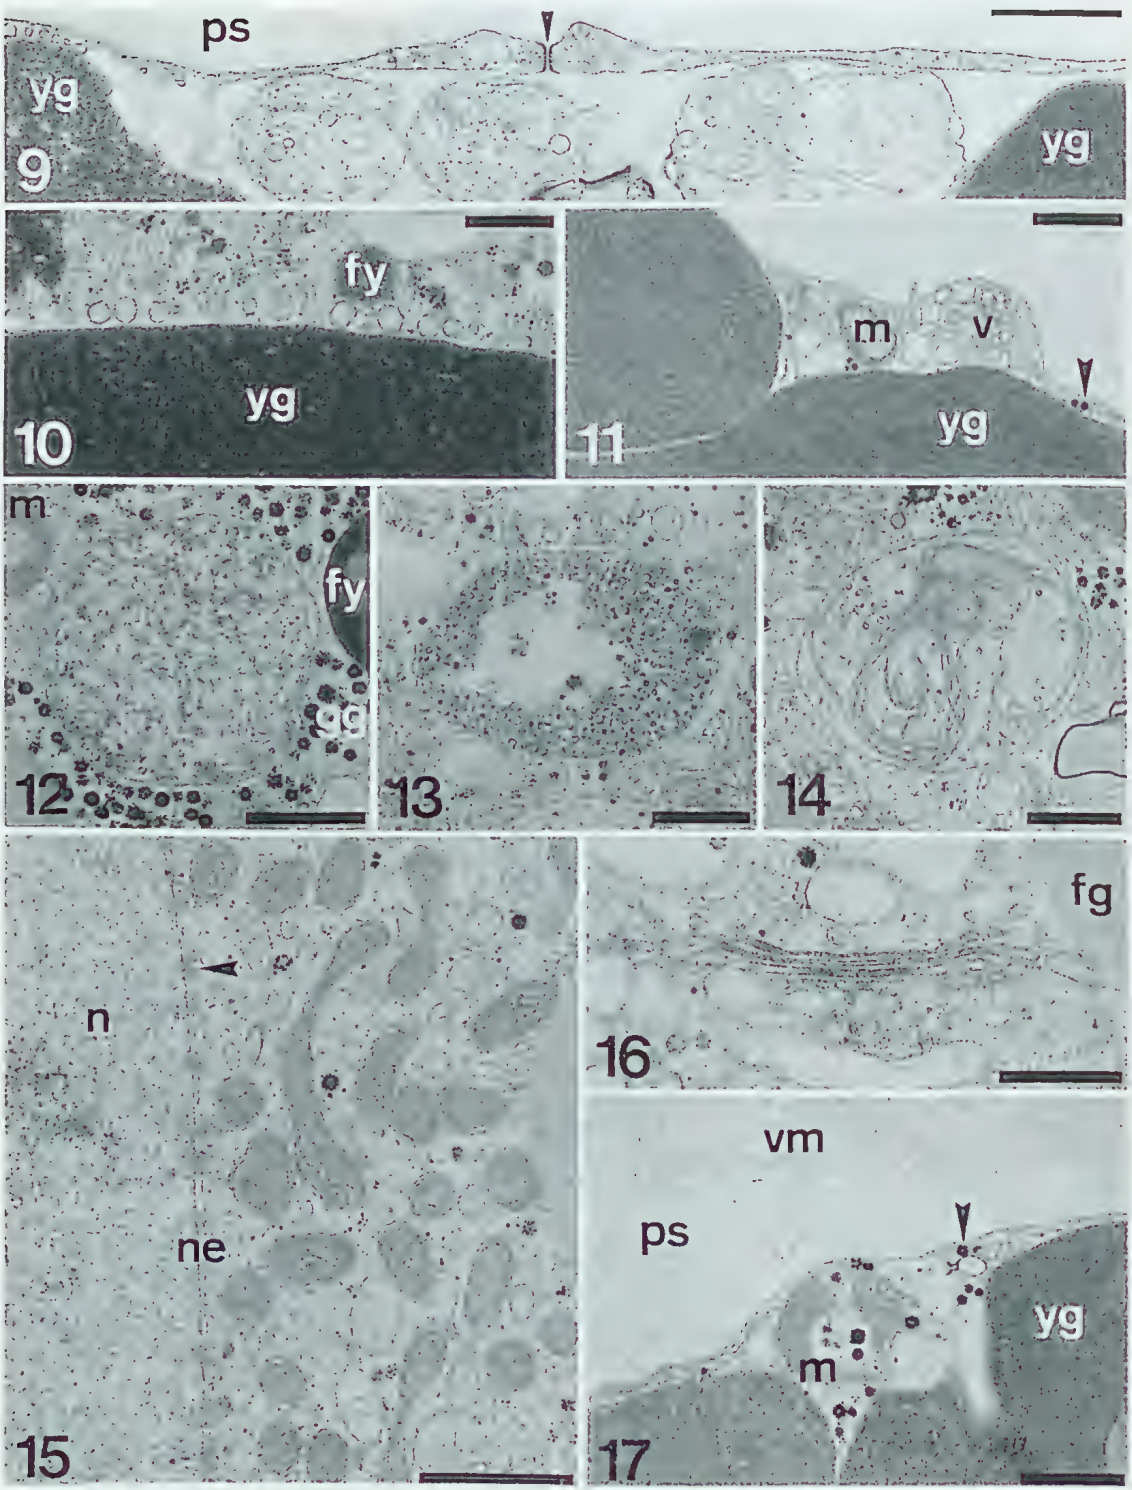
The germ disk was a single layer of spherical cells, but the cells piled up in its central region. The cell diameters were about 45μm, and those of nuclei were about 20μm. Between these cells, there were desmosome-like structures but no interdigitations.

Various types of lysosome-like bodies were observed (Figs 12-14). Mitochondria often crowded around the nucleus (Fig. 15). Several Golgi bodies were observed (Fig. 16). Other components of cytoplasm were similar to those of *A. japonica*.

No blastoderm cells were observed in the surface region where the germ disk was not formed (Fig. 17).

DISCUSSION

In this study, some cup- or ring-shaped



mitochondria were observed. These types of mitochondria were not reported in the embryos of lycosid spiders (Kondo, 1969, 1970), but they were figured in embryo of *A. tepidariorum* (Suzuki and Kondo, 1991). In *N. nautica*, many mitochondria were found surrounding the

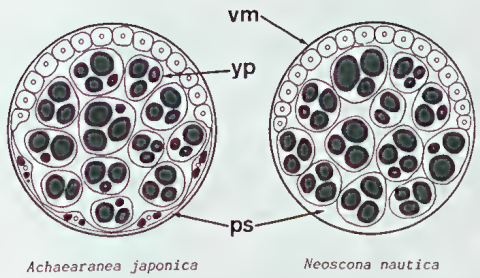


FIG. 18. Schematic figures of embryos at germ disk stage in *A. japonica* (left) and *N. nautica* (right). In both spiders, the germ disk is composed of spherical cells, which have almost no large yolk granules. The interior of the embryos is filled with yolk packages (yp). In *A. japonica*, there are very flat cells which possess several large yolk granules in the surface region where the germ disk is not formed. In *N. nautica*, any cells are not found in that region, so the yolk packages are exposed directly to perivitelline space (ps). vm: vitelline membrane.

nucleus. This phenomenon was reported in lycosid spiders (Kondo, 1969). In *N. nautica*, many lysosome-like bodies, described also in lycosid spiders (Kondo, 1969), were observed, however histochemical studies are needed for final identification.

In both spiders, *A. japonica* and *N. nautica*, interdigitations were not observed, but they were reported in germ disk region of lycosid spiders (Kondo, 1970).

In the inner part of the embryo in both spiders, several large yolk granules were packed by cell membrane with various organelles and glycogen granules. These structures were described as yolk spheres in lycosid spiders (Kondo, 1969). Since nucleus was not observed in them, these packages of large yolk granules were distinguished from yolk cells. In this investigation, detailed observation of yolk cells was not carried out.

The embryo at germ disk stage in *A. japonica* had very flat cells with several large yolk granules (Fig. 18). Distinct differences of cytoplasm were not observed between spherical germ disk cells and flat remaining cells. As in *A. tepidariorum* (Suzuki and Kondo, 1991), except for the large yolk granules and extreme flat shape in the remaining cells, the fine structure of embryo at germ disk stage in *A. japonica* was similar to that in lycosid spiders belonging to agelenid type.

In *N. nautica*, the yolk packages were exposed directly to the perivitelline space (Fig. 18).

AN EXPERIMENT ON COLONIZATION OF KARAKURT (*LATRODECTUS TREDECIMGUTTATUS*, BLACK WIDOW SPIDER) ON ISLAND TERRITORIES IN KAZAKHSTAN

CHINGIS K. TARABAEV

Tarabaev, C.K. 1993 11 11: An experiment on colonization of karakurt (*Latrodectus tredecimguttatus*, Black Widow spider) on island territories in Kazakhstan. *Memoirs of the Queensland Museum* 33(2): 651-652. Brisbane. ISSN 0079-8835.

To create an artificial, controllable population of *Latrodectus tredecimguttatus* (karakurt) with the aim of collecting venom, an experiment on mass colonisation of southern population spiders on an island territory was carried out. Retardation of the overwintering stage under laboratory conditions ensured the availability of large numbers of karakurt for colonisation and eliminated its uncontrollable reproduction in neighbouring territories.

Pour créer une population artificiele bien contrôlée des *Latrodectus tredecimguttatus* (karakurt) dans le but d'obtenir du venin on a mis une expérience de la dissémination des Araignées de la population méridionale sur le territoire insulairs. Le delai du stade hivernant dans les conditions de laboratoire assure la stabilisation du nombre de masse de karakurt pour leur colonisation et élimine leur reproduction non-contrôlée sur les territoires adjacents.

□*Colonisation, karakurt, egg sacs, Latrodectus.*

Chingis K. Tarabaev, Institute of Zoology of Kazakhstan National Academy of Sciences, Akademgorodok, 480032 Alma-Ata, Kazakhstan Republic; 19 March, 1993.

In Kazakhstan, mass annual collections of venom-producing arachnids are carried out to obtain their venom for medicinal and other purposes. Black widow spiders ('karakurt', *Latrodectus tredecimguttatus* (Rossi)) are caught in the greatest numbers. At the same time, their abundance varies from year to year: quite often periods occur during which one can hardly find a single specimen (see Marikovskij, 1956; Levi, 1983; Tarabajev, 1990). A bite from a karakurt is an appreciable danger. Hence, during periods of great abundance, it must be controlled. In connection with this problem, we carried out an experiment on karakurt colonisation on an island with the aim of creating an abundant and controllable artificial population.

MATERIALS AND METHODS

The experiment was performed on the small island 'Malyj' (1.4km^2) in Alakol' Lake (46°08'N, 81°52'E) near the northern border of the known karakurt distribution: the 2nd instar spiderlings emerging from egg sacs are often affected here by the late frosts which occur in April-May (Tarabajev, 1990). In contrast, the development of spiders is critically restricted by the shortened warm season: if the postembryos within the egg sacs have no time to develop into the overwintering 1st instar spiderlings, they die during winter (Marikovskij, 1956). This phenomenon stipulated the possibility of creating a numerous, yet controllable karakurt population. To do so we retarded the development of spiderlings and then released the 2nd instars over the island. As a result, the spiderlings avoid the disastrous late frosts but the postembryos of the new generation in their egg sacs would not have time to develop into overwintering 1st instar spiderlings. This phenomenon is therefore the necessary condition for the possibility of creating a controllable karakurt population, as well as for elimination of uncontrollable mass reproduction of spiders on the neighbouring territories. For the intensification of degree-days deficit effect, the spiderlings from 500 egg sacs of *Latrodectus tredecimguttatus* collected in Uzbekistan (southern population from Dzhizak Steppe) were used in our experiment. Before the colonisation we made a census of the native population of karakurt on the island.

During winter, egg sacs of southern population spiders with overwintering first instar spiderlings were kept in the laboratory (temperature 0-5°C). In the second half of May these were placed into a gauze-covered 20 litre vessel at room temperature (18-22°C), for their reactivation from winter diapause. After moulting in their egg sacs, many spiderlings emerged; then the vessel which contained them was placed in a refrigerator (4-5°C) until June.

Before mass colonisation, a census of the natural karakurt population on 'Malyj' Island was carried out by the visual investigation of the

whole island territory fit for the settling by the southern population spiders of karakurt (ca. 8500 m^2).

RESULTS

While making a census of the native karakurt population on 'Malyj' Island before mass colonisation on 12 June 1988, we found one nest from the previous year with two empty egg sacs, and two more old nests. Six living karakurt specimens of 4-5th instar were also found. By late August there were 3726 nests from the southern population, or one specimen per 2-3m^2. Three females of the native karakurt population were also found: they differed by their larger size (no females were measured). In 28 nests of southern population spiders there was only one egg sac per nest: no egg sacs were found in the rest, while in three nests of native population spiders there were two egg sacs in each. Dissection of egg sacs confirmed our views. In four egg sacs of the native karakurt population there were postembryos, in two there were first instar spiderlings, while only eggs were found in 20 egg sacs of the southern population.

Of 100 nests examined in May 1989, 74 nests were without egg sacs–some nests were ruined; 26 nests each had one egg sac, all eggs were dead. These results confirmed that due to the artificially retarded development of southern population spiders in the northern conditions of Alakol' Lake the eggs had died within the egg sacs as they had insufficient time to develop to the overwintering first instar spiderlings (the average Alakol' area temperature in September is no more than 10-15°C).

We therefore propose the following scheme for the creation of many controllable artificial black widow populations for the purpose of obtaining venom.

In August-September, mass collection of females must be carried out. These females are kept in collection boxes for 2-3 weeks until they lay their egg sacs in these boxes. (This phenomenon was first noticed by us when studying the technique of mass collecting from the field). Females are subsequently used for obtaining venom while egg sacs are kept at room temperature until the 1st instar spiderlings emerge (overwintering stage). After that the egg sacs must be kept in a refrigerator at 0-5°C until the following season.

After the reactivation of spiderlings in spring, they are released over the island, which they recolonised effectively. Every August-September, mass collection of females is carried out, and the cycle is renewed.

Thus, the indubitable advantage of our method is the elimination of uncontrollable mass reproduction of karakurt and the absence of any necessity of special egg sacs collecting for colonisation.

DISTRIBUTION OF *LATRODECTUS* (THERIDIIDAE), *ERESUS* AND *STEGODYPHUS* (ERESIDAE) IN KAZAKHSTAN AND CENTRAL ASIA

CHINGIS K. TARABAEV, ALEXEY A. ZYUZIN AND ANDREY A. FYODOROV

Tarabaev, C.K., Zyuzin, A.A. and Fyodorov, A.A. 1993 11 11: Distribution of *Latrodectus* (Theridiidae), *Eresus* and *Stegodyphus* (Eresidae) in Kazakhstan and Central Asia. *Memoirs of the Queensland Museum* 33(2): 653-657. Brisbane. ISSN 0079-8835.

The distributions of three *Latrodectus* species (*L. tredecimguttatus*, *L. dahli* and *L. pallidus*), and of three eresid species (*Eresus niger*, *E. tristis* and *Stegodyphus lineatus*) within the Kazakhstan-Central Asian region are analysed based on the literature and on original data. *Latrodectus tredecimguttatus* presumably occupies almost the entire Kazakhstan territory, while two other widow species are local and more southern: both of them are first recorded here within Kazakhstan. Preliminary morphological and mating analyses show that both '*Latrodectus tredecimguttatus*' and '*Eresus niger*' within the territory of Kazakhstan and Central Asia are composite species: the first consists of at least one species different from the European *L. tredecimguttatus*, and the second consists of at least three separate species. On a analysé la distribution de trois espèces du genre *Latrodectus* (*L. tredecimguttatus, L. dahli* et *L. pallidus*) et de trois espèces de la famille Eresidae (*Eresus niger, E. tristis* et *Stegodyphus lineatus*) dans la région du Kazakhstan et de l'Asie centrale d'après le données littéraires et originales. L'aire d'habitation de *Latrodectus tredecimguttatus* comprend, hypothétiquement, presque tout le territorie du Kazakhstan, tandis que deux autres espèces sont locales et plus méridionales: l'une et l'autre sont mentionnées ici pour la première fois pour Kazakhstan. L'analyse morphologique préalable et les expériences d'accouplement montrent que *Latrodeetus tredecimguttatus* aussi bien que *Eresus niger* au Kazakhstan et à l'Asie Centrale sont des espèces collectives: dont la première se compose, au moins, d'une espèce différente de *L. tredecimguttatus* d'Europe et l'autre se compose, au moins, des trois espèces séparées.□*Latrodectus, Eresus, Stegodyphus, distribution.*

Chingis K. Tarabaev, Alexey A. Zyuzin, Andrey A. Fyodorov, Institute of Zoology, Kazakhstan National Academy of Sciences, Akademgorodok, 480032 Alma-Ata, Kazakhstan Republic; 19 March, 1993.

The genus *Latrodectus* (Theridiidae) and the family Eresidae have not been studied very much in Central Asia. Before 1950 only one *Latrodectus* species was known from the former territory of the U.S.S.R.–*L. tredecimguttatus* (Rossi), or 'karakurt'. Two years later, Spassky (1952) first reported *L. pallidus* O. Pickard-Cambridge from the western, desert regions of the Turanian zoogeographic province [=Turkmenistan territory]. Later Charitonov (1954) described the new subspecies *L. pallidus pavlovskii* from Turkmenistan (the so-called 'white karakurt'). Twenty years later Tystshenko and Ergashev (1974) found in Uzbekistan another black widow species, *L. dahli* Levi. Amongst the Eresidae, three species have previously been recorded: *Eresus niger* (Petagna), *E. tristis* Kroneberg and *Stegodyphus lineatus* (Latreille).

This paper deals with new collections and data relating to the two groups and species distributions. Also, we suggest that previous broad species concepts, especially within *L. tredecimguttatus* and *E. niger*, must be revised.

MATERIALS AND METHODS

This work is based on material collected mainly by us in Kazakhstan and Central Asia. Our specimens were compared with those from Europe and North Africa. Spiders were examined in 70% alcohol using binocular microscopes MBS-1 and MBS-10. Preliminary experiments on mating between European *L. tredecimguttatus* and Widows from Kazakhstan were also carried out.

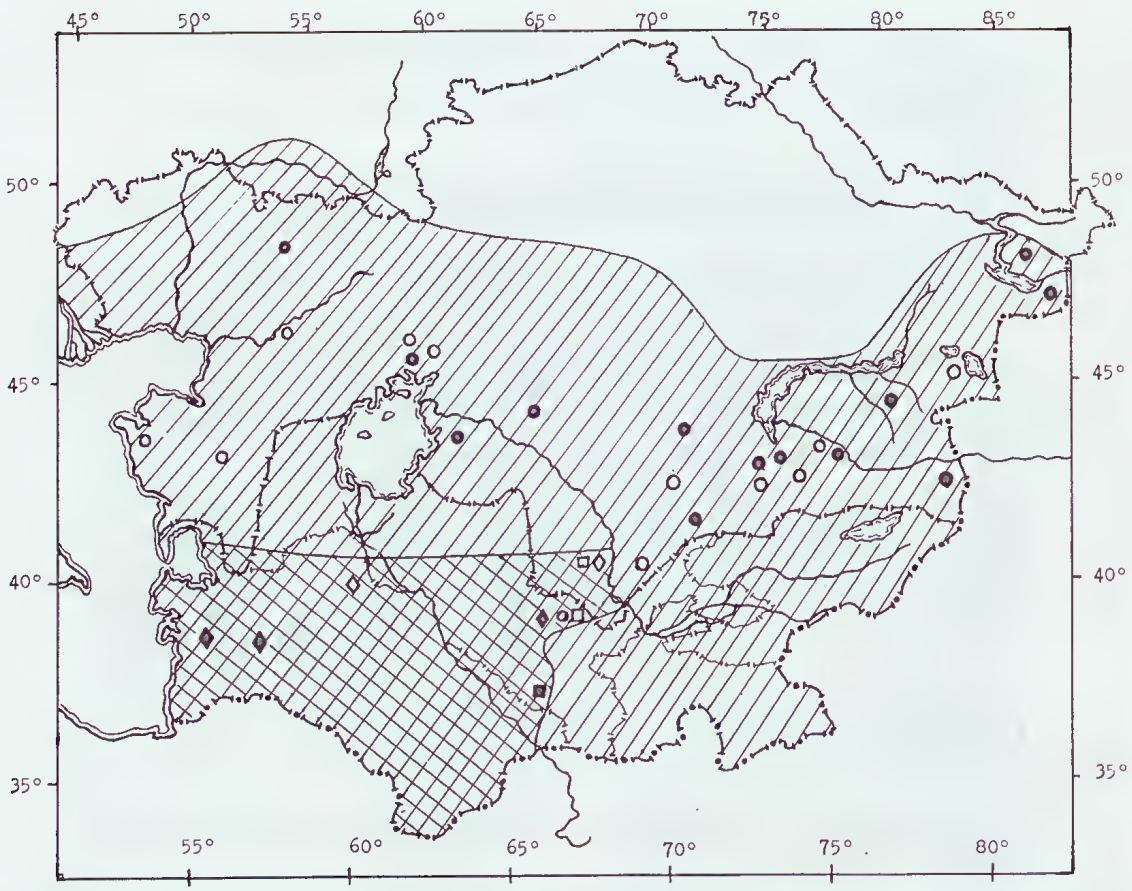

FIG. 1: Distribution of *Latrodectus* spp. in Kazakhstan and other Central Asian Republics. Legend: ○= *L. tredecimguttatus*; □= *L. dahli*; ◇ = *L. pallidus pavlovskii*; oblique hatching = distribution of *L. tredecimguttatus* after Marikovskij (1956); cross hatching = suggested distribution of *L. pallidus* within the distribution of *L. tredecimguttatus*. Black figures = published data; white figures = original data.

RESULTS AND DISCUSSION

FAMILY THERIDIIDAE

Latrodectus Walckenaer

REMARKS

The northern border of the widow spiders' distribution within the former USSR seems to pass near 52°N (Fig. 1).

Latrodectus tredecimguttatus (Rossi)
'Karakurt'

REMARKS

Within the former USSR this species has been known under the names *L. conglobatus* C.L. Koch, *L. erebus* Savigny and Audouin, *L. lugubris* Motchoulsky, *L. tredecimguttatus* var. *lugubris* (Dufour), etc. (Charitonov, 1932). Rossikov (1904) devoted a monograph to this species and Marikovskij (1956) analysed the biology and distribution of *L. tredecimguttatus* within the former USSR. According to this author, karakurts are found over almost all of Kazakhstan (Fig. 1). However, existing difficulties in the systematics of *Latrodectus* species (see Levi, 1983), as a rule, result in too wide an interpretation of their distribution. When investigating *Latrodectus* species, we found that adult females of *L. tredecimguttatus* from Italy had a light spotted abdomen while Kazakhstan specimens were completely black. Dr G. Schmidt (pers. comm.) considers the karakurt from Kazakhstan to be the species *Latrodectus lugubris* (Dufour) described from Egypt. Preliminary experiments on mating carried out in 1991 together with Mr D. Weickmann-Zwoerner (Germany) showed that

Kazakhstan specimens could not cross with European *L. tredecimguttatus* (two males from Kazakhstan were used).

At present the distribution of *L. tredecimguttatus* as delimited by Marikovskij (1956) must be revised, as we now suppose the traditional '*L. tredecimguttatus*' in Kazakhstan to be a separate species.

Material Examined

Italy: 3 ♀, Lazio, near Priverno, 16 May 1962, fields and stones, H. Levi (MCZ). Kazakhstan and Central Asia: many males and females from different localities (IZA).

Latrodectus dahli Levi

Remarks

This very localised species among the Central Asian republics occurs in Uzbekistan only (Tystshenko & Ergashev, 1974; Ergashev, 1990); in Kazakhstan, it was found by us first in the Kyzylkum Desert (two females, det. Dr Y.M. Marusik)(Fig. 1). We have compared our specimens with the female paratype of *L. dahli* from Iran and found their resemblance in the hairiness of the abdomen's dorsum (long slender spines and rather long setae between them: see also Tystshenko and Ergashev, 1974, fig. 3). Nevertheless, the epigynal opening in all our specimens is 4 times as wide as long, while in the female paratype it is only 3.4 times as wide as long; slight differences are also in the vulvae (cf. Levi, 1959, figs 11, 12; Tystshenko and Ergashev, 1974, figs 4, 5). As the male of *L. dahli* from the type locality is up to now undescribed, we cannot be sure that our specimens belong to real *L. dahli*.

Material Examined

Iran: 1 paratype ♀, Bushire, Persian Gulf (MCZ). Uzbekistan: 1 ♂, 1 ♀, Kashkadarja Area, Karshi Steppe, N.E. Ergashev. Kazakhstan: 2 ♀, South Kazakhstan Area, Kyzylkum Desert, 77.5k NW of Chardara Vill., 5-6 Jun 1989, Tarabaev, Fyodorov, Zyuzin (IZA).

Latrodectus pallidus pavlovskii Charitonov
(Fig. 1)

Remarks

Within Kazakhstan, it was found by us first in the Kyzylkum desert, which is probably its northernmost limit. To clarify the taxonomic position of *L. pallidus pavlovskii*, thorough comparison of our spiders with the type material or topotypes of *L. pallidus* is necessary.

Material Examined

Turkmenistan: 1♀, Tashauz Area, Shakhsenem, under *Artemisia*, 9 Oct 1983, O.S. Soyunov. Uzbekistan: 4 ♀, Dzhizak Area, 'Kyzylkum' state farm, 16 Jul 1982, N.E. Ergashev. Kazakhstan: 1♀, South Kazakhstan Area, Kyzylkum Desert near Tabakbulak Vill., 24 Aug 1991, A.A. Zyuzin, B.M. Gubin (1 ♂, 2 ♀ of Tabakbulak population in laboratory) (IZA).

Family Eresidae

Eresus Walckenaer

Eresus niger (Petagna)

Remarks

Published and original data on the distribution of this species within the Sibero-Kazakhstan-Central Asian region, in the European part of Russia (see Charitonov, 1932) and in Europe (see Bonnet, 1956) show that the northern limit of its area seems to pass near 56°N: thus, *E. niger* is theoretically distributed over the whole Kazakhstan and the Central Asian region. Preliminary analysis of material we have at our disposal show that at least three separate species of the '*Eresus niger*' complex occur in Kazakhstan (Fig. 2). The acute deficit of specimens of both sexes taken from the same place is the main obstacle to a detailed taxonomic study.

According to Merrett and Millidge (1992), the correct name for the species *Eresus niger* (Petagna) is *Eresus cinnaberinus* (Olivier) (see also Lehtinen, 1967, p. 233).

Material Examined

Eresus tristis Kroneberg

Remarks

According to published data, this species was previously found only in southern and South-Eastern Kazakhstan (Kroneberg, 1875; Spassky and Shnitnikov, 1937); beyond the borders of the former USSR, *E. tristis* was found only in China by G.N. Potanin's expedition: see Simon (1895), 'la riv. Sotschshan au N. de la chaîne du Tjan-Shan'. [Charitonov (1932) wrongly placed this site within the former USSR territory].

Males of *E. tristis* can be readily separated from those of *E. niger* by the black colour of their abdomen and legs (as in *E. niger* females), sometimes with white markings. Despite this very distinctive feature, *E. tristis* was recently synonymised with *E. niger* based on the similarity of their genitalia (see Nenilin and Pestova, 1986). However, our preliminary data showed sufficient differences of *E. tristis* from all of our 'red' males in the fine structure of the male palp; at the same time, black males from different parts of Kazakhstan and Central Asia have very similar palp structure. The main taxonomic problem is that the female of this species is up to now unknown.

Material Examined

Kazakhstan: 1 ♂ holotype, South Kazakhstan Area, 'Syrdarja, the end of April', A.P. Fedtschenko's Turkestan Scientific Expedition by the Natural History Amateurs' Society (ZMMU No. Ta 1104); 1 ♂, Alma-Ata Area, 5k NE of Kapchagaj City, A.A. Fyodorov (IZA).

Turkemistan: 3 ♂, Western Kopetdag Ridge, near Kara-Kala Vill., 7 Feb 1979, I. Morozova (ZISP). Tadzhikistan: 1 ♂, 'turn to Chashma, 9.V.1986, Itka' (BIN).

Stegodyphus Simon

Stegodyphus lineatus (Latreille) (=*Eresus arenarius* Kroneberg)

Remarks

This species was previously known from Turkmenistan, Uzbekistan and Southern Kazakhstan. We have found it considerably northwards and eastwards (Fig. 2).

Material Examined

Many males and females from: Spain; Italy (Sicily); Algeria; Tunisia (Kairouan) (MNHN No. AR 785, 786); different parts of Kazakhstan and Central Asian republics (see Fig. 2) (IZA).

ACKNOWLEDGEMENTS

For placing the necessary material at our disposal and for assistance in experiments we are grateful to: Prof. H.W. Levi (Cambridge, Massachusetts, USA), Drs D.V. Logunov, V.V. Dubatolov (Novosibirsk), K.G. Mikhailov (Moscow), V.I. Ovtsharenko (St. Petersburg) (all Russia), Ch. Rollard (Paris, France), and Mr D. Weickmann-Zwoerner (Weissenburg, Germany).

GEOGRAPHIC VARIATION OF THE NUMBER OF B-CHROMOSOMES IN *METAGAGRELLA TENUIPES* (OPILIONES, PHALANGIIDAE, GAGRELLINAE)

N. TSURUSAKI

Tsurusaki, N. 1993 11 11: Geographic variation of the number of B-chromosomes in *Metagagrella tenuipes* (Opiliones, Phalangiidae, Gagrellinae). *Memoirs of the Queensland Museum* 33(2): 659-665. Brisbane. ISSN 0079-8835.

Chromosomes of *Metagagrella tenuipes* (L. Koch) (Arachnida, Opiliones, Phalangiidae, Gagrellinae) were surveyed in 8 populations in Japan. Almost every individual examined had one or more (highest number per cell was 19) supernumerary or B-chromosomes, in addition to the basic set of chromosomes (2n=18). These B-chromosomes are heterochromatic, and during meiosis they appear to behave as univalents. The number of B-chromosomes varied both among and within populations. The number also fluctuated to some extent among cells from the same individual, suggesting nondisjunction at mitotic anaphases. No correlation could be elucidated between the number of B-chromosomes and external morphologies or habitat type. The number of B-chromosomes may affect growth rate, and in turn reduce the synchrony of breeding within a population.

Die Chromosomen von *Metagagrella tenuipes* (L. Koch) (Arachnida, Opiliones, Phalangiidae, Gagrellinae) wurden in 8 japanischen Populationen untersucht. Fast jedes überprüfte Individuum wies eines oder mehrere (die höchste Anzahl pro Zelle war 19) überzählige oder B-Chromosomen zusätzlich zum Standardchromosomensatz (2n = 18) auf. Diese B-Chromosomen sind heterochromatisch und scheinen sich während der Meiose als Univalente zu verhalten. Die Zahl der B-Chromosomen variiert sowohl zwischen als auch innerhalb von Populationen. Sie schwankt in gewissem Ausmaß auch zwischen Zellen aus ein und demselben Individuum, was auf Non-Disjunction bei mitotischen Anaphasen schließen läßt. Zwischen der Anzahl der B-Chromosomen und der äußeren Morphologie oder Habitattypen konnten keine Korrelationen gefunden werden. Es besteht die Möglichkeit, daß die Zahl der B-Chromosomen die Wachstumsrate beeinflussen und in der Folge die Synchronie der Fortpflanzung innerhalb einer Population reduzieren kann.□*Opiliones, Metagagrella tenuipes, Japan, B-chromosomes, geographic variation.*

Nobuo Tsurusaki, Department of Biology, Faculty of Education, Tottori University, Tottori 680, Japan; 29 October, 1992.

The harvestman *Metagagrella tenuipes* (L. Koch) is widespread throughout Japan but with a peculiar habitat and distribution pattern. In southern Japan, this opilionid is typically coastal. However, in northern Japan, it also occurs inland and prefers open habitats, e.g. parks and gardens, that are affected by moderate human disturbance.

During a chromosomal survey of this species, the number of chromosomes varied both within and among populations, with a range of 2n=18 to 36. Moreover, the number of chromosomes varied somewhat from one cell to another in almost all individuals. Close examination of mitotic and meiotic chromosomes revealed that the karyotype of this species is usually composed of 2n=18 standard chromosomes and one or more supernumerary or B-chromosomes, and that the latter cause the overall chromosome number to vary. Here, I will describe the karyotype, nature of the B-chromosomes, and pattern of geographic variation in the B-chromosome number.

MATERIALS AND METHODS

The specimens used for chromosome examination are listed (Table 1, Fig. 1). Cytological data were obtained from air-dried preparations of testes or ovaries of field-collected adults and penultimates. The technique used is described in Tsurusaki (1985) and Tsurusaki and Cokendolpher (1990). In some cells, patterns similar to C-bands were observed despite the fact that these cells had received no special treatment. In many individuals the number of B-chromosomes varied from cell to cell. In such cases, the chromosome number of each is represented by a modal number.

For two populations (Nakajima and Maruyama), lengths of femur I of the specimens used in the chromosome preparation were measured with an eyepiece graticule.

Detailed collection data on the specimens examined are listed in the appendix.

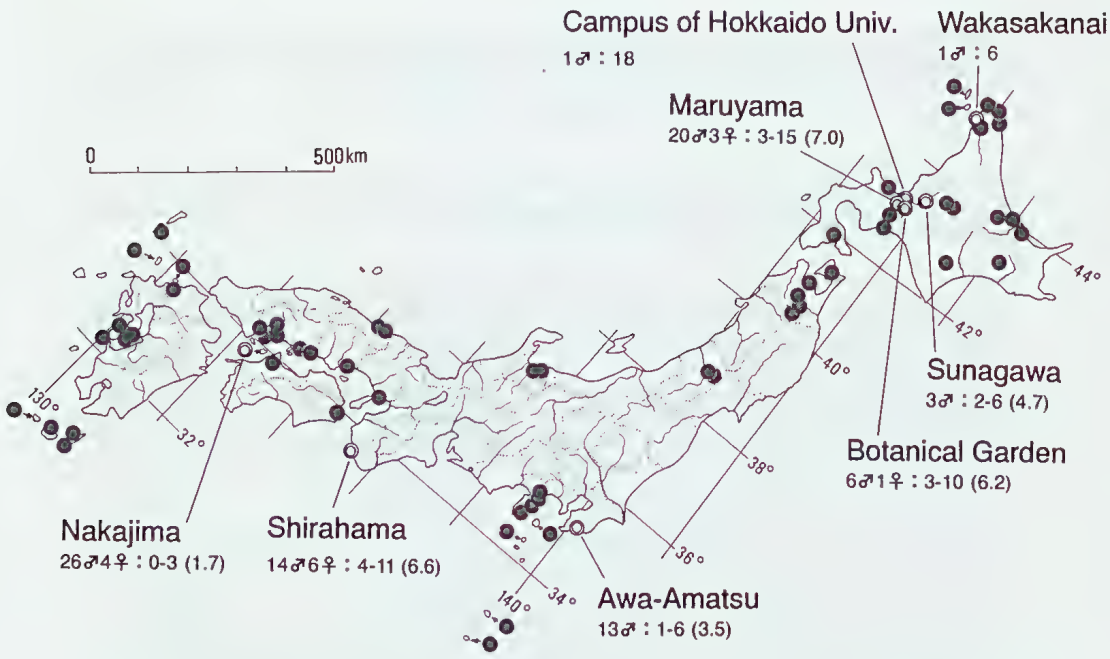

FIG. 1. Map of populations of *M. tenuipes*, Japan, used here (double open circles) with records compiled from literature (e.g. Suzuki, 1973; Suzuki and Tsurusaki, 1983) and data in the appendix (solid circles). No. of samples and range of B-chromosome number in each study population are shown, with means in parentheses.

RESULTS

Karyotypes and Nature of B-Chromosomes

The chromosome number of this species varied enormously among and within populations. From comparisons of the karyotypes of individuals with the lowest chromosome number, 2n=18, to those from others with 2n=19 and greater, and from analyses of both meiotic chromosomes and unintentionally obtained C-banded chromosomal spreads, the chromosome number of the standard karyotype, which consists of so-called A-chromosomes alone, was determined to be 2n=18 for both males and females (Figs 2-3).

1. Standard karyotype (Fig. 3)

Autosomes consist of 8 pairs of medium-sized metacentrics (Nos. 4 and 5), submetacentrics (Nos. 1, 3, 7, 8), and subtelocentrics (Nos. 2 and 6). The X chromosome, the largest, is subtelocentric, while Y is submetacentric and similar in size to chromosome No. 1. In C-banded mitotic metaphases, centromeric regions of the A-chromosomes were positively stained (Figs 4-5). No prominent differences were found among the

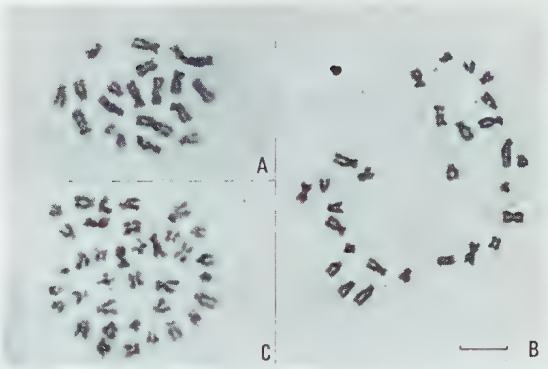

FIG. 2. Representative chromosome complements at spermatogonial mitotic metaphase of male *Metagagrella tenuipes*. A, Nakajima, 2n=18 (18A's); B, Maruyama, 2n=28 (18A's + 10B's); C, campus of Hokkaido Univ., 2n=37 (18A's + 19B's). Scale = 5μm.

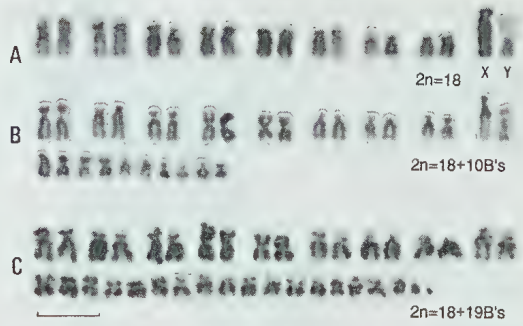

FIG. 3. Karyotypes of male *Metagagrella tenuipes* based on the photographs in Fig. 2. A, Nakajima; B, Maruyama; C, campus of Hokkaido Univ. B-chromosomes are arranged on the second row in B and C. Scale = 5μm.

standard karyotypes of individuals from various populations.

2. B-chromosomes

In addition to a set of standard chromosomes described above, almost all chromosomal spreads contained at least one B-chromosome. These were meta- or submetacentric, equal to or smaller than the shortest pairs (No. 8) of the A-complement (Fig. 3). In C-banded chromosome spreads, the B's were heteropycnotic, darkly staining along their total lengths (Figs 4-5). During meiosis, the B's remained univalent (Fig. 4-5) even when the cell carried 2 or more. The number of B's varied considerably from one cell to the other within a single individual, possibly due to nondisjunction at anaphase during mitosis.

Numeric variation in B's among individuals within populations was also evident (Fig. 6). No significant differences were found in the number of B's between the sexes from any population (Mann-Whitney U-tests for each of four populations where both sexes were sampled, P=0.48-0.96).

Geographic Variation in Number of B's

The number of B-chromosomes varied significantly among populations (single classification ANOVA: F=34.6; d.f.=7; P<0.001) (Figs 1 and 6, Table 1). The lowest and the highest population means of the number of B's were 1.7 for Nakajima (n=30) and 18 for the campus of Hokkaido University (n=1), respectively, and the means of the other populations lay between the two extremes, range = 3.5-7. However, no significant correlations could be detected between the number of B's and characteristics such as latitude (Spearmann's coefficient of rank correlation, r_s=0.19, n=8, P>0.05) and habitat types (seashore or inland: Mann-Whitney U-test, P>0.05).

DISCUSSION

Characteristics of the B-Chromosomes

According to Jones and Rees (1982), B-chromosomes have been reported in over 1000 species of plants and more than 260 species of animals. In Arachnida, however, only three species of Acari have been shown to have B's: *Aponomma fimbriatum* and two species of *Haemaphysalis* (Oliver and Bremner, 1968; Oliver *et al.*, 1974).

The B-chromosomes in *Metagagrella tenuipes* have the following characteristics that are typical for B's recorded in various other organisms (White, 1973; Jones and Rees, 1982; Werren *et al.*, 1988; Shaw and Hewitt, 1990; Jones, 1991): (1) they are smaller than most members of the A-complement; (2) they appear to be comprised of a large amount of constitutive heterochromatin; (3) they remain univalent during meiosis; (4) the number of B's varies from one cell to another even within an individual, indicating they display nondisjunction at anaphases of spermatogonial mitoses.

However, the frequency and the number of B's were rather unusual. In this species, every population sampled contained B's and the frequency within a population was up to 87% in Nakajima and 100% in the other 7 populations. The number of B's retained per individual of this species was also extraordinarily high; the population means had a range from 3.5 to 7 in 6 out of 8 populations

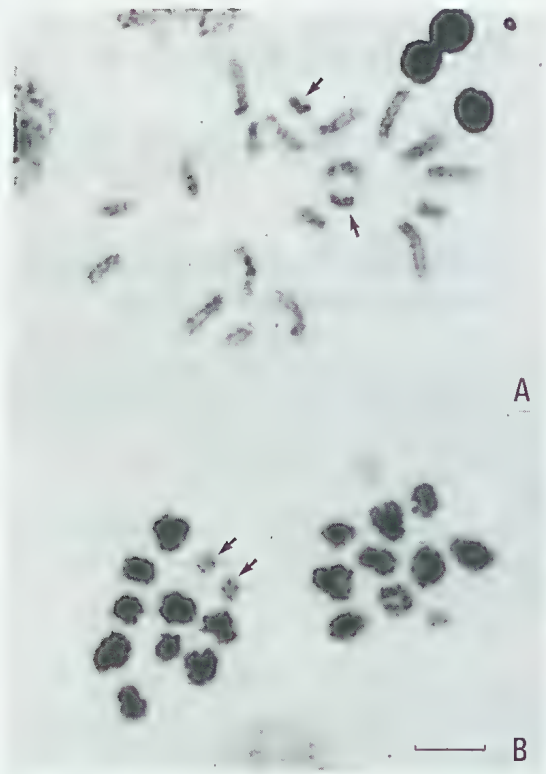

FIG. 4. C-banded mitotic metaphase (A) and meiotic metaphase I (B) in ♂ *M. tenuipes* from Sunagawa, with 2 B-chromosomes (arrowed). Scale = 5μm.

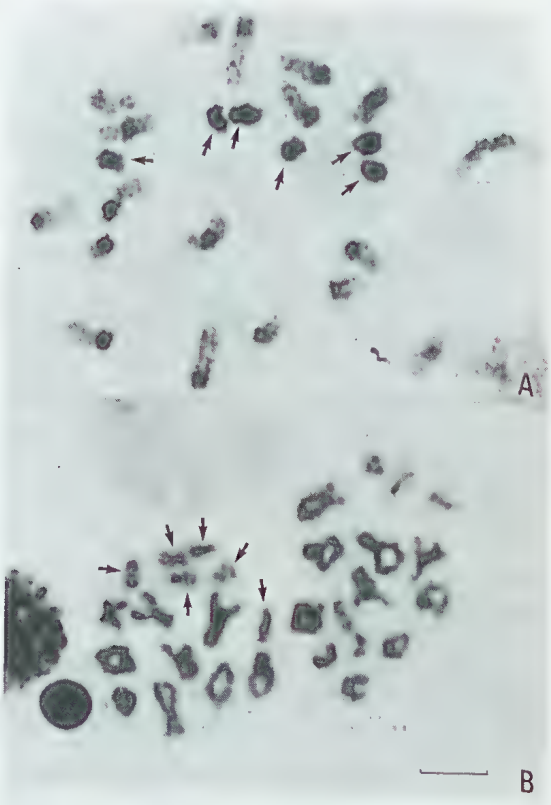

FIG. 5. C-banded mitotic metaphase (A) and diakinesis - metaphase I (B) in ♂ *M. tenuipes* from Maruyama, with 6 B-chromosomes (arrowed). Note: 9 bivalents formed by 9 pairs of A-complement of chromosomes. Scale = 5μm.

(Table 1). The higher end was found in the single male sampled from the campus of Hokkaido University, whose modal number of 18 B's was exhibited by 30 cells and the maximum number of 19 in 3 cells (Figs 2-3). These are among the highest numbers of B's in animal species so far recorded, close to the number 'about 20' in *Xylota nemorum* (Diptera: Syrphidae) (Boyes and Van Brink, 1967).

Effect of B's on Phenotype

Metagagrella tenuipes shows marked variation both among and within populations in external morphology, such as body size, leg lengths, degree of development of a spine on the dorsal scutum, number of noduli on the legs, and coloration of the body (Suzuki, 1973; Suzuki and Tsurusaki, 1983). However, no correlation was found between these characters and the number of B-chromosomes (Fig. 7). These facts are consistent with the observation that the B's are C-band positive. If these B's are indeed genetically inactive, numerical variation of B's would lead to no effect on the phenotype of their owner.

Although few studies have demonstrated any exophenotypic effect due to B's, some show a relationship between the number of B-chromosomes and the rate of development (Hewitt and East, 1978; Harvey and Hewitt, 1979). Thus, there is a possibility that the presence of B-chromosomes retards the cell cycle due to the additional DNA or its organization which is possibly different from A-chromosomes. In turn, these effects may influence the growth and development of the whole organism (Jones and Rees, 1982). Such influences might be related to an unusual feature of the life history of this species, namely, high variability among individuals in the time to reach maturity. The duration of coexistence of juveniles and adults of this species at Maruyama is estimated to be about three weeks, whereas it is less than 1-2 weeks in other species of opilionids having no B-chromosomes, such as *Oligolophus aspersus*, *Leiobunum japonicum*, and two species of *Nelima* from the same locality (Tsurusaki,

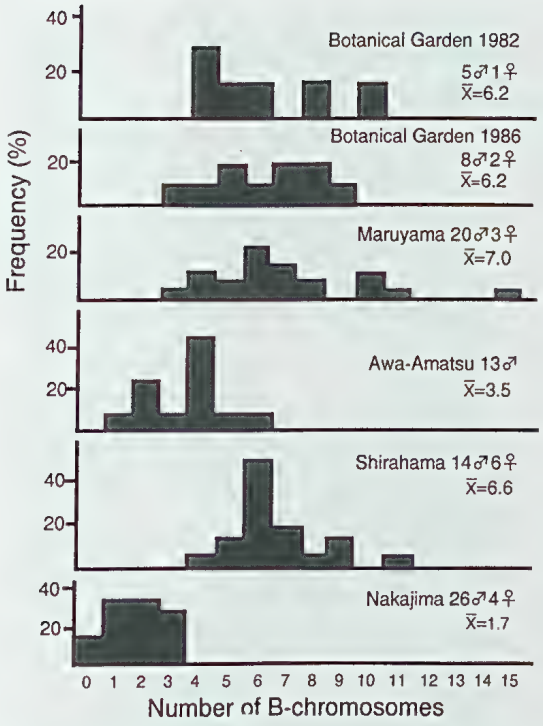

FIG. 6. Frequency distribution of B-chromosome numbers in 6 samples from 5 populations. The other 3 populations (Wakasakanai, Sunagawa, and campus of Hokkaido Univ.) omitted due to paucity of specimens surveyed.

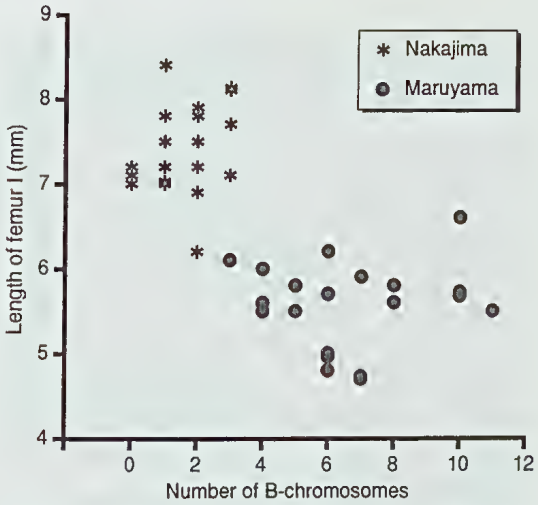

FIG. 7. Relation of length of femur I to number of B-chromosomes in 2 populations (Nakajima and Maruyama) of *M. tenuipes*. No significant correlation between 2 variables in each population [r = 0.305 (P>0.1) for Nakajima; r = 0.065 (P>0.1) for Maruyama], although both characters show prominent differences between two populations. Two variables may be negatively correlated (although spuriously) between populations. Leg lengths decrease with increase in latitude (Tsurusaki, unpubl.) but the number of B's does not.

unpublished data based on weekly field-collections made in 1979). The same phenomenon is also inferred from field-data from various localities all over Japan. This versatility in the timing of final molting of this species might be ascribed to the numerical variation of B-chromosomes. Further study is needed.

Geographic Variation in Number of B's

The fact that the B's are found in every population over a wide geographic range of this species indicates that they are of rather ancient origin. Marked morphological variation among the B-chromosomes also attests to their long evolutionary history. However, it is also possible that they might be produced *de novo* from the A-complement by recurring mutation.

Although B's appear widespread across the species range, the number of B's considerably varied among populations, with a fairly wide range from 1.7 at Nakajima to 18 on the campus of Hokkaido University. In each population, the number of B's may be stable for at least several years; there was no significant difference in their frequencies in the Botanical Garden at Sapporo which were sampled in 1982 and 1986 (Fig. 6). If B-chromosomes were inherited in a non-Mendelian manner, and were neutral in phenotypic expression, the frequency of B's would not be stable. For example, it might be expected that the crossing of a male with 3 B's and a female with 3 B's would produce some offspring with 4 or more B's. However, no individuals with more than 3 B's are found in Nakajima population. This indicates that some selection pressure limits the number of B's that one individual can retain in a particular population. It is still uncertain what factors determine the population mean and the range of the number of B's. However, this species may be useful in studying various aspects of B's and 'selfish' DNA, including the controversial issues on the level of selection discussed by Werren *et al.*, (1988) and Shaw and Hewitt (1990).

ACKNOWLEDGEMENTS

I would like to thank Dr. R.G. Holmberg of Athabasca University, Alberta, and two anonymous referees for useful comments and careful reviews that improved the manuscript. An abstract in German was kindly prepared by Dr. J.

Gruber of Naturhistorisches Museum Wien. Late Dr. T. Ito and the staff of the Seto Marine Biological Laboratory, Kyoto Univ. and Dr. S. Otsuka, Hiroshima Univ., provided facilities for chromosome preparation of the Shirahama population. The following persons kindly provided material used to map the range of *Metagagrella tenuipes*: Drs. Sk. Yamane (Kagoshima), A. Otaka (Hirosaki), N. Yoshida (Sapporo), Ms. T. Sato (Tokyo), and Messrs. T. Kuwahara (Wakkanai), T. Tanabe (Tokushima), K. Ishii (Gumma), H. Okada (Himeji), Y. Nishikawa (Osaka), N. Nunomura (Toyama), M. Yamashita (Iki). This work was partly supported by Grants-in-Aid nos. 63740434, 02854100, and 03740393 from the Ministry of Education, Science and Culture, Japan.

MATING BEHAVIOUR AND FEMALE SPERM STORAGE IN *PHOLCUS PHALANGIOIDES* (FUESSLIN) (ARANEAE)

G. UHL

Uhl, G. 1993 11 11: Mating behaviour and female sperm storage in *Pholcus phalangioides* (Fuesslin) (Araneae). *Memoirs of the Queensland Museum* **33**(2): 667-674. Brisbane. ISSN 0079-8835.

Females of *Pholcus phalangioides* do not possess receptacula seminis but store transferred spermatozoa in their genital cavity. The spermatozoa are embedded in glandular secretion that is discharged from two accessory glands situated in the posterior wall of the genital cavity. The gland cells belong to a complex type of class 3 cells according to the classification of Noirot and Quennedy (1974, 1991). With the sperm mass of a single copulation the females are able to fertilize several batches of eggs, although the sperm might be easily washed out with the passage of the first batch of eggs (Forster, 1980). Nevertheless, females allow repeated copulations. The first copulation usually took over an hour but subsequent copulations lasted only a few minutes, no matter whether the female mated with the same or with a different male. Copulations after egg-laying tended to be long. Male spiders might achieve reproductive advantage in copulating with any female they meet and females might have an interest in filling up their storage capacities.

Pholcus phalangioides Weibchen besitzen keine Receptacula seminis im üblichen Sinne, sondern speichern die während einer Kopulation übertragenen Spermien im Hohlraum des Uterus externus. Die Spermien werden dort in ein Sekret eingelagert, welches von zwei akzessorischen Drüsen produziert wird. Diese Drüsen befinden sich in der posterioren Wand des Uterus externus. Die Drüsenzellen sind nach einem Klassifikationssystem, das für epidermale Drüsenzellen von Insekten erstellt wurde (Noirot and Quennedy, 1974, 1991), einem komplizierten Typ der Klasse 3 zuzuordnen. Mit den Spermien, die während einer einzigen Kopulation übertragen wurden, können die Weibchen mehrere Eigelege befruchten (Uhl, in press a), entgegen der Annahme, die Spermien könnten während der ersten Eiablage leicht ausgewaschen werden (Forster, 1980). Die Weibchen lassen dennoch mehrere Kopulationen zu, wobei die erste Kopulation gewöhnlich über eine Stunde dauert, jede weitere Kopulation schon nach wenigen Minuten abgebrochen wird, unabhängig davon ob es sich um das selbe oder um ein neues Männchen handelt. Nach einer Eiablage lassen die Weibchen wieder lange Kopulationen zu. Für die Männchen mag es von Vorteil sein sich mit jedem Weibchen zu paaren dem sie begegen, und Weibchen könnten ein Interesse daran haben ihre Speicherkapazität voll auszuschöpfen. □*Araneae, Pholcidae, Pholcus phalangioides, sperm storage, glands, secretion, ultrastructure, repeated matings, copulation duration.*

Gabriele Uhl, Institut für Biologie I (Zoologie), Universität Freiburg i.Br., Albertstraße 21a, 7800 Freiburg i.Br., Germany; 28 October, 1992.

Most female spiders store sperm within storage structures that are spatially separated from the genital cavity. Some 'primitive' spider families such as Diguetidae, Liphistiidae, Archaeidae and Pholcidae retain the sperm mass within the genital cavity itself (Forster, 1980). Forster assumed that the bursal storage mode has little survival value as the sperm mass gets flushed out with the passage of the eggs and therefore, storing the spermatozoa in spatially separated storage structures would eliminate the need for repeated insemination. Despite the bursal storage mode, female *Pholcus phalangioides* (Fuesslin) are able to fertizile numerous batches of eggs with the sperm of a single insemination (Uhl, in press a). However, the females probably do not rely on the amount and fertility of the spermatozoa transferred during a single copulation. This would be risky as the spermatozoa might be defective or insufficient. I expect the females to fill up their storage capacity by means of repeated matings at least after egg-laying when few clumps of spermatozoa remain in the genital cavity after oviposition. However, if the female does not have the opportunity to copulate repeatedly, the stored spermatozoa can be sufficient for fertilizing following egg batches successfully. This study will also give a brief morphological account on the bursal storage mode in *P. phalangioides* and will present histological and ultrastructural findings on the glandular tissue that exudes its product into

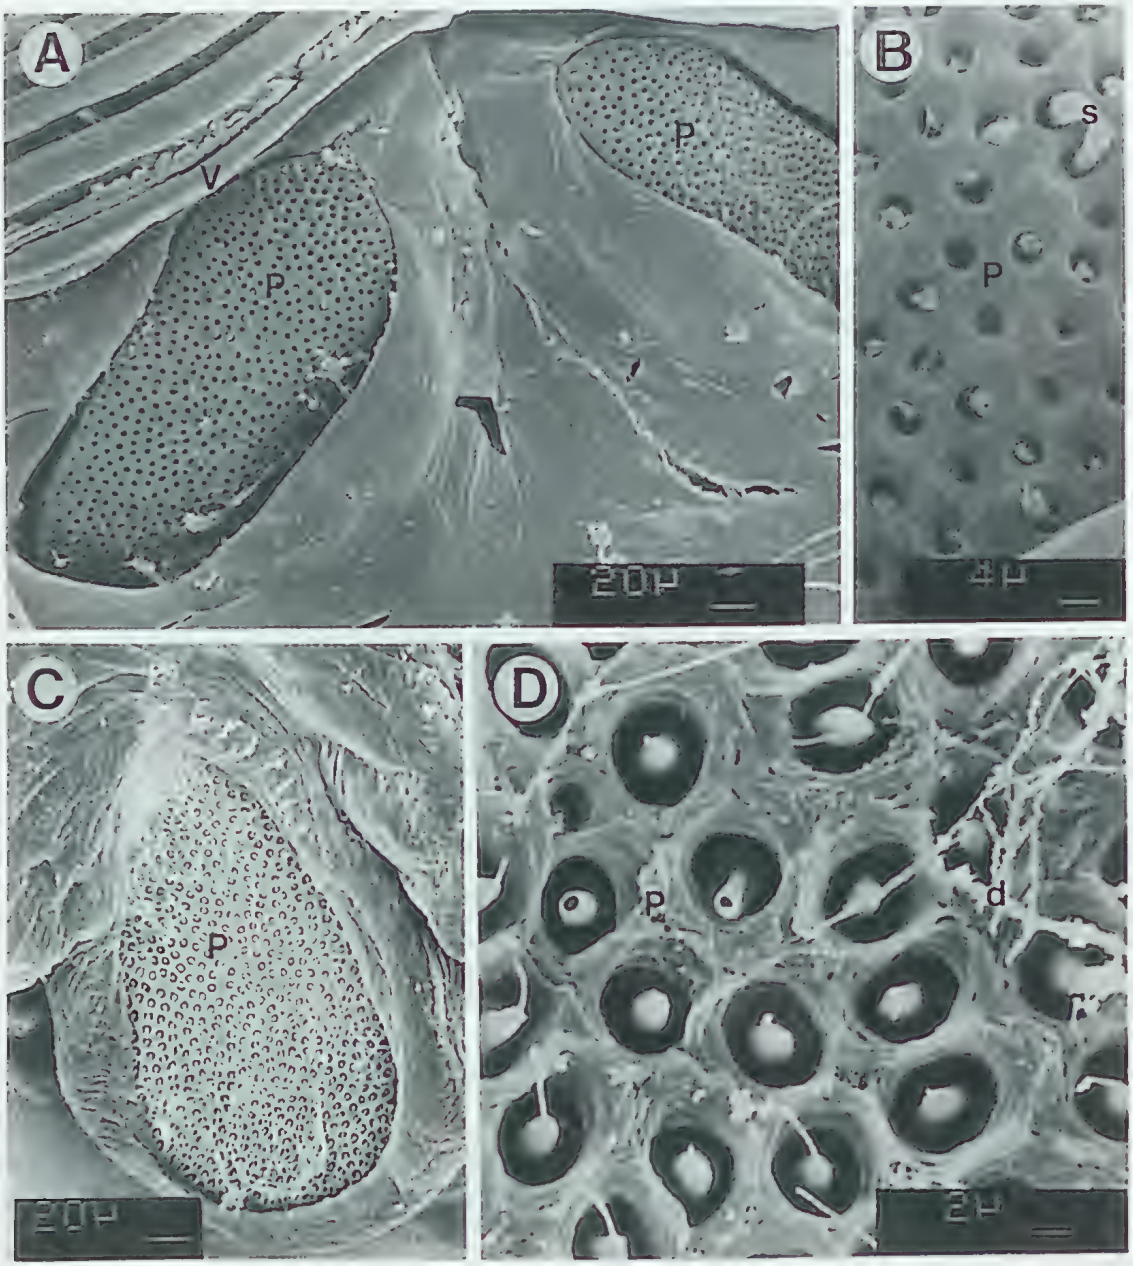

FIG. 1. Dorsal wall of genital cavity of *P. phalangioides*. A, Pore plates viewed from genital cavity; B, Pores that exude secretion, C, One pore plate from its dorsal side, glandular tissue removed; D, cuticular ductules of accessory glands.

the genital cavity for sperm storage. For more detailed information see Uhl (in press b, c).

MATERIAL AND METHODS

Juvenile *Pholcus phalangioides* were reared individually in the lab. To investigate mating behaviour the spiders were kept in couples in plastic boxes (16.5x9x6.5cm) and their behaviour was recorded day and night on video tape.

Five different experimental set-ups were used in order to answer the indicated questions:

1. Duration of copulation: Virgin females were offered unexperienced males.

2. Copulation duration with sperm-depleted males: Virgin females were offered recently experienced males (1/2 hour after termination of copulation).

3. Repeated matings with same partner: Previously virgin females were kept with previously unexperienced males for up to 20 days.

4. Repeated matings with changing partner: 1/2 hour after their first copulation females were offered unexperienced males.

In order to check the influence of box-size on mating behaviour 4 experiments were carried out using 2.5 times bigger boxes (18x12x11.5cm).

5. Duration of copulation after egg-laying: Post-oviposition females that had mated once were allowed to copulate again with unexperienced males.

For SEM studies adult females were anaesthetized, dissected and fixed in 70% ethanol or Bouin. In order to investigate the sclerotized parts of the female genital tract, the female genitalia were put in 5% NaOH solution until the soft parts were dissolved. Some genitalia were opened or cut with a sharp razorblade to locate the sperm mass in the genital cavity. They were dehydrated in ethanol, CP-dried, sputter coated with gold and examined in a Zeiss Semco Nanolab 7.

For light- and electron microscropy the spiders were anaesthetized and dissected in glutaraldehyde. After fixation in 2% osmium tetroxide/-glutaraldehyde, they were post-fixed in osmic acid (modified after Franke *et al.*, 1969), dehydrated in graded series of alcohol followed by propylene oxide and embedded in Epon. The semithin sections (0.7-1μm) were cut with glass knives on a Reichert OmU3 and stained with toluidin. Ultrathin sections were cut with glass knives and diamond knife. They were stained with uranyl acetate, counterstained with lead citrate and examined in a Zeiss EM9 electron microscope.

RESULTS

Mating Behaviour

1. Virgin females copulated with unexperienced males over an hour ($\bar{x}$=64.5 minutes; sd= 26.6; shortest duration: 16 min, longest duration: 122 min; n=42). This supports findings of Reagan and Reagan (1989) who investigated 104 pairs (mean copulation duration: 72.3 min; sd=43.3; shortest: 10 min, longest: 304 min).

2. Five males that had mated with virgin females (long copulation I) were brought half an hour after copulation to another virgin female. All copulations were long ($\bar{x}$: 56.8 minutes). The males probably refill their copulatory organs prior to the second copulation. The filling was observed in only one case by chance and was not detectable on the video recording.

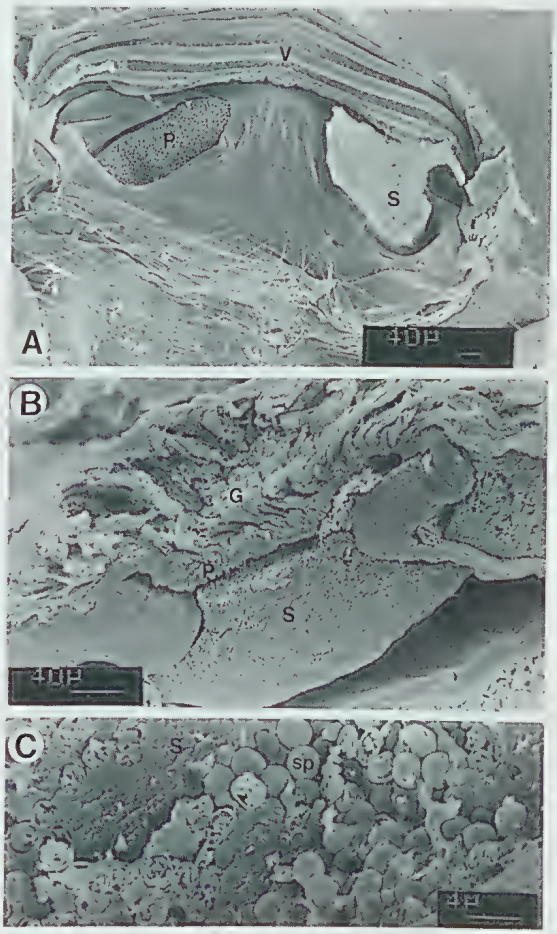

FIG. 2. A, Genital plate flipped back, dorsal wall of genital cavity revealed. Two pore plates, one concealed by secretory 'plug'; B, secretory 'plug' in genital cavity cut sagittally; C, Sperm mass in female secretion in female genital tract.

3. Unexperienced males and females were kept in pairs up to 20 days. Six females out of 12 allowed copulation from time to time: one female copulated twice, four females copulated 3 times, one female copulated five times. The second and the following copulations were always very short, they took only 2 to 5 minutes. Copulation duration tended to decrease in successive matings.

4. Unexperienced males were brought to females that had already mated once (long copulation I). In 9 of 14 cases the females allowed

Experimental set-up	n	Copulation duration (min.)
1. Virgin ♀ with unexperienced ♂	42	64.5 (16-122; 26.6)
2. Virgin ♀ with recently experienced ♂	5	56.8 (37-75; 13.9)
3. Second copulation with same ♂	6*	3.6 (2-5; 1.02)
4. Second copulation with unexperienced ♂	9*	2.6 (1.5-5; 1.0)
5. Post-oviposition ♀ with unexperienced ♂	7	59.6 (21-103; 31.4)

TABLE 1. Mating behaviour in *P. phalangioides* as a function of female reproductive history.* Only cases of copulation given. Range and standard deviation in parentheses.

further copulation. Again, second copulations lasted only a few minutes (1.5-5 min). Control experiments using bigger boxes showed that 3 females out of 4 allowed repeated matings (4.5; 2; 1 + 1 min).

5. Seven females that had mated once (long copulation I) and were kept separately afterwards, had access to males after oviposition. Copulation duration was long.

Copulation duration seems to depend on the reproductive history of the females (Table 1).

The Genital Cavity

The dorsal (posterior) wall of the genital cavity is characterized by two oval pore plates (Fig. 1A). The pore plates converge in direction of the ridges and grooves that make up the heavily sclerotized valve which separates the genital cavity from the oviducts. Both plates are perforated by pores of 3-5μm in diameter (Fig. 1B). The pores are in contact with gland cells that exhude their glandular secretions into the cavity (Fig. 1B).

The tissue-free pore plates reveal the canal zones of the glandular tissue when looked at from their dorsal side (Fig. 1C). Situated in cavities, cone-shaped hollow structures are apparent (Fig. 1D). These are the distal regions of the canals that open into the uterus externus as the pores of the pore plate. Proximally the canals change into thin ductules that exhibit a rough surface after 6-10μm (Fig. 1D).

Sperm Storage

The accessory glands discharge their products through the pores of the pore plates into the genital cavity and form two portions of secretory 'plugs'. (Fig. 2A). During copulation, the male transfers sperm mass into the female secretion (Fig. 2B). The spermatozoa are surrounded by individual secretory envelopes, they are coiled and inactive (Fig. 2C).

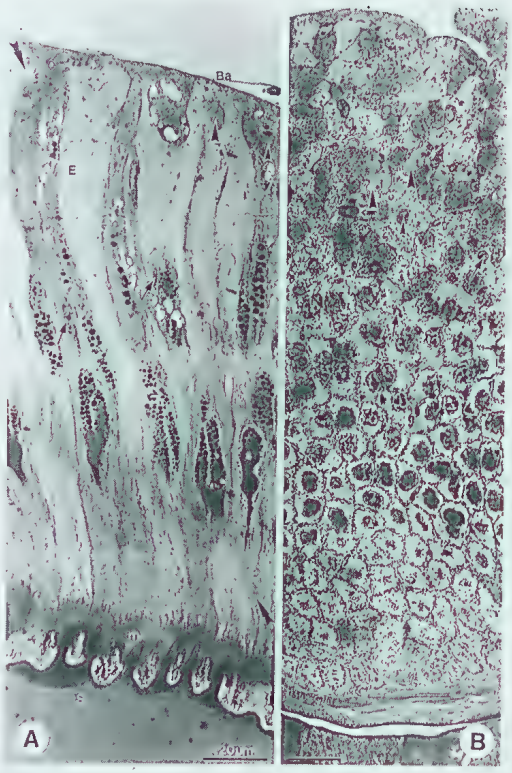

FIG. 3. Semithin section of accessory glands. A, Longitudinal section. Arrows mark nuclei of different cell types. Arrows and stars mark nuclei of different cell types. Scale lines: 20μm.

The Accessory Glands

The glandular tissue is composed of highly elongated cells (Fig. 3). Different cell types form the gland with various nuclei at different levels (Fig. 3A). The gland consists of lightly stained cells whose nuclei lie close to the basal lamina, and densely stained cells with more distal nuclei. Nuclei of other cell types lie mainly in the centre.

Secretory vesicles are apparent in the densely stained cells (the gland cells G). Accumulations of such vesicles are found in the apical second third of the glandular tissue. Each accumulation forms two portions of tightly packed secretory globules that discharge their contents into a common reservoir which is homogeneously coloured (Fig. 3A, B).

Bordering on the gland's orifices is a zone of

greyish coloration that is formed by the light coloured cells (outer envelope cells E2).

Histology and ultrastructure show that the glandular tissue includes many similar units, each provided with a cuticular ductule that leads to the pore plate (Fig. 3A). Each unit comprises two gland cells and two envelope cells. The two gland cells (G1, 2) join each other to form a common reservoir (Fig. 4, 5B). They are rich in granular endoplasmic reticulum (Fig. 5A), mitochondria and dense secretory vesicles and exhibit numerous golgi complexes in the supranuclear region. The vesicles vary in size (up to 1.5μm in diameter) and get more numerous in the distal cell region. They are enclosed in a close-fitting membrane which is obscured by the matching density of the mature granula. The inner envelope cell (E1) surrounds and partially separates the two gland cells (Fig. 5B, C, D) and forms the proximal part of the ductule (Fig. 4C). The outer envelope cell (E2) surrounds all of the previously mentioned cells. Its cytoplasm is poor in organelles (Fig. 5A, B, D). It produces the distal part of the ductule and forms numerous microvilli that gather round the ductule and the orifice (Fig.5E) and represent the greyish zone visible in the semithin section of Fig. 3A.

The gland cells and the outer envelope cell form a so-called basal labyrinth adjacent to the basal lamina (Figs 4, 5A). The glandular units are separated from each other by elongated epithelial cells.

DISCUSSION

The glandular units of the accessory glands in *P. phalangioides* belong to class 3 cells (Noirot and Quennedy, 1974, 1991). According to that classification, a gland cell is associated with a cuticular ductule that has been secreted by a 'canal' cell. In *P. phalangioides* however, there are two gland cells that are always connected by a common microvilli region, one inner and one outer envelope cell that form a double ensheathing of the gland cells. Moreover, both envelope cells take part in producing the canal that leads to the pore plate. Therefore, the glands studied here belong to a complicated type of class 3 cells.

There is some information on gland structures in female spider genitalia. The glands of the receptaculum seminis of Telemidae belong to class 1 type of gland cells (Lopez and Juberthie-Jupeau, 1983), and in some Theraphosidae De Carlo (1973) stated a class 1 composition. However, the light microscope study of Kovoor (1981) indi-

cates that a more complex gland composition as in *P. phalangioides* might not be exceptional.

The glandular units of *P. phalangioides* could function as a two-component-system, as the outer envelope cell shows conspicuous microvilli that surround the orifices of the ductules. This indicates secretory activity although the outer envelope cell contains no stainable secretory droplets or granules. Their product could have got lost during fixation or, the cells produce and release their product only on demand. Not all the secretory activities of cells are accompanied by microscopically detectable accumulation of the product in the cytoplasm. Apart from that, the outer envelope cell exhibits a basal labyrinth. It contributes to enhance the exchange of molecules between the haemolymph and the cells (Berridge and Oschmann, 1972) and characterizes active cells that take up or transfer material from or to the haemolymph.

The glandular secretions might serve various functions such as nutrition of the sperm (Coyle *et al.*, 1983; De Carlo, 1973; Engelhardt, 1910; Forster, 1980), pheromone production (Kovoor, 1981) or sperm displacement from the spermathecae into the genital cavity during oviposition (Forster *et al.*, 1987; Lopez, 1987; Lopez and Juberthie-Jupeau, 1983). Brignoli (1976) and Lopez and Juberthie-Jupeau (1983) considered activation of sperm prior to fertilization. The glandular tissue might be responsible for triggering activation via a secretory product that gets released exclusively before oviposition. Further, the females might achieve advantages from resorbing the sperm mass out of the genital cavity.

I consider the secretion in the female genital tract of *P. phalangioides* serves primarily as a depot for the sperm that guarantees successful storage as the onset of the female receptivity corresponds with the time needed to fill the genital cavity with glandular secretion (Uhl, in press a). Concerning any other possible functions, specific investigations are still lacking.

The bursal storage mode is considered a 'primitive' mode with little survival value as the spermatozoa are liable to be washed out during oviposition (Forster, 1980). Nevertheless, females of *P. phalangioides* succeed in producing several fertile batches of eggs after a single mating (Uhl, in press a).

Although females do not depend on repeated insemination, they allow further copulations. These always last only a few minutes in constrast to the first copulation that lasts over an hour and there is no apparent difference in copulation duration between second copulations with the same or with a different male. If new males are able to replace sperm of a previous male, longer copulations would be expected. Such short copulations may suggest that males are able to assess female virginity or reproductive history during insertion of their palpal structures and then decide on further investment of time and energy.

It has yet to be investigated whether successive copulations result in a transfer of spermatozoa at all, which will also give information on sperm precedence. Provided they transfer sperm and fertilise at least some eggs, it would be advantageous for males to mate with any female they meet. The females, on the other hand, can be expected to fill their storage structure with as many spermatozoa as possible to achieve the highest possible reproductive success. Depending on the amount of sperm already accumulated in the genital cavity females might allow further copulations and hence, decide on copulation duration. Indeed, there is some evidence that the female terminates copulation.

ACKNOWLEDGEMENTS

I wish to thank my supervisor Prof. Dr. P. Weygoldt (Freiburg) for making this work possible. Dr. M. Schmitt (Bonn) and two anonymous referees gave helpful comments on the manuscript. Without a grant from the Studienstiftung des Deutschen Volkes and additional support from the Organizing Committee participation at the XIIth Congress of Arachnology, Brisbane would have been impossible.

THE BIOLOGY OF SPIDERS AND PHENOLOGY OF WANDERING MALES IN A FOREST REMNANT (ARANEAE: MYGALOMORPHAE)

GRAHAM F.C. WISHART

Wishart, G.F.C. 1993 11 11: The biology of spiders and phenology of wandering males in a forest remnant (Araneae: Mygalomorphae). *Memoirs of the Queensland Museum* 33(2): 675-680. Brisbane. ISSN 0079-8835.

Eight syntopic mygalomorph species, four of one genus, are recognised as inhabitants of a small remnant forest. Over six years 1,207 mature males were trapped and collected from a nearby home swimming pool and the wandering times of mature males of the species are compared. The population density within the forest is estimated. It is suggested the high number is because of an 'edge effect' supported by a reduction in predator numbers, an 'island effect' and that mygalomorphs have low dispersion powers, long life cycle and sedentary life style.□*Mygalomorphae, Hadronyche, Misgolas, Stanwellia, community, forest, remnant, phenology, population, syntopic, wandering.*

Graham F.C. Wishart, 'Scalloway', Willowvale, Gerringong, New South Wales 2534, Australia; 23 November, 1992.

Phenological studies of spiders commonly consider the distribution and abundance of species in relation to habitat variation or disturbance (Peck and Whitcomb, 1978; Koch and Majer, 1980). Studies of male spider wandering patterns are less common and are usually associated with taxonomic revisions of particular groups (Coyle, 1971; Raven, 1984). Main (1982) synthesised male wandering data for her studies of arid zone spiders.

This paper presents male wandering patterns over a six year period for six species of syntopic

FIG. 1. Aerial view, easterly aspect, from study site towards Gerringong township.

FIG. 2. Aerial view, south-westerly aspect, of study site. Pool length is 10m.

forest mygalomorphs and also discusses possible ecological effects which could account for the viability of the spider population. The long term data gathering was enabled by the serendipitous location of an in-ground swimming pool acting as a large pit-fall trap close to remnant forest.

STUDY AREA

The study site is on the property 'Scalloway' (34°44'11"S, 150°47'23"E) (Figs. 1, 2), near Gerringong, N.S.W., and is a remnant piece of marginal Complex Notophyll Vine Forest (Bywater, 1978) at an altitude of 110m. It is a fragment (ca 95m x 55m) of the original 'Illawarra Scrub', varying forest types which occupied much of the coastal strip east of the escarpment in South Eastern Australia between the towns of Stanwell Park in the North and Bomaderry on the Shoalhaven River in the south, a distance of 75km. Land clearing removed over 80% of this original vegetation (Fuller and Mills, 1985) and took place mainly between 1850 and 1910, the remnants being restricted to land unsuitable for grazing because of steep gradients and rock outcrops.

The forest overstory includes the trees *Syncarpia glomulifera* and *Alphitonia excelsa* and several vine species forming a discontinuous canopy at a height of about 12m. The understory consists mainly of the small tree *Commersonia fraseri* and the exotic woody scrambling shrub *Lantana camara*. *L. camara* intrudes within the forest but is dense and extensive around the forest edge (not allowed for in the forest dimensions) preventing the entry of cattle.

The site is on the edge of a ridge and slopes rapidly downwards to the north east. The soil is of volcanic origin. The surface soil is thin and spread over a basalt bedrock. Large but moveable rocks are prolific. Leaf litter is ca 5cm deep.

METHODS

Wandering mygalomorph spiders trapped in a 10m long swimming pool 15m from the forest edge were collected daily from 1 July 1985 to 30 June 1991. Variables possibly affecting the numbers of spiders trapped, such as domestic lighting, maintenance of grounds and ability of different species to wander further or more quickly than others, were not taken into account. For three years from 28 August 1986 to 25 October 1989 the burrows within a plot 1.5m^2 were examined weekly.

RESULTS

Community Composition

Mature males of eight species of mygalomorph spiders were collected from the pool, viz.: *Misgolas hubbardi* Wishart, 1992 (Idiopidae), *M. dereki* Wishart, 1992, *M. kirstiae* Wishart, 1992, *M. robertsi* (Main and Mascord, 1974), *Hadronyche* sp. (Illawarra group) and *Atrax* sp.

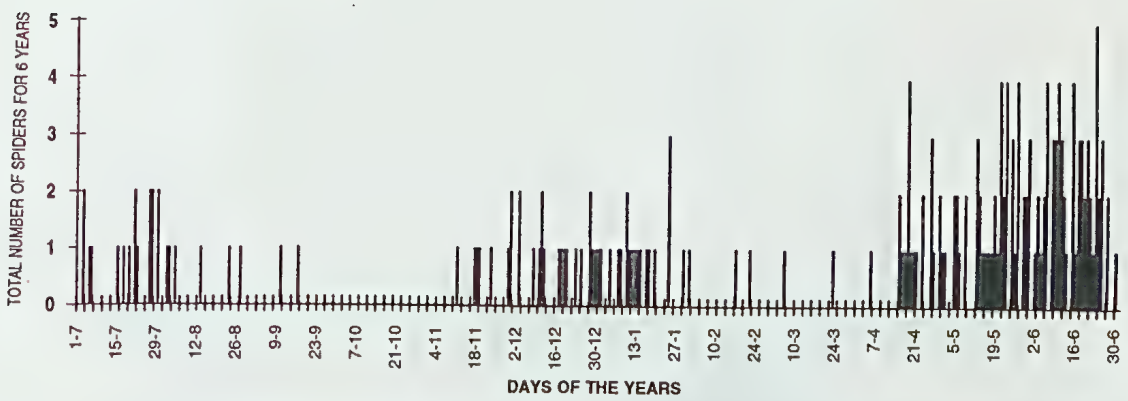

FIG. 3. Total number of *Misgolas hubbardi* captured on same days of years for six years from 1.7.85 to 30.6.91.

(Hexathelidae), *Stanwellia hoggi* (Rainbow, 1914) (Nemesiidae), and *Kiama lachrymoides* Main and Mascord, 1971 (Cyrtaucheniidae). The *Hadronyche* sp. is that referred to as *Hadronyche* sp. 20 by Gray (1987). The *Atrax* sp. is smaller but similar morphologically to *A. robustus* Cambridge, 1877. It differs also in that males wander from October to December whilst those of *A. robustus* wander mainly in January (Gray, 1986). They are considered here to be different species.

Population Density

Because much of the surface area of the forest floor is covered by large rocks and occupied by trees the 1.5 m^2 plot cannot be representative of the whole forest area. However, an extrapolation (based on the assumption that the ratio of the number of burrows occupied by all mature female spider species to the number of burrows occupied by *M. hubbardi* is equivalent to the ratio of the number of captured mature male spiders of all species to the number of captured mature male spiders of *M. hubbardi*) indicates there should be 41 mature female mygalomorphs per m^2 in the 1.5m^2 plot.

In the 1.5m^2 plot the maximum number of burrows counted at one time was 55. These included open burrows, those known to exist but temporarily sealed and very small open burrows of which most failed to persist. There were 27 burrows larger than 8 mm in diameter of which 10 were each occupied by a mature female *M. hubbardi*. Due to physical limitations in accurate-

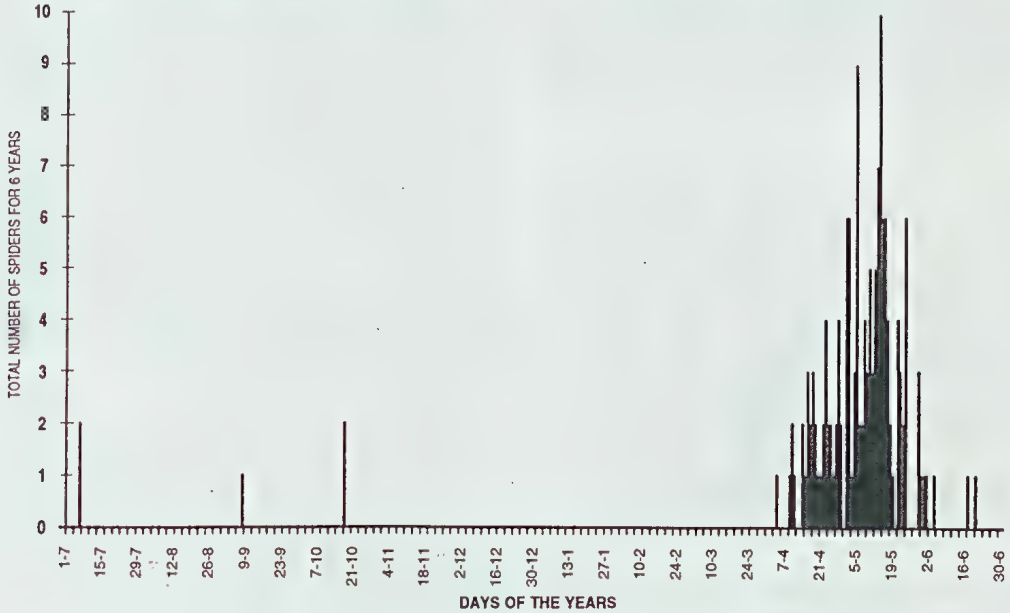

FIG. 4. Total number of *Misgolas dereki* captured on same days of years for six years from 1.7.85 to 30.6.91.

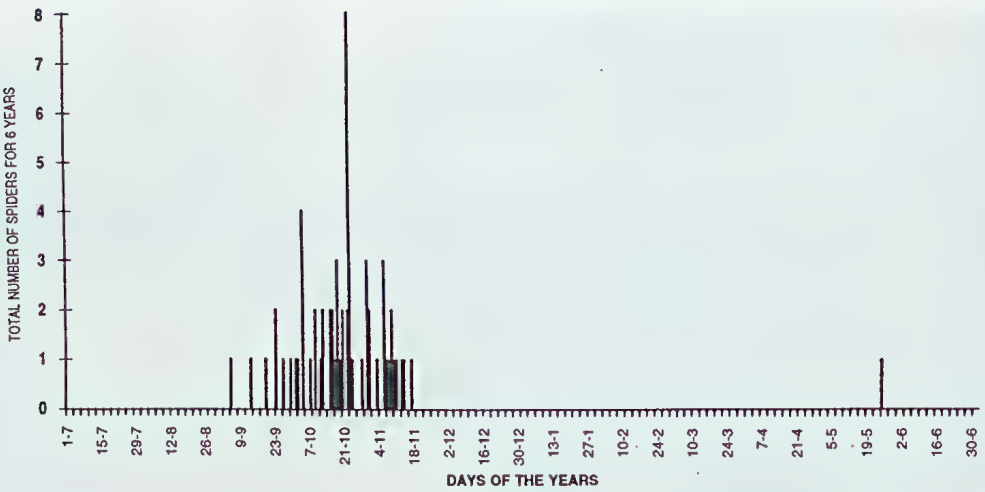

FIG. 5. Total number of *Misgolas kirstiae* captured on same days of years for six years from 1.7.85 to 30.6.91.

ly counting small burrows and recognizing the presence of the burrows of *M. kirstiae* and *Hadronyche* sp. the total count must fall short of the actual mygalomorph population.

PHENOLOGY OF WANDERING MALES (Table 1)

Wandering mature males of *M. hubbardi* were found almost throughout each year (Fig. 3). The extensive wandering period of *M. robertsi* is interrupted during January and February when the frequency of capture is reduced (Fig. 6). The wandering period for *S. hoggi* is also long, extending over six months (Fig. 8). As is customary to expect of male mygalomorphs, the wanderings of *M. dereki* (Fig. 4), *M. kirstiae* (Fig. 5) and *H.* sp. (Fig. 7) are restricted to short and more precise annual periods. The collections of *Atrax* sp. and *K. lachrymoides* were too small for deductions to be conclusive.

During the six year period, 11 female *S. hoggi* were also trapped in the pool during the months from March to October.

TABLE 1. Summary of numbers and timing of male spiders trapped in pool from 1 July 1985 to 30 June 1991.

DISCUSSION

No previous reports have been found of either eight species of mygalomorph spiders or four species of one genus (*Misgolas*) of spiders existing elsewhere syntopically or sympatrically.

The high proportion of mature female *S. hoggi* collected is surprising, 11 females to 26 males, and 10 of the 11 were taken at times coincidental with the male wandering period. The number reflects the long-legged, male-like morphology of the female adapting it to roam. Further, that only one male *K. lachrymoides* was collected may indicate the inability of the male of this species to wander a long distance a reflection in this case of the male's short-legged female-like morphology. The usual sexual dimorphism of mature burrowing mygalomorph spiders (female bulky, stout legged; male less bulky, long legged) is contradicted in these two species.

Some possible reasons for the dense mygalomorph spider population are offered. First, predators of mygalomorph spiders may have become extinct in the area following human settlement. For example, the bandicoot (*Perameles nasuta* Geoffroy, 1804), reputed to be a mygalomorph spider predator (Main, 1976; Preston-Mafham, 1984) and once very common in Willowvale, has been rarely seen by the author and not at all for 15 years. Here then, possibly, is

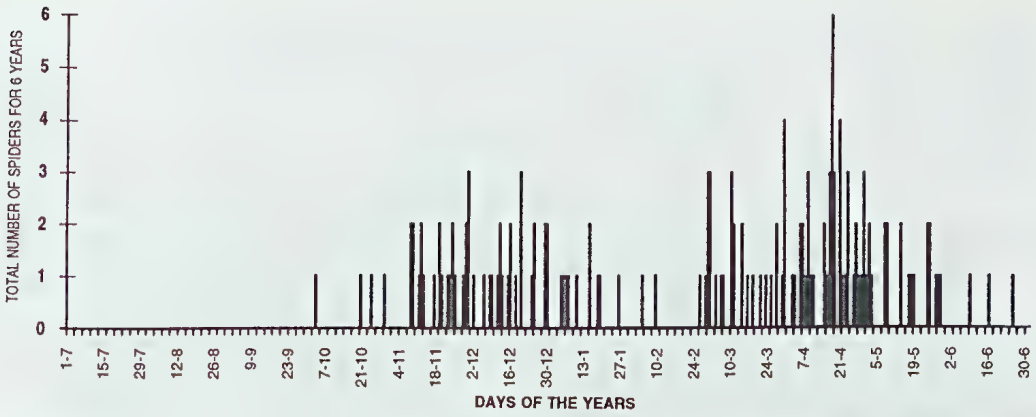

FIG. 6. Total number of *Misgolas robertsi* captured on same days of years for six years from 1.7.85 to 30.6.91.

a paradox where habitat destruction and the introduction of feral animal pests, may increase, not decrease, mygalomorph spider numbers by decreasing spider predators.

Second, the concentration may result from an 'Island Effect' where it is found that the population of an individual species can be far greater than expected when the species is insulated within a small ecological system (separate pers. comms, M.Gray and R.Raven). Also Main (1987) proposed that mygalomorphs are admirably fitted to persist in small isolated areas because of their low dispersion powers, long life cycle and sedentary life style.

Finally, in a larger (ca. 300 ha) forest with complete canopy and separated from the 'Scalloway' site by *ca.* 400m of pasture land there is a paucity of mygalomorph spider burrows and few insects suitable for prey. Burrows are more common near the forest edge, and so too is insect life with grasshoppers, moths and crickets prolific. Because the 'Scalloway' forest remnant is small it is in effect a forest edge throughout with an abundance of suitable prey. Laurence (1991) states, 'In the tropics, forests near edges exhibit striking changes in microclimate, vegetation structure and composition, disturbance regimes, and invasions of species from adjacent habitats. Thus, in fragmented systems, species that tolerate edge conditions are often favoured'. I suggest that this is the explanation for the presence of this dense mygalomorph population.

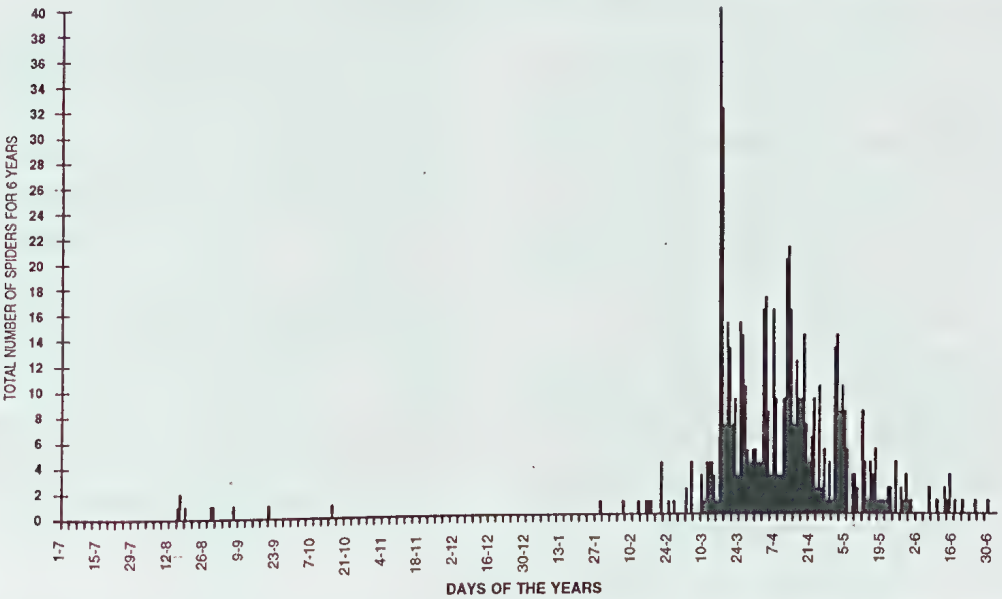

FIG. 7. Total number of *Hadronyche* sp. captured on same days of years for six years from 1.7.85 to 30.6.91.

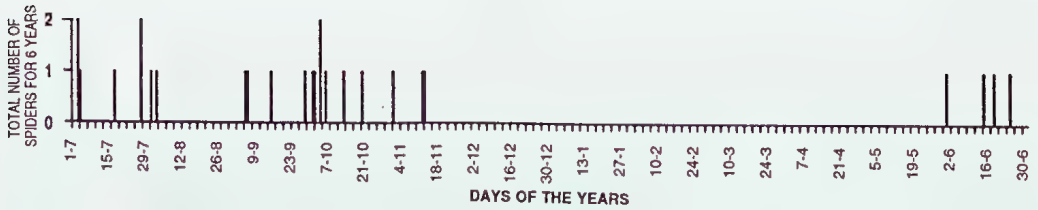

FIG. 8. Total number of *Stanwellia hoggi* captured on same days of years for six years from 1.7.85 to 30.6.91.

ACKNOWLEDGEMENTS

My thanks to the Australian Museum and Dr Michael Gray for the provision of facilities and advice; Mr Paul Askew for field assistance; Mr Harry Mitchell for aerial photographs; Mr George Browning for helpful criticism; and Dr Robert Raven of the Queensland Museum for computing suggestions and encouragement. Especially do I thank my neighbour, Dr Peter Linklater, for the execution of statistical work and the preparation of the graphs and Dr Bill Humphreys of the Western Australian Museum for comments on the data and guidance. I am grateful to the CSIRO Science and Industry Endowment Fund for its support.

THE MACARONESIAN CAVE-DWELLING SPIDER FAUNA (ARACHNIDA: ARANEAE)

JÖRG WUNDERLICH

Wunderlich, J. 1993 11 11 : The Macaronesian cave-dwelling spider fauna. *Memoirs of the Queensland Museum* 33(2): 681-686. Brisbane. ISSN 0079-8835.

The composition of the cave-dwelling spider fauna of the Macaronesian Islands–Madeira, the Azores and the Canary Islands–is compared with the endemic epigean spider fauna of these archipelagos. The grades of adaptations in the cave-dwelling spiders are compiled, and the following questions are discussed: from which geographic regions did the stem species come? What can be said about the evolution of the species? How old are the cave-dwelling spider species?

Die Fauna der Höhlenspinnen der Makaronesischen Inseln - Madeira, Azoren und Kanarische Inseln- wird mit der endemischen epigäischen Fauna dieser Archipele verglichen. Der Grad der Anpassung an das Höhlenleben wird untersucht und verglichen; die folgenden Fragen werden diskutiert: Wo liegt der Ursprung der Stammarten? Was kann über die Evolution und das Alter der höhlen-bewohnenden Arten gesagt werden?□*Araneae, troglobites, Canarian and Macaronesian Islands, Island biology, biogeography, evolution.*

Jörg Wunderlich, Hindenburgstr. 94, D-75334 Straubenhardt 3, Germany; 7 December, 1992.

Some island groups in the northern Atlantic–the Canary Islands, the Azores, the Archipelago of Madeira, the small Ilhas Selvagens and by most authors (but not by me) the Cape Verde Islands–are called Macaronesian Islands (Fig. 1). The Macaronesian Islands are mainly of volcanic origin, only the Eastern Islands (Fuerteventura, Lanzarote) are partly of continental origin and have been probably connected with Africa some million years ago.

The first troglophilic and troglobitic Macaronesian spiders were described in 1985 from Tenerife. Now cave-dwellers are known from Madeira (1 species), from the Azores (1 species) and from the Canary Islands (at least 17 endemic species, see Wunderlich, 1991), by far most species are known from Tenerife: at least 11 species = 10% of the endemics (and perhaps there are hundreds of mostly undescribed insect species of different orders).

Especially on the Canary Islands there are many caves. The best studied system of caves on Tenerife - cueva del Viento, cueva Reventon - is more than 16km long; the length of all Macaronesian caves is perhaps more than 100km, and only a few have been examined intensively.

MACARONESIAN CAVE-DWELLING SPIDERS

Nearly all cave-dwelling spiders are endemics of one island or even only one cave (Table 1):

Three species of those listed (Table 1) are not restricted to a single island:

1. *Meta bourneti* Simon, 1929 (Tetragnathidae) is a west-palearctic species introduced to a cave on Tenerife (Canary Islands);

2. *Agraecina canariensis* Wunderlich, 1991 (Liocranidae) is known from caves on Gran Canaria and Tenerife (Canary Islands);

3. *Rugathodes pico* (Merrett and Ashmole, 1989) (Theridiidae) is known from caves on Pico and Fajal (Azores).

Here I deal with five questions: 1. What is the composition of the Macaronesian fauna of troglophilic and troglobitic spiders and what are the differences to the epigean fauna? 2. Which species are extremely well adapted as cave-dwellers? 3. From which geographic regions did the stem species come? 4. What can be said about the evolution of the species? 5. How old are the cave-dwelling spider species?

Cave-Dwelling and Epigean Spiders

The most diverse spider families are shown in Figs 2-3. In the Canarian troglophilic and troglobitic cave-dwellers (Fig. 2): Dysderidae (at least 35%), Linyphiidae (25%) and Pholcidae (25%), the sum of these 3 families is 85%. (No Oecobiidae).

In the epigean endemic species (Fig. 3) the composition is quite different: Dysderidae 16%, Linyphiidae 15%, Pholcidae 13%, the sum of these 3 families is 44%, only half compared with the cave-dwellers. In the families Dysderidae

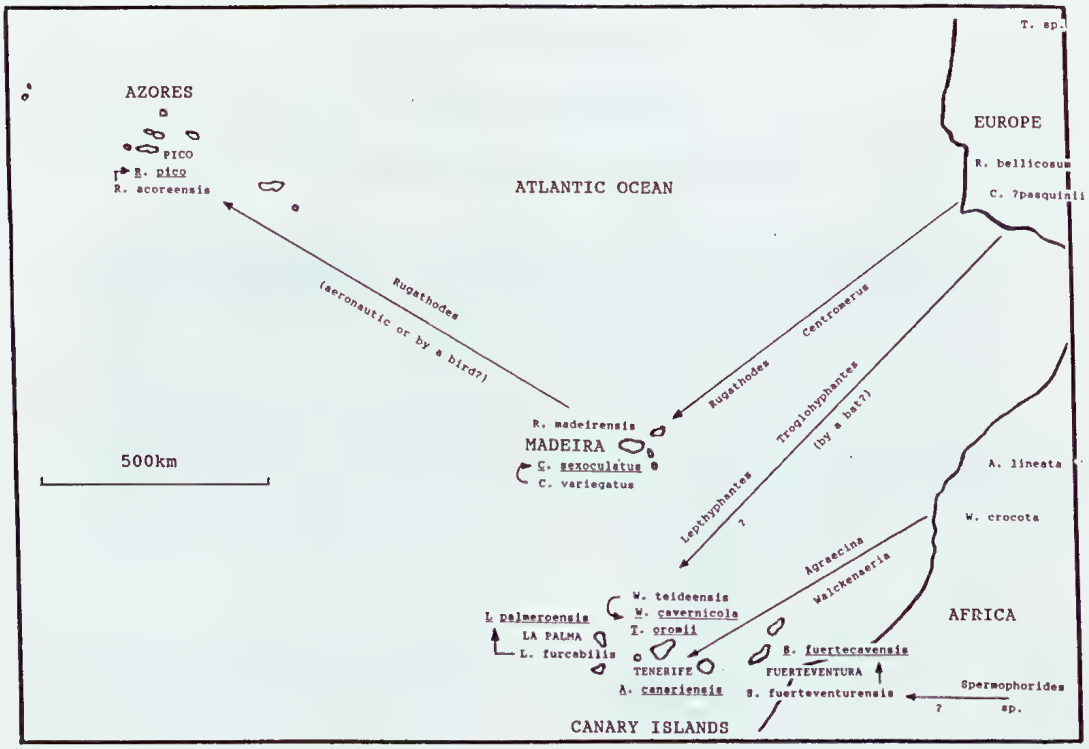

FIG. 1. The Macaronesian Archipelagos. Some Macaronesian cave-dwelling spiders (underlined) and their European and Macaronesian relatives.

(only *Dysdera*) and Pholcidae (*Pholcus* and *Spermophorides*) *all* epigean genera have evolved cave-dwelling species; in the Linyphiidae only members of 5 from 21 genera with endemic species have evolved cave-dwellers (= 25%). *Dysdera* is the genus richest in species in caves and out of caves on the Canarian and Macaronesian Islands. Oecobiidae probably do not find their prey -ants- in the caves.

Highly Adapted Cave-dwellers?

Different grades of adaptation to cave life in the Macaronesian spiders is evident in three structures (Table 1): the size of the eye lenses, the body pigmentation and length and slenderness of legs.

Some true cave spiders of *Dysdera* have reduced eyes, but neither depigmentation nor long and slender legs. I do not know the explanation. Thus, perhaps the eye reduction is the best indicator regarding the grade of adaptation to cave life in spiders. For discussion below I choose the following five spider species.

1. *Meta bourneti* (Tetragnathidae, Tenerife) is restricted to deeper parts of caves, but the eyes are not reduced, the body is only slightly depigmented, and the legs are nearly of normal length. This species has been introduced from Europe or North Africa.

2. Not strongly adapted is *Agraecina canariensis*, but very variable in the depigmentation and in eye reduction (grades 1-3, Figs 4- 5). The variation is intrapopular. This seemingly troglophilic subterranean species is not restricted to caves.

3. In four Canarian species of *Spermophorides*, the eyes are more or less reduced (Figs 8-11); the eyes of an epigean *Spermophorides* sp. from Tenerife are normal (Fig. 12). Cave-dwelling *Spermophorides* spp. are not strongly related. The known species occur on four different islands. So the eye reduction must have been evolved independently four times.

4. *Rugathodes pico* is restricted to caves. The spiders are strongly depigmented, they have strongly reduced eyes and the legs are long and slender (grades 3-4, Fig. 6a; cf. Fig. 6b the related epigean *R. acoreensis*).

5. In *Troglohyphantes oromii* (Ribera and Blasco, 1986) (Linyphiidae, Tenerife), the eyes are tiny or completely absent (Fig. 13), body and legs

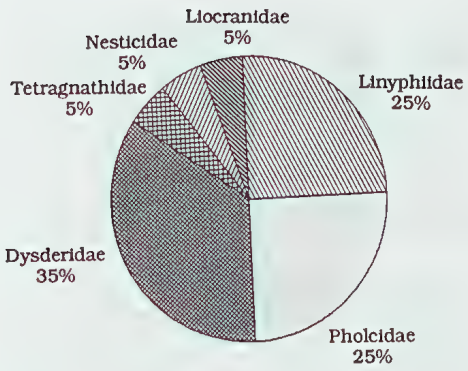

FIG. 2. Composition of Canarian families of troglophilic and troglobitic spiders based on 18 species.

are completely depigmented, the legs are very long and slender (all grades between 3 and 4). The adaptations in *Canarionesticus quadridentatus* (Nesticidae, Tenerife) and in ?*Metopobactrus cavernicola* (Linyphiidae, Tenerife) are similar. These species show the strongest adaptations to cave life.

Origin of the Stem Species

Macaronesian cave-dwelling neoendemic spiders and their European relatives. The hypothetical origin of all species is the West-Mediterranean area, most came from Europe (Fig. 1), e.g. species of *Rugathodes* to the Azores - Madeira seems to be a 'stepping stone', *Centromerus* to Madeira. *Troglohyphantes* came perhaps from Spain to Tenerife, but the sister species is unknown. *Walckenaeria* came from North Africa to Tenerife, *Agraecina* came from

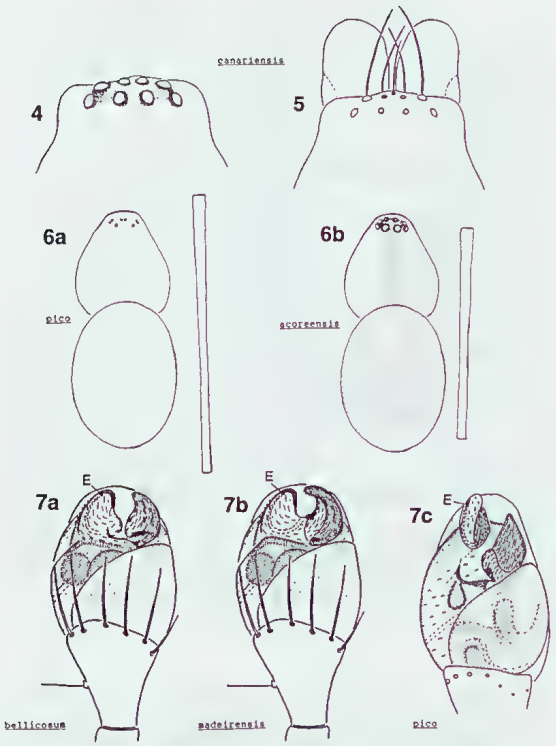
Europe or North Africa to Tenerife (and Gran Canaria).

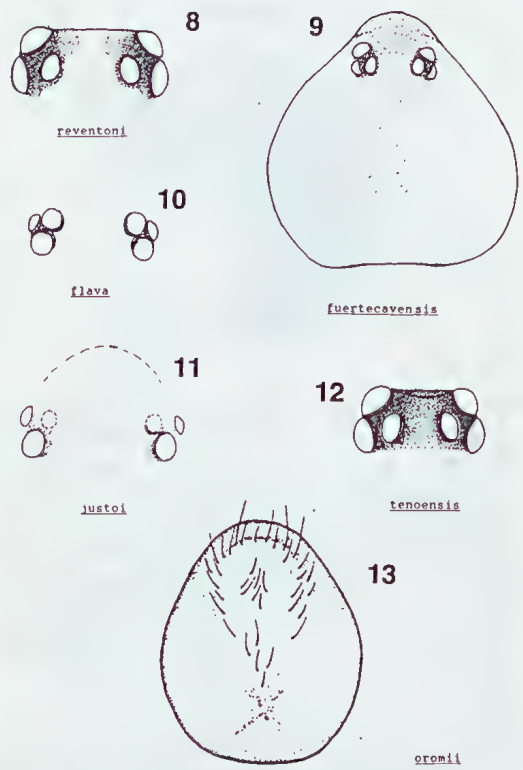
The occurrence of cave-dwelling species of the different genera on *Tenerife* - e.g. *Walckenaeria*, *Troglohyphantes* and *Agraecina* - are remarkable (Fig. 1). The highest Macaronesian mountain, the 3718m high Teide on Tenerife, seems to be a 'catcher' of aeronautic (ballooning) spiders which came from the Western Mediterranean area. This finding is supported by the relationships of the endemic spider fauna of the Teide and the Cañadas, an area surrounding this high mountain (cf. Wunderlich, 1991: 104-107).

Evolution of Macaronesian Cave-dwelling Spiders

In some spiders, e.g. *Canarionesticus quadridentatus* and *Troglohyphantes oromii*, no related epigean species is known, and almost nothing can be concluded about their evolution.



FIGS 4-7. 4-5. Variable eye reduction in subterranean Canarian *Agraecina canariensis* Wunderlich, 1991 (Liocranidae). 6, 7. *Rugathodes*. 6, ♂ body with eyes and right tibia I from the Azores: 6a, of the cave-dwelling *R. pico*; 6b, of the epigean *R. acoreensis*. 7. Right male pedipalps ventral: 7a, *R. bellicosum* (Simon, 1873), Europe; 7b, *R. madeirensis* Wunderlich, 1987, Madeira; 7c, *R. pico* (cavernicolous) and *R. acoreensis* (epigean), Azores. These species show no differences. (E = embolus).



FIGS 8-11. Eye reduction in Canarian cave-dwellers spiders: 8, *Spermophorides reventoni* Wunderlich, 1991; Fig. 9, *S. fuertecavensis*; 10, *S. flava* Wunderlich, 1991; 11, *S. justoi* Wunderlich, 1991. 12. Eyes of the epigean *S. tenoensis* Wunderlich, 1991, Tenerife. 13. Sometimes completely eyeless prosoma of cave-dwelling *Troglohyphantes oromii*, Tenerife.

(Several species are not well studied, e.g. *Dysdera* species, or only one sex is known). In this connection *Troglohyphantes oromii* is of special interest because nearly all species of this genus are troglophilic or troglobitic cave-dwellers as well as the species from Tenerife. I can imagine that there has never existed an epigean stem species on Tenerife and that the ancestors, perhaps as a cocoon, has been transported by a bat directly from a European cave to a cave on Tenerife. Several species or subspecies of bats fly from Europe via Madeira to the Canary Islands (Dr. Biscoito, Mus. Munic. Funchal, Madeira, pers. comm.). This hypothesis would explain why there is no epigean *Troglohyphantes* spp. on Tenerife or another Canary or Macaronesian Island. Otherwise I do not want to exclude the possibility that this species is a paleoendemic relict (Peck, 1990: 372-373).

Based on the very similar genital organ, in *Rugathodes pico* and *acoreensis* they are identical, I found some strongly related spider species (Table 3). In the cave-dwelling *R. pico* (Table 1 and discussed above), the adaptations to cave life and the differences in some non-genital structures compared with epigean species are very distinct: the eye reduction, the depigmentation and the prolongation of the legs, Fig. 6a; compare Fig. 6b of the epigean species, which is also known from the Azores. Otherwise the genital structures in the two Azorean species show *no* differences in both sexes (Fig. 7c), but there are distinct differences to *madeirensis* from Madeira (Fig. 7b) and *bellicosum* from Europe (Fig. 7a). So I do believe that *R. pico* and *R. acoreensis* are true sibling

Introduced species	Paleaoendemic species	Neoendemics
Meta bourneti	*Canarionesticus quadridentatus* (Nesticidae, Tenerife). No known relative.	The epigean sibling or sister species/stem species is known, usually from same island. To this group belong most Macaronesian cave spiders, see below (genesis/evolution), Dysderidae, Pholcidae, Linyphiidae, Theridiidae and Liocranidae.

TABLE 2. Historical groups of Macaronesian cave-dwelling spiders. Position of *Troglohyphantes oromii* in list is uncertain; it has no known epigean relative. See below: possible transport by a bat.

species (or even subspecies?) and that *R. acoreensis* also is the stem species of *R. pico*.

In *Spermophorides*, differences in genital and non-genital structures are distinct in both sexes, and perhaps they are not sister species. The remaining species in this list are known only from females.

Martin *et al.* (1989) assume that some Canarian troglobites can be considered as relict species which evolved after changes in the climate 'since there have been alternating wet and dry periods ... causing important changes in the fragile insular ecosystem on the surface.' (See below: *Rugathodes*). Furthermore the yearly seasonal changes–hot and dry summers, cooler and more humid winters especially on the Eastern Canary Islands–did perhaps initiate vertical movement of some species into the ground in the summer and also autecological changes for instance in *Centromerus fuerteventurensis* Wunderlich, 1991 (Linyphiidae). In this species, which is not a cave-dweller, the eyes are reduced as well as in species of *Scotargus* (Linyphiidae) and *Altella* (Dictynidae) of other Canarian islands (Wunderlich, 1991).

Borges and Oromi (1991) do prefer the 'adaptive shifting theory' of Howarth (1973). 'This theory does not invoke isolation during climatic (or volcanic?) changes but instead proposes that the partly adapted ancestors shifted into newly developed niches.' In my opinion this theory can well explain the genesis of some Macaronesian cave-dwelling spider species including the ones listed above (see Peck, 1990: 366-368). Especially there exists large caves and lava tubes on the Canary Islands, and there are many ecological niches.

From the Macaronesian Islands and its spiders I know three kinds of preadaptations which support the 'adaptive shifting theory':

1. A lot of Canarian species are known as hypogean spiders and were caught using special traps in the ground in the so-called 'mesocavernous shallow stratum' (Wunderlich, 1991: 11). From this stratum and from accidental captures under stones I know Canarian species of *Dysdera*, *Spermophorides*, *Lepthyphantes*, *Walckenaeria*, *Altella*, *Zimirina* and others. These spiders have moderately reduced eyes and are more or less depigmented, they seem to be troglophilous and not macrocavernicolous, but microcavernicolous or myrmecophilous. *Agraecina canariensis* is a species of this stratum but it also penetrates caves. (A closely related species has been newly discovered in a Romanian cave).

2. Another preadaptation is offered in the conditions in the laurisilva (the relict laurel forest): high humidity and low changes in temperature. For example I found the laurisilva species *Troglonata madeirensis* Wunderlich, 1987 (Anapidae s.l.) in the wet and light part near the entrance of a cave on Madeira (Sao Vincente). I collected ♂ ♀ of *Lepthyphantes mauli* Wunderlich, 1991 (Linyphiidae) in the same part of this cave; this species probably also came from the wet forest near the cave.

3. The third kind of biotopes that lead to troglobitic conditions are under stones and under leaves on trees at places with a high humidity near stretches of water. At such places, under stones as well as under leaves on trees, I found on the Azores *R. acoreensis*, the epigean sibling/stem species of the cave-dwelling *R. pico*. Under a stone over flowing water on Tenerife I found partly depigmented spiders of *Walckenaeria alba*.

Age of Macaronesian Cave-dwelling Spider Species

The age of the Macaronesian caves remains unknown. The youngest Macaronesian Islands, the Western Azorean and the Western Canarian Islands, are only very few (1-2?) million years old. Two spider species, *Pholcus roquensis* and *Walckenaeria cavernicola*, are cave-dwellers at the Cañadas on Tenerife. The greatest age of these species could be the same as the age of this part of Tenerife, at least 200 000 (up to 2 million) years.

Rugathodes pico is known only from caves of the Azorean islands Pico (a young island) and Fajal. After Ashmole (in litt. 1991) these Azorean

Cave-dwelling species	Epigean relatives	Island	Family
Spermophorides fuertecavensis	*S. ?fuerteventurensis*	Fuerteventura (Canary Is.)	Pholcidae

TABLE 3. Macaronesian cave-dwelling troglophilic or troglobitic spiders and their nearest epigean relatives, possible stem/ sister/sibling species from same island.

Islands had perhaps a land bridge during the last glaciation. So this species probably evolved from its closely related epigean stem species, near or identical with *R. acoreensis*, perhaps not later than 10 000 years ago (= 10 000 generations). From genital structures, in both sexes there are no differences, speciation should have happened, geologically, not long ago, that means at the end of the last glaciation. But this idea is very vague; perhaps the speciation happened much later, and *R. pico* was transported by bats from one island to the other only very few thousand years ago (Wunderlich, 1991: 200-201). Wunderlich (1991) gives further details of these cave-dwelling spiders and their taxonomy.

ACKNOWLEDGEMENTS

I like to thank the Deutsche Forschungsgemeinschaft, Bonn, for the loan of optical instruments, and I also like to thank S.B. Peck, Ottawa, for his kind comments to the first version of the manuscript.

RELATIONSHIP BETWEEN FOOD INTAKE AND SPIDER SIZE IN TEMPERATE ZONES: EXPERIMENTAL MODEL FOR AN ORB-WEAVING SPIDER

FRÉDÉRIC YSNEL

Ysnel, F. 1993 11 11: Relationship between food intake and spider size in temperate zones: experimental model for an orb-weaving spider. *Memoirs of the Queensland Museum* **33**(2): 687-692. Brisbane. ISSN 0079-8835.

A method is presented that allows calculation of the energy intake by an orb-weaving spider, *Larinioides cornutus* (Araneae: Araneidae) under natural conditions throughout the spider's life. A laboratory study provides several relationships between individual energetic consumption and size of spiders depending on the thermal conditions of their environment. I observe a preferred temperature (21°C) at which spiders have the biggest consumption. A model (pseudo-cubic spline) is constructed for the calculation of energy intake by each juvenile instar. Energy requirements of the adult population are estimated from the reproduction rate observed in the field. The energy requirements under natural conditions and the total weight of prey consumed by the population in the course of its biological cycle can be inferred. In the mesophilous heathland investigated, the total fresh weight of prey consumed by the population during the life cycle is 18.2 $kg.ha^{-1}$.

Cette étude vise à relier les taux de survie, de croissance et de reproduction d une espèce Orbitèle *Larinioides cornutus* (Araneae: Araneidae), au nombre de proies consommées en milieu naturel au cours du cycle biologique. Cette analyse est déduite d une approche bioénergétique. Au laboratoire, les consommations énergétiques et la croissance des araignées sont testées en fonction de l environnement thermique. Ces expériences mettent en évidence la présence d un optimum thermique d ingestion qui modifie la croissance et la consommation des individus. Un modèle d ajustement (spline pseudo-cubique) liant la température, la taille des araignées et la température ambiante est proposé pour estimer l énergie ingérée en phase juvénile. L énergie ingérée en phase adulte est estimée en comparant les paramètres taux de reproduction -consommation calculés en élevage, au taux de reproduction observés en milieu naturel. Les besoins énergétiques sont ensuite convertis en quantité de proies capturées. Sur la lande mésophile étudiée, la population capture en poids frais, 18.2 kg de proies par hectare au cours du cycle biologique.□*Population energetics, Araneae, Araneidae, Larinioides cornutus.*

Frédéric Ysnel, Laboratoire d'Evolution des Systèmes Naturels et Modifiés, URA 696 du CNRS, Campus de Beaulieu, Université de Rennes I, 35042 Rennes Cedex, France; 8 March, 1993.

Among the many studies already carried out about the trophic spectrum of the araneids (Nentwig, 1987), some suggest that the population of spiders–wandering spiders or non-migrant spiders–can utilize a significant proportion of the secondary productivity of natural areas (Kajak, 1967; Robinson and Robinson 1970; van Hook, 1971; Blandin and Celerier, 1981; Nyffeler, 1982). Moreover, some studies emphasize that the growth increment (Vollrath, 1988), the rate of reproduction (Riechert, 1974; Wise, 1979) or the density of individuals (Kajak, 1977) observed in the populations can fluctuate with the number of prey caught. Thus, the characteristics of population dynamics of spiders partly depend on the quantity of prey captured; they can give data about the secondary productivity and consequently about the biological resources of natural biotopes.

However, no study has been done in temperate climates to link the characteristics of population dynamics of spiders with the quantity or the quality of trophic resources. My work on *Larinioides cornutus* (Clerk, 1758) (Araneae: Araneidae) (Ysnel, 1989) describes demographic evolution and reproduction rate of a population in a mesophilous heathland in western France (Ysnel, in press). Besides this, laboratory studies showed a thermal dependance between spider size and food intake (Ysnel, 1990). This study attempts to combine previous results to estimate the number of prey captured by a natural population of spiders during its development.

MATERIALS AND METHODS

This study is based on the calculation of the energy intake during the postembryonic develop-

ment of *L. cornutus*. To estimate energy requirements during juvenile development, I refer to results on the individual energy consumption of spiders at different temperatures (Ysnel, 1990); thus, only the main references of the experimental conditions are described. Young spiders from cocoons reared in the laboratory were divided into three groups by temperatures-16.5°C, 21°C and 26°C. (These values are a little lower than those in my previous work; they agree with more accurate values using an electronic thermograph). Spiders required a varied diet for survival therefore they were reared to maturity using three prey species: the first instars were fed with adult *Drosophila melanogaster* and the last instars were fed with calliphorid flies (*Calliphora vomitaria* and *Lucilia sericata*). Three times a week, all spiders received a fixed number of prey according to their age. Juvenile spiders were kept under a light regime of LD 12:12. Furthermore, 8 spiders collected in the field at stages 4 and 6 and were reared in the laboratory at 13°C. For these spiders, the energy consumption was studied after the first moult in captivity.

As adults, only females feed (adult males no longer build webs). In nature, females can mate in autumn but egg-laying occurs only under long days from May to August. During this period, females lay, on average, only one egg-sac and disappear soon after laying (Ysnel, in press). Therefore, energy consumption is estimated in

adults based on the energy intake needed to produce one cocoon. With this aim, 22 over-wintering fecund females were collected and reared in the laboratory under long days (LD = 16 : 8) and different temperature conditions (13°C, 16.5°C, and 21°C). After the females oviposited, we determined the relationship between the energy intake, the female size (length of tibia IV) and the number of eggs per cocoon.

For each juvenile instar and the adult, the energy intake was determined by the difference between the energy in the whole captured prey and that in the food remains. Calorific determinations for all prey and food remains were made using a Parr bomb calorimeter (Ysnel, 1990).

From the phenology of different instars in nature, the developments of the species have been worked out (Ysnel, in press). Spiderlings emerging from egg sacs laid from late spring to early summer become adult before winter and form a first cohort of individuals (cohort C1). Spiderlings which appear later (end of summer) form a second cohort in the population (cohort C2); they are still immature in winter and become adults early next summer. In analysing the demographic evolution of the population (from 20 m^2 sample areas) during the life cycle, the number of surviving spiders per instar was counted for the two cohorts (Ysnel, 1992). For each juvenile instar, the energy consumption was inferred from the average size of spiders (length of tibia IV) and the thermal environment in the field. Daily meteorological data were classified in four temperature classes (T< 16°C; 16.5°C <T< 18°C; 18.5°C < T < 22°C; T > 22°C) and the average value of each class calculated. The energy ingested is determined from the relative proportion of each phase of temperature during one intermoult period. The average value of the caloric

equivalent of insects captured in the field is 22.6 J/mg dry weight (Ysnel, 1992). Cummins and Wuyscheck (1971) found that the dry weight of most insects is equivalent to 20-30% of the wet weight. To transform dry weight (x) into wet weight (Y), I used the conversion factor calculated for calliphorid flies (Y = x/0.262; Ysnel, 1990).

RESULTS AND DISCUSSION

Individual Consumption, Spider Size and Thermal Conditions of Juveniles

The number of instars needed to reach maturity varied with the growth conditions. In Araneidae, the first free-living instar is called J2 (Canard, 1987). From 5 to 8 immature instars may variously precede adulthood. Average consumptions per instar are calculated for four temperatures (Table 1). Average consumption also varies with instar and growth conditions. In each group, an overall connection between the instar of development of a spider and the energy intake of that instar cannot be deduced because individual variation is considerable. However, for all individuals, whatever the instar, there is a good correlation between individual consumption and spider size the intermoult (Table 2). For each temperature with all instars merged, we can fit all the observed values to four exponential graphs corresponding to four different equations (Fig. 1). The four curves show that the individual consumption varies with temperature. For the tested temperature range, and spiders of similar size, I observed a 'preferred temperature of consumption' (21°C) at which the energy intake at the intermoult is maximal (Ysnel, 1990).

Near the thermal preferendum, spiders have the highest consumption but the growth increment is paradoxically the smallest. From instars J4 onwards, individuals kept at 21°C are significantly smaller in size than individuals kept at 16.5°C and 26°C (Kruskall-Wallis test, Table 2). Using the energy budget equation of Petrusewicz and MacFadyen (1970), the energy dissipated as heat (respiration) could be increasing (while the energy retained as growth is decreasing) and the spiders must be more active at 21°C. In contrast, when the temperature deviates from the thermal preferendum, the energy allowed for the activity of spiders must be less important (probably because spiders progressively fall into quiescence or aestivation) and the energy retained as growth increases.

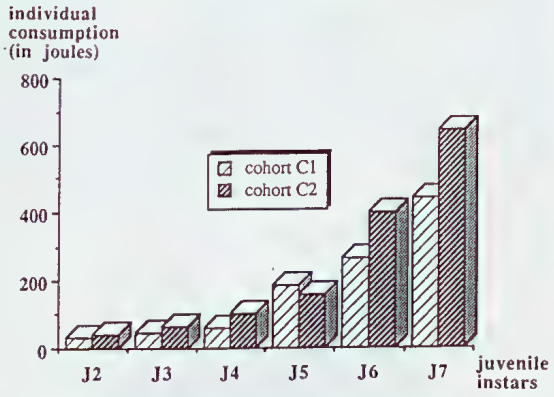

FIG. 6. Estimated individual consumption per instar under field conditions.

One can estimate the energetic requirements of spiders C (ρ)(x, y), by interpolating the pooled data to a single regression model linking spider size and air temperature during the intermoult, to the individual energy consumption. The method, based on the 'homogeneous spline functions with several variables' (Duchon, 1980) allows us to

	Cohort C1				Cohort C2				Population

TABLE 6. Estimated mean energy consumption of adults (N = estimated no. of eggs/cocoon; E/egg = energy intake to produce one egg; E/F = energy intake by ♀; n: = no. ♀ ♀ per cohort; C = total consumption of ♀ ♀/ cohort).

adjust significantly the whole experimental values to a pseudo-cubic spline (Fig. 2) by means of the following formula :

$$C(\rho)(x,y)=\sum_{i=1}^{n} \lambda i \, (\rho)((x-xi)^2+(y-yi)^2)^{\frac{3}{2}}+\alpha 1x+\alpha 2y+\beta$$

where ρ is the tension parameter ($\rho = 5$), x = spider size at intermoult, y = air temperature. αi, $\alpha 1$, $\alpha 2$ and β are calculated by the solution of a linear system.

This model estimates the energy requirements during an intermoult period of any juvenile instar, under these experimental conditions.

Energy Consumption during Adult Phase

The individual consumption of all females (Table 3) is plotted against spider size (Fig. 3); the regression line can be used as a calibration curve to estimate the consumption of females independent of thermal environment. The number of eggs per cocoon also showed a significant linear relationship (Fig. 4) with female size.

However, the number of eggs in cocoons in the laboratory (line 2) and those in nature (line 1) clearly indicate that breeding females produce fewer eggs in the laboratory. Two hypotheses can be advanced to explain this result:

- the food consumption of breeding females in the laboratory is lower than that of females in nature; consequently fewer eggs are produced in the laboratory.
- for females of the same size, the number of eggs produced in nature is favoured by a varied diet.

The ratio 'energy consumption/number of eggs produced' gives an index (C/egg) of the energy required to produce one egg (Table 3). The values of 'C/egg' are dependant on female size (Fig. 5). Two methods are now used to study the energy consumption of females:

- method 1: For females of a given size, the regression equation I (Fig. 3) allows the calculation of the energy consumption to produce a given number of eggs. When females produce more eggs (as in nature), we estimate the energy consumption using a simple rule of 3.
- method 2: In nature, we can estimate the number of eggs produced by females using the regression equation I (Fig. 4). The energy consumption is then calculated by referring to the values of 'C/egg' given for the females of the same size (Fig. 5, regression equation II).

Theoretical values of the consumption of females derived by the two methods are similar (Table 4). Hence, the energy required to produce one egg is not influenced by the feeding regime of spiders. The number of eggs per cocoons is dependant on female size and on the quantity of food intake. We use the ratio C/egg to estimate the energy requirements of the adult population in the field.

Energy Requirements in Nature

For individuals of the same juvenile instars, the consumption varies with time of year of the spiders appear (Table 5). Individuals of cohort C2 have, in most instars, an higher consumption than those of cohort C1 although the average size in the two cohorts is similar (Fig. 6). Hence, the spiders of cohort C2 live closer to the thermal preferendum than those of cohort C1.

According to the caloric equivalent of the prey caught in natural areas (22.6 J/mg dry weight), we can estimate the food consumption of the orb-weaving population. In the mesophilous heathland investigated, the total fresh weight of prey consumed by the population in its biological cycle is 0.036 kg/20 m^2 which amounts to 18.2 kg/ha. The amount of food ingested varies with the instar. The high mortality rate (Table 5) reduces total consumption in the first three juvenile instars. In later instars, although the spider density decreases, food intake by the population increased owing to a concommitant increase in individual consumption. The quantity of prey caught by adult females is higher than for the whole juvenile population (Table 6, Fig. 7).

CONCLUSIONS

The species responds to variation of the trophic conditions in both body size and the number of eggs produced. These two biological parameters constitute indices of reference to estimate the quantity of prey caught by the population during the biological cycle. Compared with the results of others (Table 7), the food intake by the population of *Larinioides cornutus* represents from 8.2-36.4% of the total food consumption of the spider communities of different ecosystems. In other respects, the food ingested in the biotope studied

Biotope	Prey killing rate (kg/ha/year)	Country

STUDIES ON THE WOLF SPIDERS (ARANEAE: LYCOSIDAE). I. A NEW GENUS AND SPECIES FROM KAZAKHSTAN, WITH COMMENTS ON THE LYCOSINAE

ALEXEY A. ZYUZIN

Zyuzin, A.A. 1993 11 11: Studies on the wolf spiders (Araneae: Lycosidae). I. A new genus and new species from Kazakhstan, with comments on the Lycosinae. *Memoirs of the Queensland Museum* **33**(2): 693-700. Brisbane. ISSN 0079-8835.

A new genus *Oculicosa* (Araneae: Lycosidae: Lycosinae) is established and a new species *Oculicosa supermirabilis*, sp. nov. is described from South-western Kazakhstan. Relationships of the new species are analysed. The role of some morphological features of burrowing lycosids is specified. Tegular (median) apophysis in all members of the subfamily Lycosinae is declared to serve as the functional conductor of the embolus: the mechanism of its action is analysed. The role of some structures and the use of corresponding names is specified, the comparison of the main subfamilies is given. The structure of the tribe Trochosini Zyuzin, 1990 is revised: this tribe is divided into two subtribes including non-burrowing and burrowing forms.

On établit un genre nouveau *Oculicosa* (Araneae: Lycosidae: Lycosinae) et décrit une espèce nouvelle *Oculicosa supermirabilis* sp. n. du Sud-Ouest du Kazakhstan. Les affinités de l'espèce nouvelle sont analysées. On précise le rôle des quelques indices morphologiques des Lycosidés creusants. On a déterminé que l' apophyse tegulaire (median) chez tous les membres de la sous-famille Lycosinae sert de conducteur fonctionnel d'embolus: le mécanisme de sont action est analysé. On précise le rôle de quelques structures el l'usage des noms correspondants, la comparaison des principales sous-familles est donnée. On fait une révision de la structure de la tribu Trochosini Zyuzin, 1990: cette tribu se divise en deux sous-tribus insérant des formes non-creusantes et creusantes. □*Lycosidae, Oculicosa, conductor.*

Alexey A. Zyuzin, Institute of Zoology, Kazakhstan National Academy of Sciences, Akademgorodok, 480032 ALMA-ATA 32, Kazakhstan Republic; 18 March, 1993.

Burrowing spiders of the family Lycosidae within Kazakhstan are poorly known. Records exist only for *Allohogna singoriensis* (Laxmann, 1770), *Lycosa nordmanni* (Thorell, 1875) (= *L. narbonensis* auct., non Latreille, 1806), and *L. alticeps* (Kroneberg, 1875) (see Charitonov, 1932; Dubinin, 1946). However, of those, only the distribution in Kazakhstan of *A. singoriensis* has been well studied (see Marikovskij, 1956). The only large non-burrowing lycosid reported from Kazakhstan is *Hogna radiata* (Latreille) (see Schmidt, 1895: Aral Sea and Mangyshlak Plateau). That report is very doubtful, as the author studied juvenile specimens only.

MATERIAL AND METHODS

Spider material I collected in 1989 in Karynzharyk sands, South-western Kazakhstan, are used here. Specimens were captured at night with the use of a miner's head torch: spider's eyes reflect torch light at the distance of 20-25m and even more. Spiders were examined in 70% alcohol using binocular microscopes. To understand the relative position of different parts of the male and female genital apparatus during copulation, dissected tegular apophyses of males were attached to female epigynes (Fig. 5). Eye measurements are given in eyepiece micrometer units (x32). Genitalia and their parts for scanning electron microscopy were preserved in ethanol, air-dried, mounted on stubs, gold-coated and examined in a JEOL JSM-T200 at 15kv.

Abbreviations: ALE, anterior lateral eyes; AME, anterior median eyes; ARE, anterior row of eyes; AZ, private collection of the author; L, leg; LC, carapace length; P, palp; PLE, posterior lateral eyes; PME, posterior median eyes; TA, tegular apophysis; WC, carapace width; ZMMU, Zoological Museum of the Moscow University.

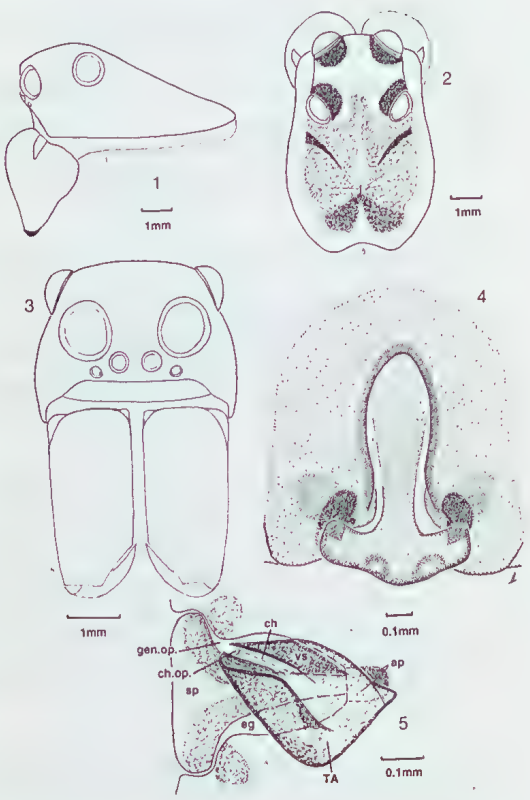
towards abdomen (Fig. 1), lateral sides of head are almost vertical. Carapace is relatively narrow, ratio LC/WC is 1.44-1.50. PME and PLE are very large, height of ocular field is 0.39-0.42 of LC (Fig. 2). ARE recurved, AME larger than ALE (Fig. 3). Row 1 is 1.64-1.70 times shorter than row 2; row 3 is 1.19-1.23 times wider than row 2. Clypeus narrow, its height less than 1 diameter of AME. Retromargin of cheliceral fang furrow with 2 large equal teeth. Ti + Mt I and II with 2 ventral pairs of spines except apical ones. Base of embolus in lateroapical position, TA is transverse lamella with narrow stout process by its base, directed ventrad, and with sclerotized edge situated distally (Figs 6-8). TA on its inner (dorsal) side with deep narrow transverse sinuous channel opened at the distal end of sclerotized edge. Epigyne has narrow anterior part and widened posterior (genital) parts where transverse genital part of septum is situated (Fig. 4).



FIGS 1-4. *Oculicosa supermirabilis*, sp. nov.: 1, female carapace, lateral view. 2, ditto, dorsal view. 3, ditto, frontal view. 4, epigyne. 5, position of tegular apophysis on epigyne in *Alopecosa cuneata* (Clerck) during copulation. Abbreviations: ap, anterior pocket of epigyne; ch, channel of tegular apophysis; ch. op., channel opening; eg, epigynal groove; gen.op, genital opening of epigyne; gps, genital part of septum; sp, septal pedicle; vs, ventral spur('hook') of tegular apophysis evident through cuticle.

DISTRIBUTION

South-Western Kazakhstan.

Oculicosa supermirabilis sp. n.
(Figs 1-4, 6-8)

MATERIAL EXAMINED

TYPES. Holotype ♂, South-Western Kazakhstan, Mangistau Area, Yeraliev District, 37 km S of Akkuduk Vill., Karynzharyk sands (42°38'N, 54°03'E), clay soil, S.I. Ibraev and A.A. Zyuzin (ZMMU), 14-15 May 1989. Paratypes: 7 ♂, 3 ♀, same data; 1 ♂, 3 ♀, same data, except 15-16 May 1989 (1 ♀ paratype in ZMMU, remainder in AZ).

DESCRIPTION

Female. Carapace brown or light brown. Lateral bands wide, continuous, forming wide light 'cheeks' at the sides of head. Median band represented by yellowish rhomboidal spot lying

Female (carapace length = 7.0mm)								Male (carapace length = 7.05 mm)

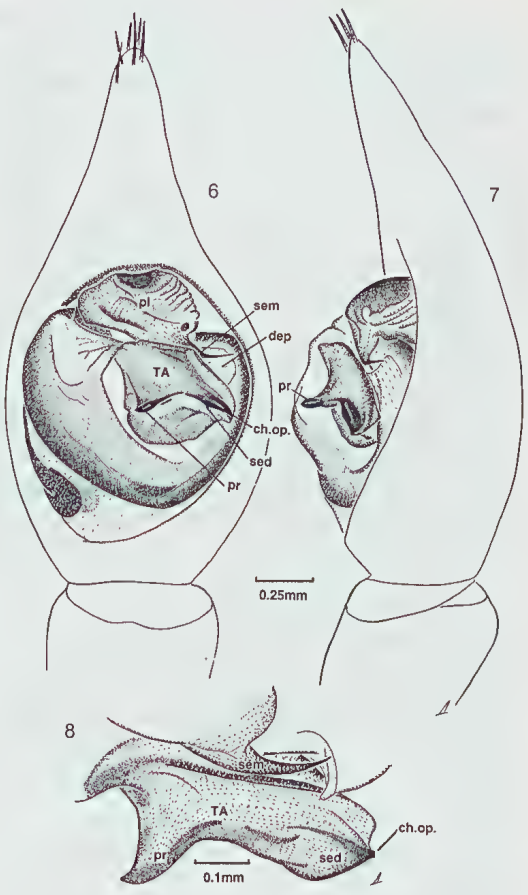
above median furrow (Fig. 2); sometimes this spot is triangular with its base near PLE. Ocular field yellowish-brown, with dark spots around eyes. Carapace evidently descending behind PLE and is supplied with dense fur-like whitish hairs at its edge. Legs: coxae covered dorsally with dense whitish long hairs. Remaining segments uniform yellowish; their length given in Table 2. Leg spination: femora I and II with 2 promesolateral spines; tibiae I and II with 2-2 ventral spines and 2 small apical ones, 1-1 mesolateral, no ectolateral spines; tibiae III and IV with 1-1 dorsal; metatarsi I and II with 2-2 ventral + 4 apical, 1-1 mesolateral, no ectolateral spines; tarsi I-IV dorsally with 2 submedian long setae. Palp: all segments uniform yellowish, but tarsus distally a little darker, tarsal claw long, slightly curved, with 4 very small teeth. Abdomen: sides with dispersed dark points; dorsal pattern consists of brownish lanceolate stripe with dark margins, series of light spots lying below, and whitish spots of different size around. This pattern is covered with dense whitish pubescence. Ventral side above epigastrum dark, with dense dark hairs and bristles, sparse dark hairs are also on spinnerets and at stigmal area, the remainder uniform whitish, but sometimes there are 2 closely situated, almost parallel longitudinal dark lines. Coxae ventrally yellowish-brown, sternum yellowish with some dark hairs on sides, labium and maxillae yellow-brown. Chelicerae reddish-brown, basal segment is covered with long dense whitish-grey hairs and bristles in front. Retromargin of cheliceral fang furrow with 2 teeth, promargin with 3. Body length 15.0-20.2 mm, LC 6.5-8.0 mm. Epigyne: Fig. 4.

Male. Body covered with white hairs. Pattern of both carapace and abdomen as in female, but carapace covered with many whitish-grey adpressed hairs. Ocular field with long and dense whitish hairs. Carapace edged with a narrow stripe of long dense fur-like whitish (silvery) hairs directed anteriad; many short, adpressed silvery hairs also at sides of head and form 'cheeks'. Legs: colouration as in female, coxae dorsally with long and dense silvery hairs. Length of legs as in Table 2. Leg spination: femora I and II as in female; tibiae I-IV with 1-1 dorsal spines, sometimes only prodorsal remains, laterally on each side 1-1, ventrally 2-2 + 2 apical; metatarsi I and II with 1-1 lateral on each side, ventrally 2-2 + 5 apical; tarsi I and II dorsally with 2 submedian long setae. Palp: segments yellow, cymbium distally brownish; all segments covered with white hairs: femur with sparse hairs, patella with many



FIGS 6-8. *Oculicosa supermirabilis*, sp. nov.: 6, male palpus, ventral view. 7, ditto, lateral view. 8, male tegular apophysis with synembolus, apical view. short and adpressed hairs, tibia and cymbium (except its distal part) with long and dense hairs. Dentation of cheliceral furrow as in female. Body length 12.0-13.8 mm, LC 6.3-7.3 mm. Palpus: Figs 6, 7.

Ecology

All adults were collected in clayey parts of Karynzharyk sands.

Discussion

Oculicosa supermirabilis is closely related to some species of *Lycosa* s. lat., namely *Lycosa alticeps* (Kroneberg, 1875) and *L. medica* (Pocock, 1889), but differs from them by the

CHARACTERS

1. Size: a1, small; a2, medium; a3, large-very large
2. Carapace, cephalic area: b1, high; b2, narrow; b3, protruding basally with anterior row of eyes
3. Carapace, posterior ocular trapezium: c1, trapezoidal; c2, wide trapezoidal; c3, +/-quadrangular
4. Carapace, size of anterior eyes: d1, variable; d2, small; d3, comparatively large
5. Male palp, origin of embolus: e1, mesolateral; e2, lateroapical; e3, distal (apical)
6. Male palp, shape of embolus: f1, long curved spine; f2, enlarged at tip; f3, short, combined with conductor
7. Male palp, tegulum: g1, no sclerotized processes; g2, with 1-2 stout well sclerotized processes
8. Male palp, tegular (median) apophysis: h1, thick, well sclerotized; h2, weakly sclerotized (membranous); h3, absent
9. Male palp, bed of tip of resting embolus: i1, small tegular depression; i2, enlarged tegular depression; i3, deep dorsal channel of TA; i4, tegular depression on upper tegular process; i5, deep ascending tegular groove
10. Male palp, character of conductor: j1, deep dorsal transverse channel of TA; j2, deep dorsal longitudinal channel of TA; j3, thick well-sclerotized basal part of palea concealed by tegulum; j4, opened (free) transverse sclerotized lateral process of the basal part of palea; j5, opened large apical; j6, combined with embolus (single complex)
11. Epigyne: k1, variable; k2, median inverted T-shaped plate; k3, entire plate with 2 parallel oblong grooves above; k4, simple entire plate; k5, simple hairy plate; k6, hairy plate with lateral sclerites; k7, posteriorly protruding hairy plate

TABLE 3. Comparison of lycosid subfamilies. Notes: [1] *Wadicosa*; [2] after Lehtinen & Hippa, 1979; [3] *Hippasa*; [4] *Aulonia*; [5] *Hygrolycosa*; [6] *Xerolycosa*; [7] *Evippa*.

shape of epigyne and tegular apophysis, by the profile of carapace (cf. Kroneberg, 1875, pl. IV, fig. 28; Pocock, 1889, pl. XIII, fig. 1), as well as by relatively larger PME and PLE, presence of only 2 teeth at the retromargin of chelicerae (in *L. alticeps* and *L. medica* 3), colouration of the ventral side of abdomen and smaller body length.

The descending carapace in both sexes of *Oculicosa supermirabilis*, fur-like hairs at the edges of carapace, and the long and dense whitish hairs on the dorsal side of coxae indicate a burrowing way of life (see also Zyuzin and Zarko, 1989; Zyuzin, 1990), although I could not find the burrows of this species. Our investigations showed that carapace pubescence together with dense hairs on the coxae considerably diminish the friction between the coxae and the edges of carapace; in the much more active males these features are more pronounced and supplemented with many dorsal adpressed whitish-grey hairs on the carapace thus facilitating their movements in burrows. The role of carapace descent is as follows. The comparatively long femora III and IV press against the carapace when moving in narrow burrows: the length of femur IV is slightly longer than the carapace slope. Long-legged males of burrowing lycosids very often have a low flattened carapace (as well as females of the genus *Lycosa* s. str., e.g. *Lycosa tarantula* and *L. nordmanni*: see Zyuzin, 1990): this compensates for the lack of descent, facilitates the folding of very long femora and improves the mobility of these spiders. I suggest that the strongly descending carapace not only in females but also in males (as in *Oculicosa*), together with comparatively narrow carapace, indicates the burrowing way of life from the early juvenile stages up to their imaginal moult: therefore, the distribution of such species is probably very restricted. On the contrary, in *Lycosa nordmanni* and *Allohogna singoriensis* with their flattened carapace in males, mature females seem to be more or less burrowing, while the juveniles, especially early stages, are active. This feature undoubtedly facilitates aerial dispersion of juveniles: as a result, both of these species are widely distributed.

PALPAL MORPHOLOGY

Further discussion concerns the terms 'conductor' and 'terminal apophysis', as their interpretation by different authors is sometimes rather contradictory.

Conductor

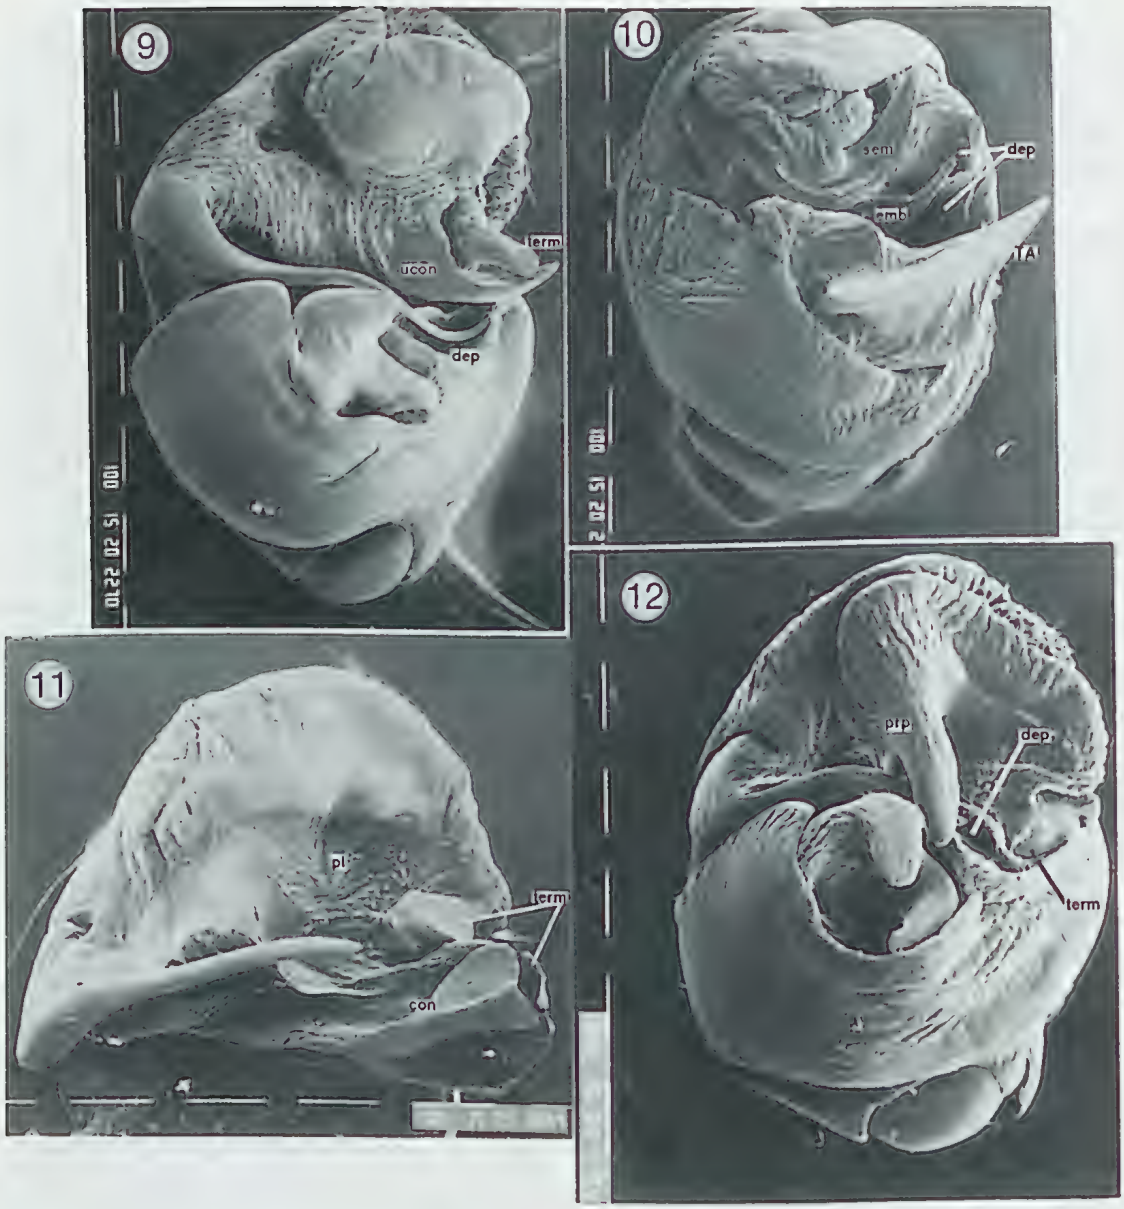
The tip of the resting embolus in both Pardosinae (at least in *Pardosa* and *Acantholycosa*) and Lycosinae lies in the oblong depression of the tegulum: in Pardosinae this depression is rather small and spoonlike (Figs 9, 12), while in Lycosinae it is enlarged, sometimes strongly, and usually forms the tegular lobe (Fig. 10; Dondale, 1986, figs 12, 13). In an unexpanded palp of Pardosinae the depression of the tegulum fully separates the embolus from the true (functional) conductor which is the transverse well-sclerotized groove situated near the base of the terminal part (shield, palea) of the genital bulb and almost fully concealed by the tegulum (Figs 9, 12). In members of Lycosinae, the enlarged depression of the tegulum is regarded as the conductor of the embolus (see Dondale and Redner, 1979; Dondale, 1986), though this bed for the resting embolus does not fit to assist the exact movement of the embolus tip to the female copulatory opening. Lehtinen and Hippa (1979) write: 'We are aware that "conductor" is not a very suitable name for the outer part of the Lycosid embolic division, because it is not always a functional conductor'. Our investigations have shown that the deep transverse channel on the inner (dorsal) surface of tegular apophysis opened at its narrow distal end and diagnostic for all members of the subfamily Lycosinae (Dondale, 1986) is intended for the embolus and undoubtedly directs its tip to the copulatory opening: thus, the TA of Lycosinae serves as the functional conductor. The mechanism of operation of such a conductor during copulation is shown in *Alopecosa cuneata* (Clerck) (Fig. 5): while the hooked ventral spur of the TA comes into contact (forms a hook-up) with the anterior pockets of the epigyne, the ventral rib of the 'hook' enters the longitudinal epigynal groove, so that the channel opening lying at the distal end of TA comes into proximity with the copulatory opening of the epigyne.

Above the embolus and behind the TA in many species of Lycosinae is situated a narrow, sharpened laminar process (see Figs 6-8) usually slightly grooved on its ventral side: the proposed name for this laminar process of palea in Lycosinae is 'synembolus', as it always accompanies the embolus and has the same direction. I suppose that the embolus during copulation enters the TA channel together with the laminar synembolus which directs the embolus to the channel and probably locks the last as a stopper, fully excluding the deviation of the embolus. Thus, the synembolus plays the role of auxiliary conductor. In species of the *Alopecosa pulverulenta* group the synembolus is fused with the base of the palea, so that only an ectal tooth remains at its external side: in this case all the base of the palea goes to the wide 'antechamber' before the channel.

Dondale (1986) correctly regards the subfamily name Hippasinae to be a junior synonym of the Lycosinae. In representatives of the genus *Hippasa* TA also serves as the functional conductor: despite the lack of an atrium in some *Hippasa* species (e.g. *Hippasa deserticola* Simon, and *H. cinerea* Simon) and the agelenid habit of the spiders, I regard them, as well as allied genera, to represent the tribe Hippasini Simon, stat. nov. in the subfamily Lycosinae (see Table 3).

Besides the Lycosinae, the conductor is represented by the tegular apophysis in two other subfamilies: Evippinae (type: *Evippa* Simon) and Allocosinae (type: *Allocosa* Banks).

1. Evippinae. Members of this subfamily have a hooked longitudinal TA which somewhat resembles the transverse trochosoid 'hook' of Lycosinae. As in the species of Lycosinae, the members of Evippinae have a distinct channel on the inner (dorsal) side of TA and a pedicled septum widened posteriad (Zyuzin, 1985, figs 15, 16, 20-22). But, despite these similarities, the genera *Evippa* and *Xerolycosa* have a number of features which allow them to be regarded as members of the separate subfamily. Thus, the channel on the dorsal side of TA in Evippinae is longitudinal (in all Lycosinae it is transverse); the whole embolus is situated in a deep depression and forms a very characteristic recurved flat loop; the base of embolus always has an apical position; the palea is strongly reduced; and the epigynal grooves are very shallow and lie at the level of the septal pedicle. Besides, in *Evippa* spp. the synembolus is transformed into a narrow functional conductor which is constantly situated in a channel of TA and projected beyond the TA limits: in this case TA serves as an auxiliary conductor. In *Xerolycosa* spp. the functional conductor is represented by TA: the embolus constantly lies in a channel (see Zyuzin, 1985); the



FIGS 9-12. Scanning electron micrographs: 9, 10, 12, genital bulbs dissected from cymbia; 11, palea with embolus and conductor dissected from genital bulb). 9, *Pardosa sodalis* Holm. 10, *Hogna radiata* (Latreille). 11, *Pardosa chionophila* L. Koch. 12, *Pardosa turkestanica* (Roewer). Abbreviations: con, conductor; dep, tegular depression; emb, embolus; pl, palea; prp, process of palea; sem, synembolus; TA, tegular apophysis; term, terminal apophysis; ucon, upper branch of conductor. Scale bar=0.1mm.

synembolus is strongly reduced and fused with the semi-transparent extension of the embolus.

2. Allocosinae. In *Allocosa* spp. TA is double-branched, the channel is situated on the dorsal side of the narrow basal branch and holds the tip of the resting embolus; and the atrium of the epigyne is lost (see Dondale and Redner, 1983; Dondale, 1986). Besides, the basal part of the pardosoid palea probably serves as an auxiliary conductor directing the embolus into the channel of TA in the expanded palpus.

In the genus *Pirata* and allied genera (*Piratula, Aulonia, Hygrolycosa*) the functional conductor is combined with a short thin embolus in a com-

mon sickle-shaped complex resting in a deep and narrow ascending tegular groove. The distal position of the well sclerotized conductor in representatives of the subfamily Venoniinae (*Venonia* and allied genera: see Lehtinen and Hippa, 1979) does not allow us to include *Pirata* in the subfamily Venoniinae, as Dondale (1986) did. *Pirata* and allied genera probably deserve to be included in the separate subfamily Piratinae (type: *Pirata* Sundevall, 1832) (see Table 3).

Terminal Apophysis

Very often the palea in Pardosinae (at least in *Pardosa* and *Acantholycosa*) above the embolic division is supplied with a stout, very sclerotized process: many authors (e.g. Holm, 1947; Tongiorgi, 1966; Kronestedt, 1975) designate this process as the terminal apophysis. Dondale (1986) writes '... the terminal apophysis ... is believed to assist the finding and penetration of the copulatory opening by the embolus tip'. It is therefore obvious that, to play this very important role, the terminal apophysis must be situated immediately above the end of the conductor (Figs 9, 11; Kronestedt, 1975, fig. 3); sometimes the dentiform terminal apophysis is situated directly at the outer part of the conductor (see Dondale and Redner, 1984, figs 21, 25, 26). At the same time, there are many cases when the much larger paleal process is situated far above the conductor, i.e. so that it cannot assist the exact penetration of the embolus tip into the female copulatory opening (Fig. 12); however, such a process is also wrongly designated as the terminal apophysis (see Lowrie and Dondale, 1981, fig. 10; Dondale and Redner, 1984, fig. 5; Dondale, 1986, fig. 7). Tongiorgi (1966, fig. 1) correctly designates the true terminal apophysis and the laminar process: the destination of such a process is otherwise, e.g. to protect the resting embolus, or to make an engagement during copulation.

An incorrect designation of terminal apophysis is also used by Buchar (1976, figs 7, 8): in his fig. 8 it is a mere tubercle of the palea, while in fig. 7 (*Pardosa thaleri*) this author confuses it with the narrow laminar conductor sharpened at the tip and characteristic for the *Pardosa bifasciata* group. The similar conductor shape, also designated as the terminal apophysis, is in the species '*Pardosa*' *oncka* Lawrence (see Kronestedt, 1987, fig. 4C).

In some works the synembolus of Lycosinae is also called the terminal apophysis (see Dondale and Redner, 1979, 1990; Dondale, 1986). But, as the synembolus only directs the embolus to the channel of TA (see above), the role of the true terminal apophysis is fulfilled by the ventral process(es) of TA fixing the last on the female epigyne. The designation of the ectal tooth of palea in the *Alopecosa pulverulenta* group as the terminal apophysis (see Kronestedt, 1990) is also incorrect: actually this tooth is the synembolus (see above).

Formerly (see Zyuzin, 1990), I restricted the Lycosini to burrowing lycosids only, and erected the new tribe Trochosini for non-burrowing genera of Lycosinae. Herein the structure of both these tribes is revised: thus, I include in Trochosini only those genera that are characterized by the very peculiar TA which has a transverse lamella with a ventrally directed trochosoid 'hook', or spur, and the epigynal septum with a distinct narrow pedicle, widened posteriad, very often in the shape of an inverted 'T'; epigynal grooves on either side of septal pedicle are rather deep and distinct. Both non-burrowing and burrowing lycosids are included in this very large tribe, undoubtedly having a common origin; in accordance with this view the tribe Trochosini is divided into two subtribes: Trochosina Zyuzin, stat. nov. (including the non-burrowing genera *Trochosa*, *Alopecosa* s. str., *Hogna* s. str., *Schizocosa*), and Geolycosina, subtrib. nov. (including the burrowing genera *Arctosa* s. str., *Geolycosa*, *Allohogna* with a very characteristic carapace profiles: see Zyuzin, 1990, fig. 1). There are many species throughout the world, including African ones, which also belong to the Trochosini: the generic and subtribal position of these remain obscure due to the artificial system of Roewer (1959-1960).

As shown in Fig. 5, the length of the epigynal groove and septal pedicle in species of Trochosini is correlated with the length of the ventral spur of TA.

As to the tribe Lycosini, I place here only the members of *Lycosa* s. str. with their very peculiar genitalia, and some allied species referred to *'Allocosa'*, *'Hogna'* and probably *Metatrochosina* (Roewer, 1959-1960, figs 124, 126, 129, 219, 304-305, 517).

ACKNOWLEDGEMENTS

For the loan of material and necessary technical assistance I am very grateful to the following persons: Dr Ch. Deeleman-Reinhold (Ossendrecht, The Netherlands); Dr C.D. Dondale (Ottawa, Canada); Mr S.I. Ibraev (Alma-Ata, Kazakhstan); Drs D.V. Logunov (Novosibirsk),

Y.M. Marusik (Magadan) and K.G. Mikhailov (Moscow) (all Russia). For the kindly given possibility of use the scanning electron microscope in my work I am very thankful to Dr V.K. Lebsky and Mr V.M. Semyonov (St. Petersburg, Russia). I am also indebted to Mr K.N. Plakhov (Alma-Ata), who organized the scientific trip to Mangyshlak and Ustyurt Plateaus.
